initis plastica of the gastro-intestinals, sclerostenosis of Krompecher. In appropriate cases excision, resection, or enterectomy are apparently the operations of choice.

Deaer J. B. Acute Appendicitis

10 Nov 10

Appendicitis is the most common intra-abdominal inflammation and the appendix constitutes the avenue by way of which infection most commonly invades the upper abdomen. There are three portions of the appendix in relation to the appendix: the ileocecal, the ileocolic and the ileocecal. The appendix being occasionally buried in one of the latter two thus explaining why the organ is believed to be bent. The author has never failed to find an appendix in the man cases he has operated upon.

The appendix may be found below and to the outer side of the cecum, to the outer side of the cecum and colon, pointing upward and outward behind the cecum pointing upward to the inner side of the cecum lying beneath or above the terminal mesentery of the ileum and pointing downward, occupying the false and even the true pelvis. Thus the location of the point of tenderness and of referred pain must differ in particular cases, and symptoms pointing to gall bladder, duodenal, pyloric, pancreatic, or pelvic disease may arise.

The etiological factors of importance are age, previous attacks of appendicitis, catarrhal conditions of the gastro-intestinal canal, infectious diseases, especially influenza and digestive disturbances, the latter resulting in a great increase in the bacterial flora of the intestine.

The peritoneum defends itself by the function of exudation and absorption, the former enabling it to form adhesion of protective character and any treatment that breaks down these adhesions, such as purgation, defeats that protective function and may be harmful in the extreme.

Appendicular abscesses are met with in several situations: (1) in front of and to the outer side of the cecum, the pus being confined by the cecum, small bowel, omentum, etc. (2) to the outer side of the cecum and ascending colon or behind the cecum in the layers of the mesocolon. (3) in the pelvis (4) near the median line to the median side of the cecum (5) free in the abdominal cavity or existing in the shape of many pockets between the coils of the intestine. In addition there are seen secondary abscesses, which occur close to the original abscess, residual abscesses occurring at the site of the primary abscess, and metastatic abscesses, which occur at any point distal to the site of the original, such as a paracolic abscess, pyelophlebitis, etc.

The clinical history is typical, a previously well individual being seized with acute abdominal pain, first referred to the umbilical or epigastric region and accompanied by vomiting. The pain soon becomes localized to the right iliac fossa and muscular rigidity is noted. If this sequence is interrupted, the diagnosis of acute appendicitis may be doubted. Fever is always present. If the appendix is in the pelvis the pain is likely to be left-sided. Suddenly subsiding pain followed by a chill points to gangrene, while exquisite tenderness denotes the presence of pus. The differentiation of importance lies between acute cholecystitis and appendicitis.

The treatment is comprehended in the following points: (1) examine the patient thoroughly and not through the clothes (2) give no aperient medicine (3) $\frac{1}{16}$ to $\frac{1}{8}$ grain of morphine will not mask the symptoms and may be safely given when the pain is severe (4) the diagnosis having been made the proper measure is immediate operation. In the presence of peritonitis and in the absence of operation set the patient up in bed give nothing by mouth place an ice-bag over the tender area, and

institute enteroclysis. Operate in the cases of localized peritonitis where the lesion can be localized and there is peristalsis in the surrounding region of the abdomen. In diffused peritonitis defer operation until the peritonitis becomes a localized one.

E. K. ARISTOTELIS.

Mayo, W. J. Radical Operation for Cancer of the Rectum and Rectosigmoid. *T. Am. Surg.* 455 Washington 9 of May.

The author discusses: (1) operability (2) operative mortality (3) operative disability (4) the action following operation, and (5) permanent cure, on the basis of a study of 753 cases of cancer of the rectum and rectosigmoid examined in the Mayo Clinic between January 8, 1901 and December 3, 1905. Of these, 43 were subjected to radical operation.

Six hundred and nineteen cases gave an operability of 53 per cent. Radical operation was seldom refused because of the local extent of the disease. Had it been possible to know the extent of the disease previously in some instances patients would not have been operated on, though many in a very advanced stage were cured. Lymphatic involvement is usually late and in no case was lymphatic extension alone the cause of inoperability. Theoretically the abdominal cavity should be explored in every case because of the frequency of metastasis in the liver and peritoneal cavity. In very few patients the posterior crural operation in one stage may be wise.

In 43 radical operations the operative mortality was 53 per cent. During the last three years, in spite of the fact that 78 patients in each were operated on, the mortality has been reduced to 25 per cent. It has now been brought to about 10 per cent. In cases in which the disease in the rectum was movable the mortality was under 5 per cent. All patients dying in the hospital are classified as cases of operative mortality without regard to length of time that death occurred after operation. Necropsy was secured on 95 per cent of patients dying in the hospital. The mortality in any given statistical group is low with low operability. High operability includes cases of advanced disease which greatly increase the mortality. Comparative statistical data of operative mortality means nothing unless the total number of patients examined whether operated on or not, is taken into consideration.

The causes of operative mortality are: (1) sepsis, 39.8 per cent, usually due to soiling of the operative field with the infected contents of the involved bowel because the rectum had become fixed and the growth had penetrated its walls (2) nephritis, 3 per cent acute developing on chronic (3) metastatic tumors undiscovered on exploration, 15 per cent (had the true condition been known operation should have been performed) (4) death from hemorrhage, 6.5 per cent, in no case immediate, but blood-loss led to exhaustion, sepsis, etc. No case of shock without hemorrhage. Secondary hemorrhages were not truly secondary but rather a continuation of badly

controlled hemorrhages (5) death due to exhaustion etc. often some days or weeks after operation.

When aseptic healing took place patients were discharged from the hospital as early as sixteen days and returned to work in thirty days. Infected wounds healed in from four to twelve weeks but the patients were not able to return to work for three or four months.

The best function followed the tube resection described by Balfour and the C. H. Mayo method of direct end-to-end union. The Wier invagination method gave excellent results when it could be used. In the Gripps operation although the entire sphincter was removed the functional results were as a rule excellent. In the majority of cases the radical operation necessitated a colostomy in the abdomen or a posterior anus more or less uncontrollable. The Mixer malilone colostomy proved most satisfactory.

As to permanent cures of the 430 patients on whom a resection was done 364 recovered from the operation. Eliminating those who were operated on less than three years ago 33.3 per cent have lived three years or more and 26.3 per cent have lived five years or more after the operation. These percentages may be fairly increased to 33 and 35.4 per cent respectively by subtracting from the mortality figures the normal death rates for corresponding ages for periods of three and five years (i.e. 4.2 and 7.5 per cent).

LIVER, PANCREAS, AND SPLEEN

Collins, C. U.: Indications for Cholecystectomy and Cholecystostomy. *Illnesses of the Gallbladder*, 1906, p. 30.

Letters were sent to 14 patients who had recovered from cholecystostomies asking if they had had any trouble with the gall bladder or stomach since the operation. In all 102 replies were received 74 said they had been perfectly well so far as the gall bladder and stomach were concerned 15 complained of some pain in the gall bladder or stomach or both while 13 complained of still having severe pain at times in the region of the gall bladder or stomach or both.

Conclusions are drawn from 196 cases.

1. The presence or absence of stones in the gall bladder should not be considered in deciding to remove or leave a gall bladder. It is entirely a question of infection.

2. An infected gall bladder had better be removed if there are no contra indications.

3. The location of a stone in the common duct may be a factor in the decision. If it has caused a recent attack of jaundice a possible pancreatitis should be considered and if present the gall bladder should be retained and drained at least temporarily.

4. An acutely inflamed gall bladder due to a virulent infection evidenced by the clinical symptoms had probably better be retained and drained.

Indecisive and mortality investigation table

A cholecystectomy is safer in these cases than a cholecystostomy. A cholecystostomy may be safely done after the acute symptoms have subsided if it is necessary.

The small proportion of gall bladder which contain stones with no present evidence of infection may be drained although it may be safe in these to open the gall bladder remove the stones and leave it without drainage.

6. The general condition of the patient may make a simple cholecystostomy the safer procedure until the general condition improves.

The history is not only the largest element in making the diagnosis but also of great importance in deciding the question of removing or retaining the gall bladder. If the history has no present symptoms indicating chronic infection the gall bladder had better be removed.

8. In spite of these conclusions it takes the highest surgical judgment to decide at times which will give the most ultimate benefit to the patient the retention or removal of his gall bladder.

EDWARD L. COLLINS

Bazy M.: End Results of Entero-biliary Anastomosis (Results of 12 Cases of Entero-biliary Anastomosis). *Bull. Acad. Chir.*, 1906, 5.

Bazy reports two rare operations (1) cholecystoduodenostomy for obstruction of the common duct at the summit of Vater's ampulla (2) cholecystoduodenostomy for obliteration of the terminal portion of the common duct. He has been able to find three similar cases in the literature and little is known of the end results. Two of these cases were reported by Terrier at the French Surgical Congress 1908.

In the two cases reported by the author both patients were women and Bazy has been able to trace their history for sixteen months and eight years respectively after operation. In the latter case the woman became pregnant a little more than a year after operation and was delivered of twins at term without any trouble. In her case the anastomosis has functioned well and at no time during the past eight years has the integrity of the bile passages or the functioning of the kidney been menaced.

In the discussion Brancet mentioned a similar operation in a case where the lower half of the common duct was almost completely obstructed and the upper half was united to the duodenum. One year later there was reappearance of jaundice with other troubles and the patient died.

ALCOCK

Mapes, C. C.: Uncertainties of Understanding Ancient Cholelithiasis. *Am. J. Surg.*, 1906, 54.

The author reaches the following conclusions:

1. That there are many uncertainties of understanding ancient the etiology, histopathology, symptomatology and treatment of cholelithiasis.

2. That the hypothesis that bacterial invasion

represents the terminal rather than the primary factor in cholelithiasis has been clearly disproved.

3 That the medicinal treatment of cholelithiasis is a delusion, there being no drug which internally administered will cause disintegration of definitely formed choleliths.

4 That the most favorable results may be expected to accrue from cholecystostomy cholelithotomy and temporary drainage.

5 That cholecystectomy is illogical and unwarranted except where the cholecyst is already damaged beyond hope of functional restoration or is involved in demonstrable malignancy.

C. G. HEYM

Einborn M. Pancreatic Stone Colic (Zur Klinik der Pankreassteinkolik) *Berl. kl. Wchschr.* 9 6 III, 10.

Pancreatic stones are rarely observed in the human organism and their diagnosis during life is rarer still. Einborn reports two cases which he has had under his observation.

Of the diagnostic signs the occurrence of colic like pain in the epigastric region which is associated with a transient appearance of sugar in the urine is the most characteristic. This pain is periodically repeated and its sudden cessation speaks of the passing off of the stone. The appearance of a stone in the feces consisting chiefly of calcium carbonate without cholesterolin crystals pigment points to its pancreatic origin.

As a general rule the pancreatic function is not disturbed for a long time. Later there are disturbances which lessen the pancreatic activity. While the occasional appearance of sugar in the urine during an attack of colic is very important, it is not a *sine qua non* in the diagnosis of pancreatic stone.

If the ordinary methods of medical treatment fail and attacks are frequently repeated and become more severe in character, operative interference is indicated. The gall bladder and pancreas should be carefully examined and if stone is present it should be removed. Frequently the palpation of small stones even in the exposed pancreas is not possible. The gall bladder should always be drained because much drainage has a favorable effect upon an existing pancreatitis in the case of calculi.

W. A. BRIDGES

Mayo, W. J. The Spleen; Its Association with the Liver and Its Relation to Certain Conditions of the Blood. *J. Am. M. Ass.* 9 6 Ivi, 76.

The regularity with which splenic enlargements and other physical changes occur in association with diseases of the liver and of the blood has strongly impressed the author who, whenever possible during an abdominal section examines the spleen. The examination of this organ by external means is often misleading and can never be relied on, although the X-ray offers some hope in the diagnosis of splenic pathology.

Investigation has shown that not only does the spleen extract bacteria and other toxic agents

from the blood but also preserves the food value of broken down blood by sending their remnants to the liver for further elaboration. But whatever the function of the spleen it must send its products through the portal vein to the liver. This close association will be maintained by the splenic hypertrophy attendant on cirrhosis and secondary liver diseases in the absence of plethoric anemia.

That the liver may not quite fit this function of conservation in the case of the power of regeneration. In all the cases of the body this power is partially lost by hypertrophy taking its place.

Adam points out that in the bacterial infection that have escaped the leucocytes in the blood giving rise to pigmented areas, and laughs at the theory that bacteria resist the action of parasitic organisms, and that disease is a phagocytic and the preventive serum is the cell of the body that resists against the organisms and to so change the body part that they are no longer bacterial food.

Rosenow further demonstrates the selectivity of bacteria and other bacteria for certain tissues or organs. Is it not probable that the spleen has the power of attracting certain substances from the blood as shown by splenic enlargement in typhoid malaria, etc?

Moreover the spleen has no internal secretion as removal does not deprive the body of an important constituent, nor is it under complete nervous control through sensory nerve-fibers from Auerbach's plexus. It does, however contain much striated muscle which is possibly responsible for the digestive rhythmic change in size.

As to the relation of the spleen to blood, normally in the fetus, the spleen liver and nodal and lymphoid structures are blood-producing organs this power in the spleen at birth, diminishing to the production of white cells.

In the various anemias, the spleen acts as a graveyard for the blood-cells, especially the red, not through its own initiative but as though the corpuscles were senescent in some other place and destroyed in the spleen. Thus the enlarged spleens so often found in these conditions may be a work of hypertrophy and it would appear that possibly this excess of splenic tissue or hyperplenism, may cause an unnecessary destruction of the red cells there being many exciting causes for the onset of splenic enlargements, for example the relief of the secondary anemia in syphilis particularly of the liver by the removal of the enlarged spleen.

In so-called primary tuberculosis of the spleen the removal of the organ has occasionally benefited a few. It is likely however that the disease is never primary in the spleen, and such diagnosis is rather the result of insufficient clinical study.

In the anemia of chronic syphilis remarkable improvement followed the removal of the enlarged spleen. In chronic septic conditions with enlarged

spleens removal does not bring satisfactory results as there is usually a very lowered resistance and a cardiorespiratory insufficiency to overcome.

In splenic enlargements associated with hepatic disease it is often impossible to determine whether the process is primary in the spleen or liver. In Hanot's cirrhosis when diagnosed undoubtedly benefit follows removal of the spleen.

In 4 cases the author has removed an enlarged spleen in conditions of portal cirrhosis of the liver with much relief of the symptoms.

It must always be borne in mind that the spleen is only one avenue of entrance to the liver for noxious agents but no matter in what manner hepatic disease occurs there is usually a concomitant splenic enlargement.

The syndrome called splenic anemia the terminal stage of which is known as Banti's disease may be cured in many cases by removal of the spleen.

Cases of stomach hemorrhage in which no other origin can be found should be carefully examined for evidence of splenic anemia as hemorrhage is one of the earliest symptoms in this condition.

In Gaucher's disease described by Brill and Mandelbaum it is the author's experience that splenectomy in the early stages is followed by a cure.

In hemolytic jaundice which is of two types that of Minkowski and that of Hayman and Widal splenectomy gives the most brilliant result.

In pernicious anemia remarkably improvement follows removal of the spleen if done before the spinal cord changes occur.

Preliminary to splenectomy and if not following it blood transfusion is necessary in the majority of cases. The donor's blood should always be tested with that of the recipient for agglutination and hemolysis.

P. M. CHASE.

Wahl, H. R. and Richardson, M. L. A Study of the Lipin Content of a Case of Gaucher's Disease in an Infant. *Am. J. Med.* 96 v. 1 238.

The case on which this study is based was that of an infant eleven months of age with a clinical picture which in general, simulated Gaucher's disease. The spleen, liver and lymph nodes presented the usual changes but the unusual feature of the case was the almost complete substitution of the medulla of both suprarenals by clusters of large pale vacuolated cells. The latter were also present in Peyer's

patches in the intestines and in the thymus besides involving the adventitia of some of the smaller vessels. The process was thus much more diffused than in any case hitherto described and also the first one described in an infant when the condition may be more diffused than when it occurs in adults.

The author made an exhaustive study of the tissues of this case and an extensive review of the literature the following conclusions being drawn.

1. In Gaucher's disease the liver and the spleen show not only a marked increase in the lipin content but also a serious alteration in normal relations of the lipins to each other. The fixed fats are greatly reduced while the lipoids such as lecithin and cholesterol are greatly increased. In the vacuolated leucithin-like body predominated but a cholesterol compound may prevail in other cases.

2. In Gaucher's disease lipoid substances accumulate in the form of small droplets within the cytoplasm of the tissue cells resulting in the formation of a cunulation of the lipin in the large pale cell so characteristic logically of this disease.

3. Gaucher's disease is due to a disturbance of lipoid and fat metabolism resulting in the accumulation of lipoid substances in the cytoplasm of the large pale cells that are mostly transformed reticulo-endothelial cells of the spleen, lymph nodes and bone marrow and the stellate cells of the liver. These cells have the physiologic property of disposing of the fats and lipoids and comprise the endothelial cells of the blood vessels.

4. Those organs that contain the reticulo-endothelial cells in large abundance (spleen, lymph glands, bone marrow, liver, stellate cells of Kupfer, etc.) show the most changes but specific parenchymal cells may absorb some of the lipoid in very advanced cases.

5. Gaucher's disease belongs to the group of xanthelasmic conditions which are characterized by a more or less diffuse accumulation of lipoids in reticulo-endothelial or in fibroblastic cells in one or more organs. It represents a more diffuse and widespread involvement of the endothelial cells than those cases of gross diffuse hyperplasia of the cells in diabetic lipoidemia with an underlying cause that is more deep-seated and inherent in the body economy. (Gruber and E. B. Taylor).

SURGERY OF THE EXTREMITIES

DISEASES OF THE BONES, JOINTS, MUSCLES TENDONS CONDITIONS COMMONLY FOUND IN THE EXTREMITIES

Ashurst, A. P. C. Multiple Cartilaginous Exostoses. *Ann. Surg. Phila.* 90 July 67.

Ehrenfried has recently studied the clinical entity which goes under the name of multiple cartilaginous

exostoses and prefers the name hereditary deformity chondrodysplasia. He was able to find only about a dozen cases which had been reported in America the greatest number of cases being reported from Germany and France. As the author has seen 11 cases within the last ten years he concludes that the disease is not so rare as it seems but that it has been overlooked or ignored.

The underlying pathology is not the exostoses, but a chondrodysplasia affecting especially the metaphyses of the long bones, though the bones of the pelvis, the clavicles, scapulae, and the vertebrae may be involved. The epiphysis is small or misshapen. The intermediary cartilage is narrow irregular, oblique or zigzag and sometimes prematurely ossified. Scattered along the ends of the shaft beneath the periosteum are clumps or nests of cartilage cells persisting uncalcified where they are left in the process of growth. Later these groups may develop into the cartilaginous exostoses, which give the disease its name but these are merely incidental. A malignant osteocartilaginous tumor may develop in one of these exostoses. Certain secondary characteristics usually are present such as low stature due to the shortness of the limbs, particularly the lower. There often is a lack of growth of the ulna and pes valgus is frequent as the result of the lack of growth of the fibula. The disease is transmitted by both affected males and females and by unaffected females but there is no evidence that it may be transmitted through unaffected males.

The author reports cases which he has observed and two others from the service of T. W. which he did not have the opportunity to observe. In addition he reports 5 cases which present no skeletal deformities and evidence of being hereditary but which are examples of some type of chondrodysplasia. CARRAJO

Davidson, A. J. Subungual Exostosis. *Am. J. Orth. Surg.* 9: 50.

The author observed 5 cases of painful enlargement of the distal extremity of the great toe due to subungual exostosis. They were all males under 30 years of age. No history of injury or infection could be obtained. The process requires from six to twenty-four months to develop sufficiently to cause the patient to seek advice.

The etiology of exostoses in general may be summed up as (1) those due to direct infection, (2) those due to direct trauma, (3) those associated with tendon or ligamentous strain, (4) static.

In the cases referred to by the author there was no history of infection of any kind nor were there any inflammatory signs of either the matrix of the nail, the bone or the soft parts. Exostoses of the variety described could not be credited to any associated tendinous or ligamentous strain for the reason that no tendon or ligament is attached to the portion of bone from which the growth arises.

By excluding these possible explanations it brings us to a consideration of trauma. The location of the exostosis is at a point which is frequently the site of trivial injuries and which is being constantly subjected to the continued pressure of the stiff boxing of shoes. The usual atrophic conditions of the flexor muscles of the toes have the effect of increasing the power of the extensors, placing the toes in a position to bear the brunt of this shoe pressure.

Regardless of the fact that no history of direct trauma could be obtained in any of his reported cases, Davidson thinks it is quite possible that subungual exostosis is the result of trivial injuries or occurs following the prolonged irritation of shoe pressure which may or may not be appreciated by the patient. PHILIP LEWIS

Berry, J. M. R. Retarded Ossification as an Etiologic Factor in Traumatic Arthritis and Epiphysitis. *J. Am. M. Ass.* 9: 611 & 68.

Three cases are reported in boys seven to ten years of age. In general the symptoms are the same pain and swelling to the joints of the lower extremity, a slight rise in temperature and some limitation in motion. X-ray examination showed retardation in ossification in the areas involved and also in the wrist.

The cases show that retarded ossification may be an etiologic factor in the production of traumatic arthritis and epiphysitis in children. The trauma in such cases consists in restraint of the joint due to abnormal activity. The child may be leading the normal active life of a child of his own age but anatomically he belongs to a type several years younger and to an old strain his activities should be correspondingly restricted. Cases of this character are probably quite common and very apt to be overlooked or wrongly diagnosed. EDWARD L. C. NELL

Fleux, G. Treatment of Purulent Arthritis of the Knee by Arthrotomy or Marsupialization of the Synovial Sac (Le traitement des arthrites purulentes du genou par l'arthrotomie ou marsupialisation de la synoviale). *Pres. Méd.* 9: 6.

Fleux affirms that in injuries of the knee joint one of the factors which engenders rapidity of suppurative diffusion is the difficulty of drainage or rather inefficiency of evacuation with drainage. According to Delore and Kocher arthrotomy for drainage is a blind method which is often insufficient.

Fleux has observed in the wounded cases under his care that there was retention of pus in the serous cavity in spite of the presence of several large permeable drains. From close observation he came to the conclusion that it was the drain itself that formed the obstacle to drainage. He therefore replaced arthrotomy with drainage by arthostomy, creating one or more articular mouths kept wide open which allowed the continuous evacuation of the infected joint contents without the aid of any tube. He gives the details of seven cases treated in this manner.

This method of evacuation of the knee-joint in no way obviates the indications for resection of the knee which have recently been formulated by Tuffier and others but it is incontestable that the more quickly and better septic products are evacuated from the synovial spaces, the less the indications are for resection. This is why he thinks that arthros-

tomy is superior to arthrotomy incisions with drainage tubes

Dunlop J A Deposit in the Supraspinatus Muscle
Simulating Subacromial Bursitis *Am J Orth Surg* 9: 10

The author reports a case of a large deposit about the tendon of the supraspinatus as well as a considerable deposit in the belly of the muscle demonstrated by tercoröntgenogram.

The treatment instituted was a plaster cast such as is used in the abduction position for fracture of the neck of the humerus. This was applied under nitrous oxide anesthesia. After ten days the cast was removed and the support and position were gradually done away with. Hot air bakes are useful in such cases in relieving pain and hastening the return of normal motion.

PHIL LEWIS

FRACTURES AND DISLOCATIONS

Hiltzot J M and Bolling R W: Fractures of the Neck of the Scapula *Ann Surg Phil* 9: 6 Jul 5

Fractures of the neck of the scapula with or without involvement of the glenoid fossa while not common have been found to be of more frequent occurrence since the advent of the X-ray. These fractures fall into the following groups:

1 Fractures of the surgical neck of the scapula.

Fractures of the lower half of the neck of the scapula.

3 Fractures of the neck of the scapula beginning at the neck and extending downward through the base of the coracoid process to the glenoid fossa.

4 Fracture of the anatomical neck.

5 Stable fractures of the glenoid fossa of the scapula.

6 Fracture of the rim of the glenoid with or without fissure running into the neck. This type is frequent in fixation of the shoulder and as they occur with complicating injuries of dislocations the authors have not included them in their review of the literature.

There is no authentic case of the fourth type recorded in the literature.

The authors report nine cases and the results of some experiments upon the cadaver. From their observations they conclude that the description of the deformity resulting from fracture of the region of the neck of the scapula as ordinarily given is not correct and that the fracture in this region may occur without any recognizable deformity. They believe that the clinical manifestations of the fracture are insufficient to make a positive diagnosis and that the X-ray is an essential factor in the diagnosis. The immobilization of the arm by a Velpau or similar bandage is all that is necessary in the way of treatment and manipulative efforts have no effect upon the displacement which occurs at the line of fracture. By massage baking and careful

after treatment practically perfect functional result will be obtained. Should the type of fracture occur in which the ligament is totally torn, the bony fragments will be felt behind and the glenoid fragment displaced into position with reference to the joint injuries by appropriate methods of repair of the ligament etc. Including these cases reported by the authors there are only about thirty cases in the literature in which the diagnosis has been confirmed by X-ray and autopsy.

(VET 1900)

Roberts, J B. The Artificial Periosteum for Fixation of Shaft Fractures. *J Surg Phil* 9: 11 5

Although the author has not changed his views in regard to the method of treating the great majority of fractures he advocates the use of an artificial periosteum in certain cases in which there is a minute incision for an open operation. Instead of the woven nitroglycerin suggested by Dr C. Strauss the author suggests the use of an autogenous graft of fascia. He states that the use of fascia may be applied for the various types of fracture for instance two narrow splints may be wrapped about the bone a considerable distance from a fracture in case of a compound fracture or a wider band where the fracture is more transverse. The object of the fascial tube is to make an artificial periosteum which will act as an absorbable support for shaft fractures. The author has not demonstrated the efficiency of such a method of fracture treatment either by experimental work or by actual use in suitable cases.

(VET 1900)

McGlannan A. Fracture of the Neck of the Femur: A Study of the Treatment and Final Results of 85 Cases. *N Y G* 16: 11 5

The author reports a case of fracture of the neck of the femur that has come under his personal observation in the past eight years. In this series 36 recent fractures and old fractures were treated and 12 patients were not treated.

In all cases full abduction with downward traction and inward rotation was the position obtained in the reduction of the fracture. The full abduction was assured by fixation of the pelvis by abducting the sound leg and the inward rotation by lifting the trochanter forward. Impaction was separated in 6 cases and in the seventh was not disturbed because the impaction occurred with abduction of the thigh. This is an unique observation.

Various forms of fixation were used from bism plaster of Paris cast to loose tying out of the thighs. Direct extension by ice tongs was used in 3 hand-capped patients one of whom died. Nailing the fracture was done twice.

For the old cases bone graft was used once, nailing twice, removal of head once, subtrochanteric osteotomy twice, freshening fragments once.

Of the recent cases four died and in one the fracture failed to unite. One of the old cases resulted fatally and the patient still walks on crutches 7 years after treatment.

Treatment was refused by young adults, with vicious union. Ten patients were not treated on account of feebleness and circulatory pulmonary renal or nervous symptoms. Two are living several years after the injury aged 88 and 90 years, respectively. Delirium tremens and evidence of drug addiction or uræmic manifestations make the prognosis grave. Loss of control of bladder rectum seems to indicate an inability to stand fixation. The effect of the healed fracture on earning capacity is noted in 20 cases, the average loss being 5 per cent, after a period of disability lasting from 6 months to 1 year and 3 months with an average close to 1 year. The occupation of these patients included hotel manager, restaurant owner, housekeeper, seamstress, laborer, tailor, motorman and market driver.

SURGERY OF THE BONES, JOINTS, ETC.

Burckhardt H., and Landolt, F. Experiences in the Treatment of Infected Joints in War (*Erfahrungen ueber die Behandlung der Gelenke im Kriege*). *Berlin* 11 (1915) 358.

The authors have reported their methods in a previous communication but were then unable to report on the end results. They now report these

end results and are able to state their conclusions on more definite basis. This study is a contribution to the question whether resection of a joint is justifiable in war or not.

In all severe cases of joint infection, the indications alone must decide whether resection or amputation is to be resorted to. Resection is generally done (1) in the field hospital as part of the immediate treatment of the wound (2) later on on some vital indication when amputation is voided (3) after a longer period when it is thought to effect healing of a chronic joint suppuration.

The most important and the most frequently observed cases of joint infection are those of the knee-joint, which when badly infected are almost impossible to save. In the hip-joint infection as regards relation to life and function. If the fissures extend well into the ilium amputation is the best method, but if amputation is not do then radical resection with ablation of the bone end is preferable to simpler procedures.

Regarding individual joints resection in the case of the hand, foot and elbow joints gives good result. In the case of the knee-joint resection is indicated if the general result is good and there is only a moderate amount of bone destruction and if subsequently long treatment of the patient in place can be assured. But the general results are poor and although the limb is preserved pseudarthrosis usually results. Nevertheless, resection or at least some simpler operation should be tried

when the above conditions are present. If they are not, then amputation must be done to save the patient's life.

In the shoulder joint resection gives better results. In infected hip-joints the casualties are very great and resection very rarely saves the life of the patient.

W. A. BRIDGES.

Hoffman, P. An Overlapping Joint as a Substitute for Cuneiform Osteotomy. *Am. J. Orth. Surg.* 9: 111, 1915.

The author devised an operation that substitutes for the simple transverse joint made in the cuneiform section an overlapping one that is less liable to displacement. There is an underlying simple general plan that involves two linear cuts and the removal of two corners of bone, no matter what the degree of angulation.

The first cut is perpendicular to the long axis of one of the arms of the deformed bone on a level with the apex of the angle on the concave side of the bend. This divides the bone into a longer and a shorter segment.

The second cut is made perpendicular to the long axis of the longer segment on a plane parallel with but distal to the cut that would have been made in a cuneiform osteotomy. The more distal this plane the longer will be the overlapping tongue of the resulting joint.

Next the end of the longer segment is turned out from the skin incision and a corner is removed from its deeper side. The longitudinal cut should be parallel to the long axis of the segment and should divide the bone equally. The transverse cut should be on a level with what was the apex of the

angle on the concave side of the deformity. The longer segment is turned out from the skin incision and a corner is removed from its deeper side. The two corner buds are then brought together and the bone is united the same as after a fracture operation.

A bone union is secured. All healing is made with an ordinary plaster cast. The medial fragment responds in size and shape to the medial half of the original bone and the lateral fragment responds in size and shape to the lateral half of the original bone.

Kane, E. O. Preliminary Report on Device for Intramedullary Fracture Splinting. *J. Surg.* 3: 3, 1915.

An expanding screw is used to replace the bone. It is recommended to replace the bone with a screw. After clearing the medullary canal, the screw is drilled to the length of the fracture. The screw is then expanded by turning the handle. The screw expands, filling the cavity tightly and holding the fracture firmly.

This method provides sufficient support without traction or angulation of the opposing fragments. Yet a splint holds the length of the usual peg

can be inserted consequently a very blue fracture is held as accurately in position as if it were transverse. The thumb is disturbed but slightly the technique is simple, the procedure rapid. The hollow cylinder permits new medullary and bone formation, and being of the thickness of a paper (two-thousandths of an inch in thickness) the steel can corrode away.

Chaput Resection of Almost the Whole of the Humerus for Fistulous Osteomyelitis, Followed by Osseous Reproduction Without Shortening and with the Production of a New Humeral Head (Resection de la presque totalité de l'humerus pour ostéomyélite fistuleuse suivie de reproduction osseuse sans raccourcissement avec production d'une tête humérale nouvelle) *Bull. et mém. Soc. d' chir. d' Par.* 9 6, xll, 433

The author reports a case of multifistulous osteomyelitis in a boy of 16. In February 1914 Chaput resected from 2 to 25 cm. of the lower part of the humerus. Later on in May 1914, owing to the development of a fistula the upper third of the humerus comprising the articular extremity was ablated. Cicatrization occurred in from two to three months the bone reproduced and united with the new bone of the lower region.

This reproduction of almost the entire humerus Chaput explains as being due to the preservation of the periosteum and the youth of the patient. Up to the twentieth year the regenerative power of periosteum is very active. After thirty grafts are indispensable.

The continued use of extension in this case prevented shortening. The reproduction of the humeral head is very interesting. It has only been possible owing to the abundant formation of bone which has been facilitated by movement. W. A. B. RICE

Albee F. H. A Statistical Study of 519 Cases of Pott's Disease Treated by Bone-Graft. *Am. J. Orth. Surg.* 9 6, d, 34

With the object of securing a report of results obtained by others with the bone-graft treatment of Pott's disease a large number of printed questions were sent to surgeons in this and foreign countries who had performed this operation.

Thirty-three surgeons reported a total of 599 results in 229 of which the disease was pronounced arrested in 59 the condition was improved. Of the 599 patients 12 died, 4 of these fatalities being reported as due to shock. The remaining 5 cases died four months or longer after the operation, either from complications or from intercurrent disease. In 5 of these cases the symptoms from spinal disease were entirely controlled. In 3 of the 4 cases in which death was due to shock, the chisel and mallet were used to obtain the grafts.

Of the 33 surgeons 16 reported 100 per cent of the cases as arrested, 9 reported that they did not use plaster jackets or spinal support beyond the period of immediate post-operative recum-

bency, 9 reported 100 per cent of cases arrested and one secured 83 per cent of good results.

Of the author's personal cases only those that have been operated upon one year or longer are included in this report. There are 98 of these in 184 the disease was arrested, in there was improvement. To date 2 died 6 of these were entirely relieved of their Pott's disease symptoms and died of some intercurrent disease.

One case died of an unknown cause the day after operation one died of tetanus on the fourth day one from status lymphaticus, one died two years after operation from suppurative meningitis following a skull injury. Autopsy showed complete cure of the tubercular spine. One died of pneumonia one week after operation. Others died of amyloid degeneration of the viscera, tuberculosis of the lungs, and an acute abdominal condition. Only 3 of the 539 cases have died of tuberculous meningitis. In no case has there been any trouble with the ilium from which the graft was removed.

The ages of the patients varied from 20 months to 65 years. Of the total 539 cases the disease was arrested in 460 the disease was improved in 59 in 20 improved. There were 9 deaths after operation. In 6 instances death occurred long after operation and after all spinal symptoms were entirely relieved.

The author concludes his interesting paper by stating that every diagnosis of Pott's disease should be confirmed by X-ray examination which should include anteroposterior view as well as a lateral oblique lateral. The disintegration and crumbling of the vertebral bodies is always demonstrated before reaching the operation. This is necessary to confirm the diagnosis but it is most practical to determine the number and the part of the vertebra involved so that the graft can be correctly placed. PAUL L. LEE

M. Williams, C. A. Homoplastic Transplantation of a Bored Segment of a Radius. *Int. Surg. Phila.* 9 6, l, 85

Brewer in January 1910 transplanted a radius from a white into the arm of a patient operated upon a few days previously for sarcoma of the radius, in whom it had been found necessary to remove the lower two and three-eighths inches of the bone. The transplant was boiled for an hour and kept in formal salt solution for four days. Primary union occurred without any subsequent discharge.

The author reports the Brewer case as an example of a homoplastic transplant which has been at least partially successful. From the present roentgenogram it appears that the portion of the graft nearest to the living bone has regenerated completely. It has been entirely substituted so that further away has been only replaced, while the free end was entirely absorbed. The author believes that an autogenous transplant would have given better results. He concludes that dead bone merely acts

as a conductor in that it homoplastic transplantation are employed at all they should be taken from living individual and transplanted with the periosteum. The uses of a homoplastic transplant will depend upon the serological relations but even the individual from whom the graft is taken and the one into whom it is to be grafted. The case is of interest on account of the extreme rarity of reports of successful homoplastic transplantation. In conclusion the author gives a summary of the cases of living and dead homoplastic bone transplantsations in the literature between thirty and forty cases in all. (C. W. WOOD)

Freiberg, A. H. Tendon Transplantation in Infantile Paralysis. *Lancet* 1916 916

Tendon transplantation is a measure of utmost value in paralysis following anterior poliomyelitis but the end results have not yet shown unqualified success. Primary results have been attractive but the corrections have often been only temporary. The failures have been due to various surgical and mechanical additions. Successful transplantation requires (1) The transplant must bear a fairly close morphological and functional relationship to the muscle whose function it is to supplant. (2) The transplant must be fastened to it in a point of insertion and physiological tension only. (3) The transplanted muscle must not be used to hold the limb in a corrected position.

Freiberg describes his operation for paralytic equinovarus. He divides the Achilles tendon and taking the *extensor digitorum longus* passes it through the same compartment in the annular ligament with the tibialis anticus and sews it to the peroneum in company with the insertion of the tibialis anticus. Thus the insertion and insertion of the *extensor digitorum longus* practically identical. Freiberg emphasizes the necessity for little and simple operative plans and condemns the attempts at converting flexor into extensor.

In the treatment of infantile paralysis during the first year mechanical support must be used to protect the paralyzed muscles from overstretching, also muscle training massage and local heat should be used but by no means any form of electricity. Only after a long period should any operative procedure be considered. (R. G. PICKARD)

Ryerson, F. W. Deformities Due to Infantile Paralysis. Operative Treatment. *Am. J. Orth. Surg.* 1916 4 59

While it is undoubtedly true that some cases are best treated by apparatus it is especially effective in flail knee-joints where both the flexors and extensors are paralyzed and the best treatment is a brace with a lock joint. If a single hip-joint is flail arthrodosis is best if both hips are flail apparatus is a necessity. With these exceptions practically all other leg and foot deformities and weaknesses can be treated better by operation than by apparatus.

The practice of repeated tenotomy and trussing is to be strongly condemned. Where any reasonable operative procedure can free the patient from the need of apparatus it should be used. No radical operation should be performed until at least two years have elapsed after the attack of intertrigular myelitis. During this time an attempt should be made to favor the return of power to all unparalyzed muscles. Distortions should be prevented if possible by apparatus such as braces or plaster flaps. The patient should be compelled to use the weak muscles. Electricity, massage, inhalation and cold water should be used to stimulate the nutrition of the muscles. If at the end of two years the condition is not satisfactory a thorough anatomical examination should be made to determine what can be done by operation.

Torrey and Ryerson recommend either splitting or lengthening the tendo achillis if short by Ray's tenotomy. If the extensors of the toes are active they may be fastened to the metatarsal bases preferably by passing each through a hole drilled in its respective bone or by splitting the periosteum gouging out a groove in the bone and sewing the tendon into the groove beneath the peroneum.

For paralysis of toe extensors as well as of the tibialis anticus one or both of the peronei may be displaced forward in front of the malleolus and sewed to the scaphoid or middle cuneiform. If the tibialis posterior be a flail it may also be displaced forward like the peronei and may be needed to check the tendency to valgus. In simple drop-foot a cell as in varus or valgus distal to the astragaloscaphoid arthrodosis should always be performed by firmly sewing the bones with a vertical bichloride silk or kangaroo tendon sutures. In 15 cases where the author has split the gastrocnemius and passed one half of it forward to act as a dorsiflexor of the foot he failed to obtain active function although it acted as a good check ligament.

He recommends Gillis's operation to control the equinus but in his experience of 5 cases it repeatedly failed to prevent lateral deviation. He says it should invariably be supplemented by arthrodesis of the astragaloscaphoid joint or by taking a strip of periosteum and bone from the tibia and implanting it in a groove cut along the inner side of the astragalus, the internal cuneiform and the first metatarsal bones.

Heavy bichloride silk ligament from a hole drilled in the tibia running down under the annular ligament to the inner and outer metatarsal bones gives excellent results where there is no lateral deformity. It should be combined with astragaloscaphoid arthrodosis.

For pes calcaneus Whitman's operation is the best. For paralysis of the extensor quadratus of the thigh the author strongly recommends the transplantation of a healthy biceps and semitendinosus forward into the patella. In contractures of the tensor fascia lata and other structures around the

hip the subperiosteal method of Souttar is excellent
 PHILIP LEWIS

ORTHOPEDICS IN GENERAL

Cornier, E. M. Deformities of the Feet. *Cl. J.*
 9 6 21 93

The author discusses various deformities of the feet from the standpoint of the normal positions and movements of the foot. Deformities are variations from these normal conditions. The foot rests normally in a position of moderate calcaneus while the active foot is in a position of talipes equinus. At the ankle joint the movements of dorsal and plantar flexion of the foot occur at the malleolar joint abduction and adduction occur. Pes planus is a deformity of abduction and pes cavus is one of adduction. Abduction causes a depression of the normal arch of the foot but paradoxical as it may seem some persons have all the symptoms of flatness of the foot but nevertheless have an arched instep. By means of diagrams he shows the occurrence of callosities on the soles of the feet which are caused by the assumption of these varied positions, thus the abducted foot has its typical localized callosities, the adducted its own, etc. The deformities of the active foot, talipes equinus and pes cavus, usually cause few symptoms, but the deformities of the inactive foot talipes calcaneus and pes planus, require treatment.

At the metatarsophalangeal joints, he describes the deformity of hallu rigidus which in the active position develops into hallu extensus and in the inactive position, into hallu flexus. These are caused by bony development on the dorsal or under surfaces of the head of the metatarsal bone. If they grow out laterally they produce hallu valgus or hallu varus depending upon the side they grow upon. The treatment is the operative removal of these bony outgrowths, with the wearing of properly shaped boots.
 R. S. BROWN

Lovett, R. W. The Superstition of Flat Foot.
Pediatrics 9 6 xxviii, 6.

From a study of the feet of 800 nurses the author concludes that the troubles ordinarily described as flat-foot, "pronated-foot," and "weak foot" are not due to any particular type of structure of foot. A foot with a high arch was found to be slightly less enduring than the low-arch type. He concluded that the trouble was due to muscular strain. Frequently the arch of the sole of the foot is not so high as the arch of the foot and this is apt to cause strain.

Painful rigid flat-foot should be treated by manipulation under ether or by operation. Painful flexible flat-foot or foot strain will require the temporary use of a support. The arch of the sole of the shoe should also be raised sufficiently to support the arch of the foot.
 I. BARNES

Schmidt, M. Congenital and Especially Bilateral Elevation of the Scapula (Ueber den angeborenen nasbendern doppelte Schult. rblatthoch stand) *Zschr. f. orthop. Chir.* 9 xxxv Mar

There are 6 cases in the literature of bilateral elevation of the scapula. Various theories have been offered as to the cause of the deformity: lack of amniotic fluid, exostoses, muscular defect, intruterine poliomyelitis, and malformation of the scapula, also the arrest of the normal descensus of the shoulder-blade.

The technique of the operation which was performed by V. Iplius is as follows: Incision along the spine of the scapula directly to the bone elevation of the periosteum and entire resection of the bony part of the fossa suprascapularis. This part of the scapula appears to be bent forward on the shoulder. The median part of the scapula and an exostosis arising from the median border into the depth are also resected. Then subcutaneous tenotomy of the tendons of the posterior axilla is performed. A plaster-of-Paris dressing in abduction is applied and left on for four weeks followed by massage. Orthopedic gymnastics are of prime importance in the after-treatment of the deformity. In the case described the elevation of the arm was increased from 85 to 88 degrees.
 A. STERN

O'Reilly, A. Results of Non-operative Treatment of Infantile Paralysis. *Am. J. Orth. Surg.* 9 11 43

The author's paper is based on a study of the cases of infantile paralysis treated at the out-patient clinic of the St. Louis Children's Hospital and the Washington University Medical School. The majority of cases seen were paralytic of the lower extremity. The muscles are put in equilibrium and all strain is removed from the weak or paralyzed muscles. In the majority of cases, brace is applied. Originally the brace was attached to the shoe. In the past two years sandals have been used. Any deformity due to contractures which does not yield to stretching is corrected by tenotomies.

The patients come to the clinic three days a week for massage and muscle training and the mothers are instructed how to massage them on the other days.

From an analysis of 14 cases treated the author concludes that it is very difficult to treat infantile paralysis non-operatively in an out-patient clinic owing to the difficulty of inducing the patient to attend regularly for any length of time.

From 40 to 45 per cent of the cases show some improvement when treated by braces and this percentage is not materially increased by the use of massage. Improvement in all cases in which it was used was not great and recovery of muscle power in stretched and exhausted muscles seems to be slight. In the majority of cases an improvement took place after six months especially in the more severe cases. He believes that it is safe in operating on any case of infantile paralysis after the first year and that it should be done in suitable cases.
 PHILIP LEWIS

SURGERY OF THE SPINAL COLUMN AND CORD

Cates, B. B. Spina Bifida. *B. N. M.* — 3 J
915 cl. XIV 230

The author reports 9 cases of spina bifida coming under his care making in all 16 cases which he has treated. The ages varied from 21 days to 12 years though with the exception of 2 the ages averaged about eight weeks. The history of each is given in full. Of the author's 16 cases 10 survived beyond a post-operative period of three months. He believes that the age of the patient is not an important factor in determining the personal equation as the physical condition and believes the surgeon may with a clear conscience urge the lesser of two evils operation under the most favorable conditions rather than rupture with risk of infection and meningitis. F. M. C. R. MESSICK

Rugh, J. T. Bone-Grafting for Spinal Conditions. Report of Forty Cases. *Am. J. Orth.* — 18
9 6

The author claims six advantages for the bone-grafting operation viz:

1. It accomplishes fixation in less than a year in marked contrast to the four to ten years required by other methods.

2. Under this fixation treatment nature will more rapidly fill in or solidify the diseased area.

3. An abscess formed or in the process of formation will usually disappear without tapping or opening.

4. Very low mortality.

5. Manipulations are all done in normal healthy tissues in the vast majority of cases.

6. The economic advantage which in the case of the wage earner makes him an independent member of the community within a year.

In his experience with forty cases Rugh has found no disadvantages that can be attributed to the operation *per se*.

He believes that the operative fixation of the spine is the treatment of choice for spinal caries and certain other conditions and especially so in cases past 12 or 14 years of age. He reports a series of forty operations with 74.3 per cent of excellent results and Lange's requirements were fulfilled in that he placed the brace under the skin and shortened the time of efficient recovery.

PHILIP LEWIN

Claude, H. and L. Hermitte, J. Anatomical Study of a Case of Total Section of the Spinal Cord. (*Etude anatomique d'un cas de section totale de la moelle*). *Bull. Soc. med. d. hop. d. Par.* — 9 6 xviii 476

The authors consider that the case now reported upon by them presents a double interest inasmuch as it shows unusual clinical expressions of total section of the spinal cord and that it permits of

localizing the origin of certain reflexes which up to now have been matters of discussion.

There is no certain symptom which allows the diagnosis of total section of the spinal cord while some patients exhibit all the classical symptoms yet anatomical examination proves that the medullary axis is preserved in its continuity. The case now presented while showing unusual features all has this diagnosis and also indicates how certain traits must be interpreted.

The patient was a soldier who in consequence of injuries presented a vertebral fracture with a very marked gibbosity in the region of the eighth dorsal apophysis. Examination 10 days after the injury showed complete anesthesia as far as the eleventh dorsal root complete abolition of the reflex and achillean reflexes and of the lower abdominal reflexes inversion of the plantar cutaneous reflex absolute retention of urine relaxation of the anal sphincter etc. Forty-eight days after the injury there was a reappearance of the tendon reflexes which were exaggerated. Eight days later defensive movements of the lower limbs were noted and within a few weeks more there were automatic movements of the limbs. These movements were preserved up to the time of the patient's death which occurred four and one half months after the injury.

The reappearance of the automatic movement suggested a very severe compression rather than a total section of the cord and surgical interference was suggested but refused by the patient.

Autopsy clearly showed that there was a fracture of the dorsal vertebra the spinal cord was not only compressed but literally crushed thus crushing corresponding to a total section. There was complete isolation of the lumbar and dorsal cord as well as of the encephalic connections.

The authors observe that their findings show that while in the majority of cases of total section there is a flaccid paraplegia with muscular hypotonus and abolition of tendon reflexes yet sometimes after such symptoms there may be clinically a restoration of certain tendon reflexes even an exaggeration of them and an increase of reflexes of leucase and of spontaneous movement. The phenomena displayed by the author's patient was in contradiction to the law of Jackson-Bastian according to which every complete section of the cord is accompanied by an absolute anesthesia and a flaccid paraplegia with total abolition of the tendinous reflexes.

The authors account for the exaggerated tendon reflexes by the compression of the lower trunk of the cord owing to the presence of an anterior dura mater nodule. This slight compression by increasing the dynamism of the gray matter seems to be the most old cause of the tendinous hyperreflexivity. As regards the defensive movement the authors agree with Mori, Loix and Dejerine that these are due to medullary automatism.

In further considering the phenomena observed in their case, the authors observe that the preservation of the spinal vessels assured the lower segment a better nutrition than in cases where the isolated segment is deprived of all vascular connection with the encephalic segment. Moreover in their case the circulation of the cephalorachidian liquid was not sensibly disturbed, and as a consequence there was no interference with the osmotic phenomena of the nerve-cells through the pericellular and perivascular lymphatic spaces. W. A. BRIDGES

Jonas, A. F. Dislocation of the First Cervical Vertebra Produced by Manipulation. T. Am. Surg. Ass. Washington, p 6 May

The author reports one case which is made the subject of his paper. The patient was a farmer who appeared for examination in August 1915 with his head dropped forward, face partly turned toward the right side, and his chin resting on his sternum. His eyebrows were highly elevated. His neck seemed to be fixed for he did not make the slightest cervical rotation. A lateral view disclosed the posterior end of the cervical region projecting sharply backward on the occiput. His appearance suggested destructive cervical spondylitis or an occipito-cervical neoplasm. He spoke with difficulty for he could separate his jaw only to a very limited extent.

He stated that he had not been able to turn nor raise his head for more than a year and that his condition was due to manipulations received at the hands of an osteopath while under treatment for generalized rheumatism. He had been placed on an operating table and the treatment was begun with vigorous and forcible rotations of the head. The operator standing at the head of the table had grasped the patient's head with both hands one resting on either side of it, two fingers, the index and middle beneath each horizontal mandibular ramus, and while holding it thus, his head was twisted from side to side by extreme and forcible rotations, causing great pain. He suddenly felt and heard a loud painful snap in the back of his neck at the base of the skull and his head became fixed in the position described and had so remained. He stated that his condition had become unbearable on account of the pain in the back of the neck and occiput and his inability to separate his jaws enough to enable him to eat speak with freedom. He had had an almost constant vertical headache as well as pain in the neck since the accident.

On examination any attempt to rotate his head caused a marked muscular spasm involving all the cervical muscles especially the trapezi and sternocleidomastoids. An osseous projection was not only palpable but distinctly visible in the occipitocervical space. This appeared to be a spinous process belonging either to the first or second cervical vertebra. The tip of the spine appeared to deviate to the left of the median line. It was tender on pressure and caused the patient to flinch decidedly. In-

spection and palpation of the pharynx disclosed an irregularity and tenderness at the nasopharyngeal junction.

It was evident that it was a case of luxated cervical vertebra, probably the first one of the atlas. There had been no cord pressure symptom except for an occasional tingling of short duration in both arms and hands. There had been no motor disturbances all reflexes were normal and careful search for sensory changes was negative. A skiagram presenting lateral view of the cervical spine revealed a retrodisplacement of the atlas. The space between the posterior margin of the foramen magnum and the first cervical spine was clearly increased. The condition was not clear on first inspection owing to the fact that the spine of the second cervical vertebra is much larger and longer under normal conditions than that of the first the latter usually being absent or rudimentary. Further a dislocation at this point without a fracture of transverse or articular process of the axis and absence of cord lesion is improbable. Therefore, it was evident that there was a slipping forward of the head on the atlas involving the occipito-atlantal articulation. The occipital condyle, probably the left one, had slipped forward so that it rested in front of the margin of the left superior articular surface of the atlas causing a fixed rotary anterolateral deviation of the head. The patient was informed of his condition and advised to return to the osteopath as this class of practitioners never consult themselves as per bone-setters. He declined as a rigorous English his wet would permit and insisted that the author make manual lucio. He was informed that this was out of the question because one could not hope to reduce dislocation in this region that had existed more than a year in which he hoped for an accidental readjustment and at the same time did an injury to the medulla. It was agreed that an effort to make reduction should be made and if unsuccessful immediate open operation should be done.

A cordingly and complete eth anesthesia, guarded rotary manipulations with pressure over the prominent cervical spine were carried out and as was expected without results. The patient was placed in the ventral position and brought forward on the operating table so that his shoulders rested on its edge and the forehead was placed on a Cushing bench. A laminectomy had been planned because it was considered impossible to effect safe operative replacement of the dislocated atlas after having been displaced for more than a year. The chief object to be achieved was to remove the inferior articular surface as well as the lamina to enable the patient to elevate his head so as to relieve the pressure of the chin on the chest. Through the usual posterior incision the arch of the atlas together with the left superior articular surface was removed with a rongeur forceps. A distinct anteroposterior movement of the head could not yet be made. The right atlanto-occipital articulation was affected only in a rotary

way and as its articular surfaces were in contact and immovable it was difficult to move enough to the articulation to mobilize it. This was accomplished so that anteroposterior movement became fairly good. The wound was closed and dressed in the usual aseptic manner. The operative recovery was normal. The immediate operative result was

perfect in the raising of the head so that the humerus was in the position of the patient's hand. The patient could pick up the head with the hand. The patient was able to pick up the head with the hand. The patient was able to pick up the head with the hand.

SURGERY OF THE NERVOUS SYSTEM

Cosset A. Complete Section of Left Radial Nerve—Suture—Return of Voluntary Movement After 150 Days. See *Plat. J. N. Rad. I. Gau. h. s. ture ne. se. t. l. m. s. men. s. d. voluntary ap. ro. ju. B. P. I. M. m. s. d. ch. d. Pa. J. t. l. u. s. 4.*

Cosset gives the details of a case of left radial paralysis operated upon by him in February 1905 in which total section of the nerve was found in the nerve sutured. Five months later there was return of voluntary movements. He refers to two similar cases previously reported by him. *W. A. B. W.*

Monnington. In Laceration of the Radial Nerve in a Cicatrix—Total Radial Paralysis—Liberation of the Nerve—Immediate Reappearance of Motion and Sensation. See *Plat. J. N. Rad. I. Gau. h. s. ture ne. se. t. l. m. s. men. s. d. voluntary ap. ro. ju. B. P. I. M. m. s. d. ch. d. Pa. J. t. l. u. s. 4.*

In the great majority of cases the results of operative intervention in lesions of the nerves have had but a temporary success and it is only after a long interval that one can be sure of a favorable result. Lesions of this kind may be divided into two classes: those in which there is complete section necessitating suture and those in which the continuity of the nerve is merely disturbed and its physiological functioning prevented, which only requires freeing of the nerve.

In the first class of nerve suturing favorable results are exceptional. In 10 interventions Walther had 10 cases of complete or incomplete nerve section in which he was unable to note any favorable result after four months. Tuffier and Dumas stated that in 10 nerve-sutures done by them there was no recovery. The results obtained in freeing nerves and re-establishing continuity are very different. Walther's statistics show a perfect complete recovery.

Monnington reports a case of a man wounded in the left arm followed by paralysis and almost complete loss of sensation. Intervention was made 65 days later. The radial nerve was found embedded in the cicatrix and freed. In less than 8 days there was a disappearance of the paralysis and a complete restoration of sensation.

Kernig's who ulcers this report of M. A. Sangren on the same case who became under

his own observation here after it was with right humerus there was a right radial palsy. The reason on the cicatrix which occurred at the point where the radial nerve passed through the axillary edge of the humerus was found. After incision the nerve was freed and sutured. At the time of reporting it was only 1 month after the patient was entirely well. *W. A. B. W.*

Rogers, M. H. An Operation for the Correction of the Deformity Due to Obstetrical Paralysis. See *Plat. J. N. Rad. I. Gau. h. s. ture ne. se. t. l. m. s. men. s. d. voluntary ap. ro. ju. B. P. I. M. m. s. d. ch. d. Pa. J. t. l. u. s. 4.*

In the deformity the anterior ulnae of the arm and the arm are rotated inward. The patient is unable to attempt to raise this deformity by doing a osteotomy of the upper portion of the humerus about six inches below the humeral joint. It will be by a one-quarter rotation of the humeral arm, the line of rotation. An incision made between the muscles of the arm and the ulnae that there is no nerve involvement. *J. H. A. L.*

Edinger L. The Uniting of Divided Nerves. See *Plat. J. N. Rad. I. Gau. h. s. ture ne. se. t. l. m. s. men. s. d. voluntary ap. ro. ju. B. P. I. M. m. s. d. ch. d. Pa. J. t. l. u. s. 4.*

Edinger has found that there is often great difficulty in the union of the ends of severed nerves. The regenerated nerve fibers which are thrown out by the ganglia will can easily be diverted from their course by any mechanical obstruction such as a blood-clot and union between the stump at therefore be prevented. He shows that this is the case by his own observation and those of others whom he quotes.

The only way that the regenerated fibers may be kept in the proper direction to effect union is to permit them to grow in a tube. Nevertheless the attempts made to grow nerve tubes in tubes of previous workers did not give good results because it was necessary for the fibers to be surrounded in the tube by a suitable environment for growth. Thorough experiment of Edinger's proved that human nerve-fibers grow better when the tubes are united and are inserted in an artery. The tubes are made of agar jelly. The tubes grow by the action of the agar. A number of such tubes have been prepared and distributed for use to operating neurologists.

Edinger has seen the results obtained by Lindloff and Haselauer with 14 patients treated in this manner in which cases the distance between the divided nerve-ends varied from 5 to 5 cm. In every case there was clear evidence of good progress of regeneration in the nerve. Within a few weeks

the anæsthesia area became much reduced. He mentions particularly a case in which 6 cm. of the tibial and 8 cm. of the popliteal nerve had been resected. After inserting the agar jelly tube the return of the plantar reflexes was demonstrable after 16 days.

W. A. BROWN.

MISCELLANEOUS

CLINICAL ENTITIES — TUMORS, ULCERS, ABSCESSSES, ETC.

Byford, H. T. The Etiology and Prophylaxis of Cancer. *Illinois M. J.* 9 6 xxvix, 3.

The author presents a few fairly well established facts that have led him to draw certain conclusions with regard to the etiology and from these conclusions to formulate such recommendations of prophylactic nature as they may seem to justify.

We are justified in assuming for argument's sake, that carcinoma is an infection and that it will not be a waste of time to make a review of facts and probabilities on this basis.

Although carcinoma is sometimes inoculated into the skin or other external epithelial surface, it is in a great preponderance of cases introduced into the system with the food.

The human feces are carriers of germs of carcinoma, both in individuals affected with the disease and in many who are not. The same may be said as to the feces of the dog and the cat.

The occurrence of primary infection in the colon and upper rectum shows that the germs that get by the pancreatic secretions can survive to infect the rectum. If they reach the rectum alive they can, of course, be passed out and may find lodgment elsewhere.

Those who are most subject to carcinoma are those who work in dirt and eat the greatest variety of food. Thus chimney-sweepers, industrial laborers in large towns, city laborers, farmers, and carpenters, all of whom have a high rate of mortality, work in dirt and have not always the means nor incentive for frequent washing, while pressmen, compositors, and printers, whose working materials are protected from outside contamination and whose surroundings are such that they can and do wash and clean up when they go to lunch and go home from work, have a lower rate.

There are probably several factors that have some influence upon the increase of cancer in recent years. The increase of railroad traffic may be supposed to have some effect in spreading infection through travel of individuals and through the enormous amount of cold storage food that is carried every where. Some of the travelers and some of the food must be infected.

Since duodenal ulcer is a more common lesion than gastric ulcer and yet seldom becomes infected with carcinoma, and since trypsin, which is poured

into the duodenum also prevents continued superficial development of carcinoma on surfaces with which it is kept in contact, the question arises whether trypsin, possibly some vegetable ferment, or synthetic imitation, could not be used for the destruction of the disease or the production of immunity. Whether injections of trypsin or a similar substance into and around the carcinomatous mass, into the afferent blood vessels or into the col or the general circulation could be worked out so as to be curative, is perhaps worthy of serious thought if not experiment.

The following recommendations are suggested.

Carcinoma should be considered an infectious disease.

Precautions against the spread of the infection should be taken by the community as well as by the individuals affected.

3. Foods, particularly fruits and vegetables, should be protected from contamination at their source and in transit.

4. The disposal of human excrement in suburban and populous rural and manufacturing districts should be such as to avoid possible contamination of the surface soil. The feces of patients with carcinoma of the alimentary canal and pelvic organs should receive the same attention as those of patients from typhoid fever or cholera. Women should be taught the infectious nature of normal stools, with particular reference to keeping the perineum free from contamination.

5. The number of cats and dogs in populous districts should be restricted and they should not be allowed to roam about the streets by day or night. The excess should be killed. Means should be taken for the extermination of rats, mice, cock roaches, and other vermin.

6. Individuals whose occupations are known to expose them to great risk of infection from carcinoma should be taught that it may get into their systems either through the irritated skin or by way of the alimentary canal.

7. All epithelial areas affected with chronic irritation and erosion should be attended to. An attempt might also be made to prevent infection of ulcerated and eroded surfaces in the alimentary canal. Patients with such lesions should avoid all unsterilized food that might be contaminated.

8. Municipal authorities should put carcinoma upon the list of diseases to be reported in order that the patients may be traced and taught how to take

care of themselves and their infected discharges and that none of those living with them be allowed to handle foodstuff for the market.

9 The blood of patients with carcinoma should be exhaustively studied with reference to the discovery of something that will increase immunity.

10 The time would seem to be ripe for teaching the public something concerning the erroneous notions about diet that are prevalent among the idle rich and prosperous poor in order that they may stop manufacturing the serious forms of gastrointestinal disease that have of late years shown such an alarming increase in frequency the seeds of which are shown in adolescence and the fruits of which are harvested at maturity and in senescence.

11 Women who have not borne children for several years should be warned of the danger of developing carcinoma and should not only be on the lookout for symptoms, but should submit to a pelvic examination at least twice a year until it is evident that the mucous membranes are healthy and are remaining so. EDWARD L. CORNELL.

Moulton G. M.: The Classification of Tumors. In N. S. Phil. 9 6 13 5.

The great variety of tumors makes their classification difficult and according to the author no previous classification can be said to meet all the requirements. Instead of classifying tumors on the basis of malignancy, structure, or origin, the author submits what he believes to be a better classification.

Using the word in its ordinary nomenclature, tumors are divided into two classes. One is due to the reproductive power that all tissues naturally possess when suddenly aroused into action the other to changes that should take place in development but being either carried out. The power of reproducing their like directly without assistance from any other source is the common property of all living things and all parts. The extent to which they make use of this power furnishes the most satisfactory basis for the classification of tissues and of the tumors that grow from them. At a very early period of development one group of cells is marked off for reproduction the germ cells. The rest of the cells known as the somatic cells become specialized for other kinds of work and gradually lose their reproductive power. Each cell as it develops passes through all the stages through which its ancestors passed in the course of evolution. The structure of a tumor depends upon the parent stem and always resembles it though it is never so perfect. Malignancy of the tumor depends then upon the maturity of the parent cell at the moment the bud began to grow. If the parent cell has already reached the adult age the bud will increase proportionately slow, pushing the surrounding structures to one side instead of invading them. There is no separate class of malignant tumors, rapidly growing malignant forms occurring in all classes.

Under the head of tumors of the germ organ and

its derivatives the author has included fetus in tergo teratomata, ovarian dermoid, and ovarian adenomata. The classification of tumors that grow from the somatic cells depends upon that adopted for the tissues themselves. Every organ and every tissue has its own kind of tumor. Tumors of the thyroid may resemble those of the prostate but behave very differently.

Tumors due to errors in development differ from those caused by the sudden awakening of the reproductive power of the tissues in that they do not possess an independent existence and do not belong to the same generation as the structures from which they grow or to the next or mature arrest of development, one of the most important causes of tumor formation. This not only involves the progressive advance of tissues but the disappearance of those which have ceased to be of use. This group includes such tumors as the meningioma, the cerebellar tumor, the medullary groove tumor, the close to its proper time and also those tumors resembling the tumors of the hyaline duct or the thyroid duct or wherever tissues have failed to disappear in the evolution of the organism. GARDNER.

Allan A. P.: Phantom Tumors. (I. J.) (N. S.) 51.

The typical phantom tumor is resonant and is in motion conforming to that muscle or group of muscles with which it is associated it is always resonant but less so than the neighboring part. It is said to disappear during sleep but it does not invariably do so. Pain is absent though some cases run into a cramp in which case the pain is intense.

The author reports two cases both in women. In one the tumor was due to a contraction of the right rectus muscle. This patient recovered under suggestion. The second was due to a dilated cecum following mucous colitis. It disappeared.

The treatment is to move any focus of irritation that may be present or if due to occupation consider the condition for a remedy. Calisthenics and massage have proved useful and purely neurotic cases respond excellently to suggestion. It is well to bear in mind protective phantom tumors and to seek for the cause in deeper or other organs. EDWARD L. CORNELL.

Roberts J. B.: A Further Note on the Etiology of Surgical Scarlatina. T. M. S. 5 1 Wash. 1916 M. 3.

The author states his belief that true scarlatina sometimes occurs by the introduction of the infecting agent through a breach in the skin instead of by the usual faecal or nasal route and in his opinion there is reason to believe it at the difficulty in isolating the infecting organism is probably due to its ultramicroscopic size and its filarial nature. He also suggests that the anginose affection termed scarlatina may cover more than one specific infection.

tion. This last opinion is based upon the confusion which has long existed between similar infections such as typhus and typhoid fever, malarial and yellow fever and other well-known infections with similar symptoms. Reference is made to the papers of McCarty and Hamilton. He believes that many cases of so-called post-operative scarlet fever are probably of septic origin or are due to vasomotor influences. Instances doubtless occur where the true scarlatinal affection is simply coincidence in a patient already suffering from wound received about the time of exposure to the infection.

The cases are cited of Strickler who about 20 years ago inoculated children with saliva of scarlet fever patients in the hope of producing immunity. Strickler believed that he actually caused acute scarlet fever by introducing the infection through a wound in the skin. The latest investigation of the etiology of this disease known to the author is that of Mallory and Medlar of Boston who found a gram-positive bacillus which they thought to be the true causative agent.

SERA, VACCINES, AND FERMENTS

Gellhaus: Some Observations Regarding Collargol Injections in Small Doses (*Einige Beobachtungen bei Collargolinjektionen in kleinen Dosen*). *Menschen med. Wochenschr.* 9 6 hft., 9

The author draws attention to the efficacy of small intravenous injections of collargol in infective diseases. In his earlier cases he used a 2 and 3 per cent solution, but in his recent practice he has reduced the strength to 1 per cent and in the case of children to 0.5 per cent.

He has treated altogether 143 cases of different inflammatory types with collargol. These include appendicitis, peritonitis, gonorrhoea, pneumonia, etc. As a general rule good results are obtained when collargol is injected in the early stages of the inflammatory process. The action of collargol is found to be powerless only when the infection is of a high degree of virulence.

Of the cases treated 34 were cases of appendicitis. Of these operation was necessary in 6. Of the others, died and 27 recovered with 2 cases of relapse. The early use of collargol not only facilitates the results of operation when such is necessary for inflammatory conditions, but it may obviate operation altogether.

BLOOD

Rous, P. and Turner J. R. The Preservation of Living Red Blood-Cells in Vitro; Methods of Preservation. *J. Exp. Med.* 9 6 XIII, 9.

The authors state that there is practically no mention in the literature of attempts to keep red blood-cells alive for a long time *in vitro* notwithstanding the great practical advantage that such a method would afford. They believe that red blood cells could be used for serum reactions, or for cul-

ture media, or even under certain circumstances for transfusion.

In their experiment they make use of the cells of the blood of sheep and man. They seem to have proven conclusively that washed red cells are to be properly preserved they must be protected during washing and that plasma cannot be used for this purpose. They found that gelatin in one eighth to one fourth per cent in Locke's solution protected cells absolutely against injury during washing and even during prolonged shaking. This injury may express itself in hemolysis only after the cells have been kept for some days. They found it most test in the use of dog, opossums, and a ill marked sheep and rabbit cell. The fragility of the red cells, as indicated by washing or shaking them in salt solution they are different, not only for different species but for different individuals. It varies independently of the resistance to hypotonic solutions. The important point that the protection of fragile erythrocytes during washing is essential if they are to be preserved for a very considerable time. The addition of little gelatin—one eighth per cent—to the wash fluid was found sufficient for this purpose. It is the period of survival in salt solution of washed rabbit, sheep, and dog cells was greatly prolonged.

Though gelatin itself is too toxic for red cells they did find it very useful to them in the real sense. Cells did not last longer when gelatin was added to the fluids which they were kept. Locke's solution though probably better than Ringer's solution in which words in blood solution medium in which to keep red cells is it may be harmful. The addition of innocuous blood did not improve it. But the sugars especially dextrose and saccharose had the authors at it remained power to prevent its injurious action and possessed, in addition preservative qualities. Cells washed in gelatin Locke's solution and placed in a mixture of Locke's solution with a isotonic watery solution of sugar remained intact for long time—nearly two months in the case of sheep cells. The kept cells went easily into suspension free of clumps, they passed readily through paper filters, took up and gave off oxygen, and when used for the Wassermann reaction behaved exactly as did fresh cells from the same individual. The best preservative solutions, the authors state are approximately isotonic with the blood serum. If the cells are to be much handled gelatin should be present for the sugars it was found did not protect against mechanical injury.

G. M. E. BEILY

Morris, W. H. Secondary Hemorrhage in Military Surgery. *Med. Surg. Rep.* 9 6 VII, 3.

The inefficiency of accepted methods of controlling wound infections has been one of the surgical surprises of the present war. Almost every case is infected many of them seriously. Serious complications frequently arise and one of the most serious is secondary hemorrhage.

Secondary hæmorrhage may originate from one of several causes. (1) A thrombus closing the end of a severed vessel may become infected, digested and hæmorrhage result. (2) A vessel wall may be contused and hæmorrhage occur only after sloughing has occurred. (3) An intact vessel wall may be eroded by direct extension of a sloughing infection from neighboring tissues. (4) A spurious aneurism may have its sac wall infected and rupture occur.

Other factors besides infection which may lead to secondary hæmorrhage are (1) a hæmorrhagic diathesis may exist (2) the jolting and jarring incident to transportation may excite hæmorrhage and (3) a foreign body in the wound may cause hæmorrhage by eroding the vessel wall.

The onset of secondary hæmorrhage is usually sudden and the patient may be found in collapse lying in a pool of blood.

The treatment should attempt the control of the hæmorrhage and the resuscitation of the patient. The control of the hæmorrhage may be secured by ligation of the bleeding vessel as far above the area of infection as possible. Frequently however recurrent hæmorrhages occur and usually amputation of the bleeding vessel be in a limb as high as necessary is undertaken. The resuscitation of the patient is effected chiefly by normal saline hypodermoclysis and blood transfusion.

The author reports five cases coming under his own observation and gives a complete history of each case.

J. H. SMILE

Hess A F: The Blood and the Blood Vessels in Hemophilia and Other Hemorrhagic Diseases. *Arch. Int. Med.* 9:6 1913

Hess believes that the group termed the hæmorrhagic diseases includes a large number of abnormal conditions and that at the present time it is a fruitless task to attempt to unravel the various entities embraced by the clinical conditions which are assembled under this general head. Thus he considers as due partly to the fact that the physiology of the coagulation of the blood is still incompletely understood partly because of the impossibility of analyzing the various factors concerned in coagulation and in part because these hæmorrhagic states have been incompletely observed from a clinical point of view.

In this investigation therefore the author considers the condition of purpura rather as an entity and compares it to hæmophilia. The main points in his study may be summarized as follows:

The coagulation time of the plasma in hæmophilia at times may become normal without the occurrence of hæmorrhage or other apparent change in the condition of the patient.

The estimation of the number of blood platelets is of great value as has been found by others, in differentiating between purpura and hæmophilia. In some cases of purpura the platelets are abnormal and may be differentiated like other macrocytes

and microcytes of the blood into macroplatelets and microplatelets.

The puncture test — the reaction following subcutaneous puncture of the skin — is an aid to diagnosis. In hæmophilia a hæmorrhagic area rarely results from this procedure in purpura it is the rule.

The capillary resistance test is also of value. By this is understood the reaction following the application for a definite period of a tourniquet to the upper arm. In purpura this results in petechial hæmorrhages on the forearm in hæmophilia the result is negative.

There is an hereditary purpura as well as an hereditary hæmophilia. The type of purpura should be more generally recognized so that these cases will not on account of their hereditary history continue to be regarded as hæmophilia.

The male member of a family may be a bleeder of the hæmophilic type and the female of the purpura type. Two families are described in which one member suffers from hæmophilia and another from purpura.

Hæmophilia may be atypical. A case is reported which showed a album deficiency as born out by various hepatic and biliary tests (hæmophilic calculus).

In some cases manifesting hæmorrhage the vessel seem to be involved. This weakness is encountered in children and may be congenital it may appear in the course of an infectious disease or of a nutritional disorder such as infantile scurvy.

In the classification case the differentiation between hæmophilia and purpura is simple. The history of a typical hæmophilic is a male with a hereditary history of bleeding whose blood manifests a definite delay in coagulation time whose platelets are normal in number bleeding time not increased who shows no hæmorrhagic reaction following subcutaneous puncture of the skin and a negative capillary resistance test. A typical case of purpura is found to be quite different the patient may be a male or a female the plasma coagulates in almost normal time and the number of blood platelets is decreased (frequently below 100,000 in number) there is definite subcutaneous hæmorrhage following puncture of the skin an increase of the bleeding time and the development of a large number of petechial hæmorrhages following the application of a tourniquet.

GEORGE I. BELL

Meyer W: The Conservative Treatment of Gangrene of the Extremities Due to Thromboangiitis Obliterans. *J. S. G. Phila.* 9:6 1913

After a discussion of a number of cases which the author has treated conservatively with most encouraging results and a review of the various methods of treatment of both acute and chronic gangrene of the extremities, the author discusses in detail that type due to thromboangiitis obliterans. He believes that conservative treatment should always be instituted before an amputation

is considered. If gangrene has begun, it is obviously impossible to replace what is dead. The progress may however be stayed old obstinate ulcers may heal, and otherwise uncontrollable pain can be relieved.

Conservative treatment consists in the use of superheated air or Bier hyperemia. This is best combined with systematic hypodermoclysis of Ringer's solution. If these simpler methods prove of no avail conservative operative measures are indicated viz. tying of the femoral vein or arterio-venous anastomosis. Both of the latter methods should be subjected to further careful clinical research as to their real value. Superheated air treatment may bring improvement of the symptoms, but a lasting beneficial effect is rarely seen. It seldom controls the pain. The systematic hypodermic injection of 400 to 500 ccm. of Ringer's solution (Mateodma Koga) daily or every second or third day deserves a definite place in the conservative treatment. Its effect may be lasting or temporary but if temporary repetition usually again brings improvement. Two such series of injections represent a sufficient test as to their usefulness. Internally a simultaneous administration of organotherapeutic preparations deserves a careful test. Since women seem to be immune to the disease it has been suggested that something in their system protects them and for this, if for no other reason, extracts of organs should be given a trial.

Inflammation of the wall of the blood vessels of the next higher group i.e. the capillaries, arterial as well as venous, seems to be responsible for the thrombosis (Rueger). Its cause may be microbic but the fact that women are immune again seems to argue against this. The increased viscosity of the blood viz. blood that is thicker than normal, seems to play an important rôle in the etiology of the disease. It is possible that an altered quality of the blood as such represents a cause for the occurrence of the thrombosis and the subsequent gangrene. On the basis of this reasoning procedures which tend to reduce the coagulability of the blood within the body deserve to be tried in an effort to find the underlying cause of the trouble. Intravenous injections of anticoagulating substances, such as a 1 per cent watery solution of sodium citrate may prove to be a useful adjuvant to the systemic hypodermic administration of Ringer's solution. GATZWOOD.

McLean, A. Venous Thrombosis and Embolism, Its Cause, Significance and Consequences. *Proc. M. J.* p. 6 xix, 3, 8.

The author describes some experiment on dogs undertaken to explain the cause of the thrombotic process which occurs, for instance as a femoral thrombosis following an apparently clean appendectomy where the common etiological factors, such as (1) trauma to the intima, (2) stagnation or

slowing of the blood stream, (3) chemical changes in the blood, and (4) infection are wanting.

It was impressed with the tremendous amount of injury a vein could withstand without the formation of a thrombus at the site of the injury.

The following phenomena were noticed in the course of the experiments.

1. When a vein is ligated in continuity the blood in the vein will clot only on one side of the point of ligation, that is, the side from which the blood is coming.

In ligating a vein between two ligatures (two inches apart) the blood between the ligatures clots very slowly and if left for a week or more the contents of the ligated vein will have completely disappeared, a fibrous cordlike structure alone remaining.

3. The same result is accomplished by ligating an artery between two ligatures.

4. Simple crushing of a vein will not cause a clot at the point of crushing. The crushing can be repeated to forty-eight hours and a clot will not form at the site. Examination of the repeatedly crushed vein two weeks after the last crushing, will show a thickening of all the coats of the vein the intima remaining smooth and glistening.

5. Crushing the vein with the subsequent introduction of a 24 hour bouillon culture of staphylococci, and again crushing the vein, grinding the staphylococci into the vein wall did not produce a clot or thrombus at the site of the crushing or the injection of the bacteria.

6. The introduction of a sterile thread into the lumen of a vein, allowing one-half to three-fourths of an inch to be suspended inside the vein, failed to produce a clot or thrombus.

7. The same experiment was negative in the artery allowing the thread to remain four, five and seven days.

8. Thread infected with staphylococcus albus or aureus will cause thrombus in three or four days.

9. Thread infected with colon bacillus or staphylococcus aureus introduced into an artery caused the formation of a firm clot.

10. Sterile thread one-half and one inch long let go of the circulation caused no symptoms.

11. Infected thread (colon bacillus) let go caused death in three and one-half days. Thread infected with blood-clot recovered in the right lung.

In reviewing his records of the past two years in 1,610 laparotomies, thrombosis and embolism followed in 33 cases 2 per cent. There were 9 fatal cases of embolism. There were 3 cases of pulmonary embolism followed by abscess and recovery; 2 of hepatic embolism followed by abscess with one recovery; 2 of cerebral embolism followed by death. There were fifteen cases of femoral thrombosis following pelvic operations.

It is worthy of note that in all the cases of embolism and thrombosis in the entire series, there was only one case of embolism with recovery and no cases at all of thrombosis that followed operations in the upper abdomen. LUCIUS H. LAMOREY.

Palmer, G. F. The Operative Treatment of Thrombo Angiitis Obliterans. *St. P. M. J.* 1916 2: 414.

The author cites a number of cases that have come under his observation which he puts in the classification so well described by Leo Burger.

All of his cases were in young Russian Jews. Occupation can not be traced as a causative factor as his cases are found in many different callings. However his observations coincide with Ehrlich so much as excessive cigarette smoking and inveterate tea drinking has been noticed in all his cases. The unstable nervous system of the Jewish race as a whole may play a part in this condition as almost all of his patients have been temperamentally neurotics.

The patients complain of disagreeable sensations in the feet and sometimes in the calves of the leg, this increases to pain and is associated with a congestion of the toes which extends to the dorsum of the foot possibly as high as the malleoli.

A dependent position of the foot aggravates this congestion and the pain is more severe and of a burning character the longer the foot is allowed to hang. Pain and congestion are appreciably lessened by elevation. Anterior and posterior tibial pulse is very feeble or absent. Gangrenous areas may be noted if the caliber of the vessel is sufficiently encroached upon.

Pseudo-arthritides are quite prevalent among the Jewish people as described by Solis-Cohen. A certain amount of apparently bona fide capsular thickening gradually develops even in these purely functional or neurotic joint disturbances. If such actual physical changes can take place in and about joints as the result of a non-inflammatory condition the author advances the hypothesis that given the activity of a similarly disturbed nervous mechanism in the peripheral vessels of the extremities one might expect to find these vessels occupied by a thrombus which would attach itself to the walls and organize into connective tissue thus narrowing or occluding the lumen of the vessels.

The author is in favor of conservative treatment rather than amputation especially in the early cases. This treatment consists in rest, elevation of the limb combined with keeping it well wrapped in cotton wool discontinuing the use of tobacco, alcohol, tea, etc.

This necessarily means a long tedious treatment but with sufficient means or hospital facilities the end results justify the sacrifice of time.

LUCAS H. LINDAY

Lindeman, E. Reactions Following Blood Transfusion by the Syringe Cannula System. *J. M. A.* 1916 1: 64.

Lindeman states that the syringe cannula system has greatly simplified the procedure of blood transfusion which now occupies a prominent and permanent place in therapeutics. In the first 150

transfusions by his method chill followed by fever occurred in approximately 33 per cent. He has found that hemolysis never occurred without chill and fever unless the patient lies lying or shortly after the transfusion. He therefore states that chill and fever in transfusion are due to hemoglobin set free in the circulating blood. If the hemoglobin set free is abundant it appears in the urine when the amount is moderate hematuria or hemoglobinuria in the urine when hemolysis is light. No blood pigment appears in the urine.

In this series of cases the preliminary blood tests for hemolysis and agglutination were conducted by different serologists. In very few cases when hemolysis occurred and in which preliminary test had been made, Lindeman had the test repeated later and in a high percentage of patients was detected in the second examination. He notes that there was error in the primary examination and has set himself the task of eliminating this error by personal supervision of the laboratory work and following refined method of detection so as to prevent even a slight degree of hemolysis of which the only manifestation is chills and fever.

His technique for testing for hemolysis and agglutination is as follows: The red blood cells of the patient and donor are washed three times with normal saline, variable quantities of patient's serum are placed in three separate small test tubes to each of these are added 0.5 ccm. of a 1 per cent suspension of washed blood-cells of the donor. The same is done with the donor's serum and the patient's cells. Controls are made of donor's serum and donor's cells—patient's serum and patient's cells. Controls are also made with donor's cells in normal salt solution and patient's cells in normal salt solution. The total volume in each tube is raised with normal saline to 0.5 ccm. of volume. The test tubes are incubated in a water bath for a period of two hours, and readings are made. They are then set in the ice box over night and readings are again made the following morning. When a case is urgent the ice box test is eliminated.

In the last 155 transfusions performed by the syringe cannula system with personally supervised preliminary tests no case of hemolysis and no death referable to transfusion occurred. Chills followed by a rise in temperature occurred in sixteen instances. Adults received from 1000 to 1800 ccm. in each transfusion and the quantity enumerated was always taken from one donor. No foreign substance or anticoagulant was employed in any case.

In the syringe cannula method of Lindeman the entire mass of blood is outside the body for a period of from six to ten seconds regardless of the amount transferred. It passes through a minimum amount of foreign material. Embolism or clotting never occurs in transit. Syringes are cleaned as fast as used. Clotting in the syringe can not occur and the blood is transferred uninjured exactly as it exists in nature. There are no stopcocks valves or

rubber tubing about which blood may clot and there is no blood system into which air may leak.

His conclusions are as follows:

1. The preliminary hemolytic and agglutination tests when properly performed are reliable.

Incidents of hemolysis in transfusion can be eliminated entirely.

3. The reactions which follow transfusion when curat test is made are eliminated in all except 9 per cent of the cases. In this 9 per cent chills and fever alone occur. When the quantity is 800 ccm. or less chills and fever do not occur.

4. By careful, curat and complete hemolysis and agglutination tests when work is done skillfully blood-transfusion is robbed of all danger attending its use.

ALAN ST. ENNA, MD.

Cherry, T. H. and Langrock, E. G. The Relation of Hemolysis in the Transfusion of Babies with the Mothers as Donors. *J. Am. Med. Ass.* 9, 6, 1914, 625.

Cherry and Langrock consider that hemorrhagic disease of the newborn is one of the most frequent and alarming of the diseases in combating which transfusion is required. The cutaneous injection of animal or human serum (Welch) or of whole blood (Schloss) has been used with a considerable degree of success, but there have also been great many failures. The transfusion of blood, however, has given highly gratifying results.

On account of the close relationship of the maternal and foetal bloods, therefore, it is a natural supposition that complete compatibility of infant and mother's blood should exist. In order to establish this fact, the authors have performed a series of hemolytic tests in 34 instances, 30 newborn babies and their own mothers. If it is known beforehand that the mother's blood is compatible it will save delay in finding a compatible donor. In making the necessary serological tests, and in the expense which these conditions entail.

In the 34 tests carried out no hemolysis or agglutination occurred. Accordingly the authors conclude that all mothers can be used as donors for their infants in the transfusion of blood, provided no contra-indications exist on the mother's part.

The authors report one transfusion performed since these experiments were concluded in which, without preliminary blood tests, 60 ccm. was successfully transfused from the mother through the external jugular vein, by the indirect syringe procedure of Unger. They estimate that 60 to 75 ccm. are sufficient to supply the infant with necessary elements to promote clotting and to replace those lost by hemorrhage. They recommend the indirect method for its simplicity.

ALBERT EISENBERGER.

Rous, P., and Turner, J. R. The Preservation of Living Red Blood-Cells in Vitro; Transfusion of Kept Cells. *J. Exp. Med.* 9, 6, 1913, 39.

Having described in a previous paper the methods whereby red blood-cells may be kept intact for

long periods *in vitro*, Rous and Turner have undertaken to determine whether cells kept according to these methods were alive in the sense that they were capable of functioning in the animal body. Thus they have attempted to determine by transfusion if the kept cell in bulk with appropriate control. They have performed many such experiments, using rabbits.

In order to determine the suitability for functional uses of red cells kept *in vitro* by their methods, transfusion experiments were carried out with rabbits by which large parts of their blood was replaced with kept rabbit cells suspended in Locke's solution. It was found that erythrocytes preserved

mixtures of blood sodium citrate saccharose, and water for 4 days and used to replace normal blood remained in circulation and functioned so well that the animal showed no disturbance and the blood count, hemoglobin and percentage of reticulated red cells remained normal. Cells kept for longer periods, though intact and apparently unchanged when transfused soon left the circulation. Animals in which this disappearance of cells took place on large scale remained healthy save for the progressing anemia. The experiments proved that in the exsanguinated rabbit at least transfusion of cells kept for a long time *in vitro* could be used to replace the blood lost and that when the cells had been kept too long but were still intact they were disposed of without harm. The indications are therefore that kept human cells could be profitably employed in the same way.

GEORGE E. B. HAN.

BLOOD AND LYMPH VESSELS

Leclerc, W. J. A Clinical Lecture on Aneurysms of War Wounds. *Am. J. Surg.* 9, 6, 1914, 33.

Leclerc classifies 50 cases of traumatic aneurysm and emphasizes some points in regard to their treatment. Of the 50 cases, 30 were arterial and 20 were arteriovenous, 7 were of the vessels of the head and neck, 4 of the vessels of the upper extremity and 39 of the vessels of the lower extremity. The popliteal suffered more frequently than any other vessel. There were 4 deaths in the series.

The signs of traumatic aneurysms vary somewhat from those of pathological aneurysms. The bruit is usually much more marked and the thrill is harsher. Where the clot is large the pulsation, bruit and thrill may entirely disappear.

With regard to the treatment of traumatic aneurysms in general the author makes the following suggestions: (1) Delay operation as long as possible in order to allow time for collateral circulation to be established. (2) Always be prepared for profuse hemorrhage. (3) Make long incision in order to secure an abundance of room.

The methods of dealing with traumatic aneurysms are three: ligation of vessels, operations on the sac and amputation.

The application of ligatures to the artery on the

proximal and distal sides of the aneurism is quite the best method of treatment. A ligature on the proximal side alone is uncertain in its results and may not control the bleeding. The ideal method of treatment is to apply a tourniquet, open the sac, pass a probe into each communicating vessel and ligate each one externally, but it is not altogether easy and causes a good deal of disturbance.

Amputation is required if gangrene has set in and may possibly be the safest as a primary treatment where there is a diffused traumatic arterial aneurism. Quadruple ligation with excision of the intervening portion is the best method of treatment in arteriovenous aneurisms. J. W. TURNER

Haberland, H. F. O. The Epitaphs in Wound Aneurisms (Zu Epitaphen der Schussaneurysmen). *Deut. klin. Wch. Nr. 1916* No. 100.

In the case of traumatic aneurisms of the extremities it is only permissible to speak of a cure when complete functional use of the organ has been restored and provided there is no serious secondary injury.

Great caution must be observed in making the prognosis, owing to the danger of late gangrene developing; observation after operation should be continued for at least six weeks.

Early vessel-suture is favorable to early recovery. Oval suturing is to be preferred. Arteriovenous aneurisms ought always be operated upon on account of the danger of embolism. Conservative treatment will not effect an anatomical cure.

W. A. BREYER

Judd E. S. Cerebral Aneurism. *St. P. M. J.* 96 VIII 48.

The author reports quite an extensive case involving the entire forehead in which there was a large mass over the bridge of the nose which extended into the right lids, entirely closing the eye. The dilated vessels passed back through the scalp to the occipital region. The right facial artery was considerably dilated as it crossed the border of the jaw at the anterior border of the masseter muscle.

Under ether and local anesthesia, the right external carotid was ligated as well as the facial just above the submaxillary gland. The pulsation was considerably diminished in the prominent part of the angioma, but in a few days the condition was the same as before operation.

Six days later the opposite external carotid was ligated which practically stilled the vessels. The patient was comfortable for a few days, when the skin of the scalp over the aneurism became tenser and extremely painful. The scalp and tissue about the face were very sensitive. The pain was so great that morphine had to be administered freely.

Five days later the scalp was incised from the glabella to theinion, down to the periosteum. The scalp was reflected on both sides and the dilated and thrombosed vessel were dissected out. There was

no tendency to hemorrhage or active bleeding. The scalp was sutured. One or two separate incisions about the face and temporal region were necessary and the vessels in these regions extirpated. Swelling occurred in the fifth scalp-flap. The aneurism was satisfactory and the patient has been doing well in the past six months.

The author discusses the various forms of treatment which have been advocated for these lesions, such as the ligation of the internal vessel, the coagulation of blood by means of an electrolytic galvanocautery, electric puncture, etc. When the condition appears in the arm, amputation may have to be resorted to. Some observers recommend letting these tumors alone unless the action or severity of the condition enlarges them. In the patient compressed in the tumor a simple but inefficient mode of treatment. Ligation of the temporal and occipital also the branch of the artery leading to the affected part has been tried with no success.

While ligation of an external carotid may result the supply to the scalp, the ligation of both external carotids is more efficacious. Ligation of the internal carotid is far more dangerous, especially in the neck, and is not as efficacious as the ligation of the external carotid, as the brain has involved pruning of the latter vessel.

Fifty-one single ligations and forty-eight double ligations of the external carotid have been performed in the Rochester clinic without a single death, while in eight cases in which one common carotid was ligated there were two deaths.

LUCIA H. LAURA

Kuettner H. Experience in Injuries of the Large Blood Vessels in War (Miel. Erfahrungen in der Kriegschirurgie der grossen Blutgefässverletzungen). *Beit. klin. Wch. Nr. 1916* No. 101.

Kuettner's experience with injuries of the larger vessels including aneurisms is based upon 40 cases in the Graeco-Turkish, South African and the present wars.

Next to nerve injuries aneurisms are the most interesting to the surgeon. These classes of injuries give the greatest contrasts in peace and war. In vascular surgery, however, unlike surgery of the nerves, the surgeon can see the success or failure of his intervention at once without having to wait an indefinite period.

Injuries to the large blood vessels are so serious and the operator's difficulties so great that their treatment should be left to the most experienced and skillful surgeons. Kuettner classifies blood vessel injuries in three groups: (1) injuries with external hemorrhage, (2) injuries with internal hemorrhage, and (3) complete aneurisms.

Regarding external hemorrhages Kuettner states that the percentage of soldiers who die from hemorrhage on the battlefield depends on the kind of battle and the class of weapon. In artillery wound fragment of shells and especially pieces of steel

grenades cut through the vessel like a knife and there is a large external hemorrhage. The crushing effect even of the large modern projectiles counts for much less than the effects of splinters.

Aneurisms are more frequent with the present day jacketed bullets than formerly. The small entrance and exit wounds make it more difficult for the blood to flow. Regarding treatment of hemorrhage in the field the author states. In venous hemorrhage pressure bandages are usually sufficient. Ligation is rarely necessary. In arterial hemorrhage in about half of the cases, ordinary means—elevation of parts pressure bandage—suffice. Of 4 arterial hemorrhages only 1 required ligation.

When the firing is at close range death from hemorrhage is more common. Regarding aneurisms, they rarely result from grenade splinter or shrapnel wounds which are likely to be fatal. They are rare in wounds from jacketed bullets with fracture of the large bones; they occur only occasionally when the entry and exit wounds are large.

Secondary hemorrhages are even more important than primary. These may be the result of infection (septic erosion) or a splinter of detached bone may injure the vessel or it may be due to pressure of a drain in the vicinity of a vessel. It is not always noticed until the patient's condition is serious. If these secondary hemorrhages are frequently repeated amputation may be called for. If the secondary hemorrhage is from a main arterial trunk which is badly infected, amputation is the best course as suturing and ligation is out of the question.

The author has found vast benefit in parenchymatous septic secondary hemorrhage from intravenous injections of coagulum.

With regard to internal hemorrhages, the author states that hematomata are usually present in all war injuries of the larger vessels. They show pulsation. Where a vein is injured arterial blood frequently finds its way directly into the vein causing an arteriovenous fistula and the formation of hematoma is small.

Diagnosis of hematoma is usually easy but it may be confounded with abscess. On account of the possibilities of perforation, infection or gangrene of hematoma, and the fact that spontaneous healing is infrequent, the author thinks active early surgical intervention is indicated.

Kuettner treated altogether 93 aneurisms, 56 of these were complete and 37 were in the hematoma stage. 45 per cent were arterial, 55 per cent were arteriovenous, 73.6 per cent were treated by ligation, 26.4 per cent by suture. W. A. BECKMAN

POISONS

Freeman L. Chronic General Infection with the Bacillus Pyocyaneus. *T. Am. Surg.* 4 Wash.ington, 9 6 May

The author gave a brief statement of the prominent symptoms of pyocyanic infection together with

the main fact in its pathology and a somewhat detailed report of an instance of the more unusual chronic form of the disease, of which only a few cases have been recorded.

The author's case was an adult who had been ill for nearly eleven months. He had a high fever of the septic type, eruptions upon the skin, severe neuralgia, serous effusions and muscular paralysis and trophic.

During an exploratory laparotomy a cholecystostomy was done and a pure culture of the bacillus pyocyaneus recovered from the bile and thickened bile. From this a vaccine was made and administered to the patient following which the patient gradually recovered.

The features of especial interest in the case are

1. Its extreme chronicity (nearly months)

2. The typical neuralgic pains, followed by paralysis and muscular atrophy

3. The absence of the bacillus pyocyaneus from the blood and its presence in the bile. (The germ does not grow in the blood but is merely conveyed by it, lodging and multiplying in the vessel walls. It is found mostly in the parenchymatous organs, such as the liver, spleen, and kidneys; hence particularly apt to infect the bile.)

4. The absence of any discoverable point of infection unless it might be the teeth.

5. Recovery following drainage of the gall-bladder and the use of an autogenous vaccine

6. The occurrence of carbuncles of the liver

7. The presence of ascites and pleural effusion.

8. The satisfactory recovery after so severe and protracted an illness, with the exception of moderate paralysis of the lower limbs, which seems to be improving.

Burling G. Remarks on Delayed Tetanus. *Brit. Med. J.* 9 6 4, 337

Three cases are reported in which the incubation period varied from 50 to 53 days. In most of the cases the original wound had apparently healed before the onset of tetanus. The cause of the prolonged incubation period is unknown although several theories are advanced. At least two of the patients reported had prophylactic doses of a tetanic serum, which may have inhibited the growth of the organisms or neutralized all of the toxin available during the first days after the receipt of the wound. In several of the cases a lowering of resistance seemed to precede the onset of the tetanus. J. H. SMITH.

Abercrombie R. G. The Treatment of Tetanus. *Brit. Med. J.* 9 6, 4, 339.

Four cases are reported in full. The effectual daily dose would appear to be 10,000 to 12,000 units. This may be given twice a day in critical cases. The major portion of this dose should be given intravenously, subcutaneous injections being also used to maintain the effect. Intrathecal injections should be given daily or at such intervals as

the symptoms demand. The dose must be reduced gradually in order to prevent relapse.

All will agree as to the desirability of the treatment of a child wound as a preventive of tetanus, but when once the disease has declared itself, peroperative surgical intervention with the surface of the wound although recommended several authorities is a great handicap by considerable danger. Practice in animals by barrier would thus be broken down exposing the tissue to the tetanist.

SURGICAL THERAPEUTICS

McGuire S. The Post Hospital Care of a Surgical Patient. *J. M. J.*

The author urges the formulation of a plan whereby surgical patients leaving hospital would have their post-operative treatment supervised by the surgeon in cooperation with the attending physician. Patients are not immediately up after operation and they need resting time to turn to normal after the procedure. He has returned from a surgical study that the patient cannot be trusted to safeguard his health during this time for the knowledge of the patient on medical subjects often seems to be in proportion to their intelligence and common sense in everyday matters. Correspondence between surgeons and patients is usually a privilege. Use the patient usually fails to give importance and often either overexaggerates or underrates his symptoms.

In the author's opinion the best result in long up post-operative cases will result from the co-operation of the surgeon, the attending physician and the patient. The plan he suggests is as follows:

The patient on leaving the hospital is given a form setting the general points that will be of interest to him in his post-operative life with relation to his definite operation. He is told to report to his family physician for tonics, hypnotics and cathartics. A description of the operation and operative findings is sent to the physician and full explanation of the case is made to him so that he will be able to intelligently direct the patient in his post-operative care.

The author finds that about 90 per cent of the ordinary hospital cases can be covered amply with regard to their post-operative care by instructions on about 12 different types of blanks depending on the character of the operation. In about 10 per cent of cases it is necessary to enlarge on these instructions personally.

SURGICAL ANATOMY

Wood F. C. and McLean E. H.: The Effect of Phloridzin on Tumors in Animals. *J. Cancer Res.* 4: 19, 6, 1, 49.

Following the report of Benedict and Lewis in 1914 of the cure of malignant tumors in rats by the

use of phloridzin, the authors have conducted a series of experiments on the effect of phloridzin on the growth of tumors in rats. The results show that phloridzin has a marked effect in reducing the growth of tumors in rats. The authors conclude that phloridzin is a valuable agent in the treatment of malignant tumors in animals.

The authors also discuss the mechanism of action of phloridzin, suggesting that it may act by interfering with the metabolic processes of the tumor cells. They also mention the importance of the dosage and the duration of treatment in achieving the best results.

The authors conclude that phloridzin is a valuable agent in the treatment of malignant tumors in animals, and they recommend its use in conjunction with other therapeutic measures.

Concluding the review, the authors state that the results of their experiments are promising and that further studies are warranted to determine the exact mechanism of action of phloridzin and its potential for use in human patients.

Ulfredux O. Contributions to the Experimental Surgery of the Mediastinum, Excluding the Heart. *J. M. J.*

Ulfredux reviews the various methods of operating upon the mediastinum through the pleura and the various positive and negative procedures apparatus. He describes an apparatus which is a modification of the Meltzer-Yer apparatus which he believes has the advantage of preventing the reflex of ether in the respiratory tract and of permitting the use of oxygen instead of atmospheric air and of being applicable even to a positive pressure mask in case intubation should eventually fail or be contraindicated. With the aid of this device the author has been able to perform a large series of experiments upon dogs in which extensive operations were performed upon the esophagus, the thoracic aorta, the thoracic duct, the pulmonary

The elastometer (Schwartz)

artery superior and inferior vena cava and the vagi and the intercostal nerves.

With an experience of more than 300 narcooses in which the author has used this type of apparatus, he states that the method of narcoosis is not only excellent but is attended with the lowest mortality of any method that can be applied to animals. He states that he has never had a death during the narcoosis that could be ascribed to the method even when the anesthetic was prolonged for several hours, that the opening of both pleura is perfectly tolerated, that post-operative pneumonia is very rare, and that with this method one is able to work with almost no respiratory movement.

G ORGE E. BEZLEY

Schwartz, A. B. The Clinical Study of Edema by Means of the Elastometer. *Arch Int Med* 9 6 xvii, 396

The elastometer, an instrument devised by Schade to measure edema, the author believes promises to change the study of edema from a subjective one depending on the amount of pitting obtained on pressure to an objective one whereby the degree of edema may be expressed in exact terms. The instrument which Schade has devised consists of a disk mounted on a perpendicular vertical rod which is placed on the skin surface with the addition of a superimposed weight. The amount of depression caused by the sinking of the weighted disk into the

skin and subcutaneous tissue is graphically transferred by writing a vertical revolving drum making a horizontal curve. Surrounding this vertical disk is a measure of elasticity, a set of three similar vertical disks, which rest on the surrounding skin surface and divide it into separate lever on the revolving drum any movement of the central disk other than that solely the dilation or retraction of the weight. This line, known as the control line and must be straight in order to have the record of a value. Thus, if it is caused by disturbing factors, an abnormality is observed in the control line.

Schwartz believes that the use of this instrument with the elastometer, the elasticity of the skin will become more accurate. Although he thinks that with the present instrument the expression of edema in mathematical terms is not deemed desirable, but that the character of the curves, together with the deflection of the control line, would permit approximate estimation of the nature of an edema.

Furthermore, he states that the instrument makes possible the recognition of slight degrees of edema which heretofore could not be detected. Persistent evidence of elasticity loss despite the disappearance of other signs in patients with nephritis or endocarditis, Schwartz believes, indicates the advisability of more prolonged observation. Cases of this character.

G ORGE F. B. HALL

Ewing, J. Pathological Aspects of Some Problems of Experimental Cancer Research. *J Clin Research* 9 6 4, 7

The numerous experiments that have been conducted in this field seem to the author to point to the necessity of regarding all forms of neoplasms as specific diseases connected only by the fact that they are neoplastic in greater or less degree, but differing in their etiology, clinical course, and therapeutic possibilities. The habit of regarding cancer as a protean disease of uniform significance, the author believes may well be abandoned in the interests of progress, and when cancer research properly occupies itself in the study of the distinctive features of different cases of malignant disease, especially, he states, when it abandons the idea of a universal cure for cancer, it will be in accord with sound pathological sense. It will then not be necessary, he thinks, to talk wisely to the public about the obscurities of cancer etiology or to speculate about why cells grow lawlessly. Concerning the ultimate nature of neoplastic overgrowth, he says, we shall never have more than a descriptive knowledge.

G ORGE F. B. HALL

Haskins, H. D. The Uric Acid Solvent Power of Urin After Administration of Piperazine Lyssidin, Lithium Carbonate, and Other Alkali. *Arch Int Med* 9 6 xvii, 405

In a recent paper Haskins reported the results of an investigation of the uric acid dissolving power of

examethylenamine. He showed that the mode of action of that drug was quite different from that of the rest of those substances which have been used as uric acid solvents. He states that these latter if they act at all as solvents do so by virtue of being basic substances. His purpose in this paper is to report on investigation of the solvent power of the most important members of this class.

The organic compounds which he studied were uricazone and lysidin which are amine derivatives and the nitrogen of their molecules imparts to these substances a basic character so that they combine with acid. These substances are supposed to form salt with uric acid which are very soluble. The other compound which he studied were thium carbonate, sodium citrate and sodium carbonate which are supposed to act as alkalies, of uric acid forming lithium and sodium urates which are quite soluble. The conclusions which he author forms from his study are as follow:

1. Uricazone can raise the urine to dissolve an increased amount of uric acid and this effect is most marked if sodium citrate or bicarbonate be also given and if diuresis be avoided.

2. Lysidin can act as a uric acid solvent but is not a practical therapeutic agent because of the large doses required.

3. Lithium carbonate is a uric acid solvent if large enough doses are used, but is unsafe and possesses no advantage over sodium citrate or bicarbonate.

4. Sodium citrate and bicarbonate are reliable and satisfactory uric acid dissolving agents when given in such dosage as to keep the urine alkaline.

(ROGER E. BEALBY)

RADIOLOGY

Baumelster, A.: The Results of Combined Mercury Lamp and Deep X-Ray Treatment of Human Lung Tuberculosis. (Die Erfolge der Kombierten Quarzlicht Röntgen Therapie bei der menschlichen Lungentuberkulose.) *Deutsche med. Wochenschr.* 916 xiii 99.

The favorable results obtained in deep X-ray treatment of experimentally produced tuberculosis of the lung in animals have justified the extension of this method to the human subject. Kuepferle has recently reported on 44 cases in different stages treated by deep X-ray. In 19 cases in the first stages he got good results. He also got good results in 14 partly disseminated partly confluent cases, no permanent improvement was observed in 11 cases in the third stage.

Baumelster's experience is confined to 20 cases of stationary to latent phthisis subjected to one month's treatment. In 9 of these all symptoms have disappeared and in the others there were good results.

In a second group with fever and with chronic progressive symptom but without caseous sputum he counts 10 clinically cured patients. Of 23 patients

of this group in which there was no complete cure 19 have been much improved.

Baumelster abstains from the treatment of patients with high fever and rapidly progressing symptoms. As in the case of animal Baumelster thinks that the good effect of the X-ray treatment is not due to any effect on the bacillus but to the effect on the granulation tissue which is destroyed and replaced by cicatricial tissue. He thinks that combined with hygienic measures, roentgen therapy combined with mercury lamp treatment of lung tuberculosis has proved itself a valuable method in the limited number of cases in which it has been applied. W. A. BRAY.

Kuepferle and Baumelster: Experimental Grounds for Treatment of Lung Tuberculosis by X-Rays

Experimentell Grunderlagen für die Behandlung der Lunge (Tuberkulose) mit Röntgenstrahlen. *Deutsche med. Wochenschr.* 916 xiii 96.

The authors instituted a series of experiments to determine the effect of hard filtered X-rays on experimentally produced lung tuberculosis in rabbits. The conclusions which they draw from these experiments are that a beginning experimental tuberculosis of the lungs may be suppressed and an established tuberculosis may be healed.

The effect of the roaying is to transform rapidly growing tuberculous granulation tissue into cicatricial tissue. It has no effect on the tubercle bacillus.

Small doses of rays at long intervals have little effect, very large dosage without sufficiently long reaction intervals, may give rise to bronchitis and bronchopneumonia.

In animals a dosage of 20 to 23 at 3 to 5-day intervals effected healing. The mercury lamp had no direct influence on lung tuberculosis.

On the basis of their experimental findings the authors have introduced X-ray therapy for lung tuberculosis in the Freiburg Medical Clinic.

W. A. BRAY.

Hammes and Schoepf: Exact Localization of Foreign Bodies by Means of Roentgen Rays. (Zur genauen Lokalisation von Fremdkörpern mittels Röntgenstrahlen.) *Deutsche med. Wochenschr.* 916 xiii 25.

The authors describe the technical details of an apparatus to put into practice results obtained from certain mathematical equations which give the position of a foreign body located in the body. They claim that location can be obtained in a few minutes and that probably their method is superior to the many procedures described by others.

W. A. BRAY.

Wintz, H. and Baumelster, L.: The Proper Filter for Deep Roentgen Therapy. (Die geeignete Filter für Röntgentherapie tiefer.) *Deutsche med. Wochenschr.* 916 xiii 59.

The authors made a series of experiments to determine what was the best material and most

suitable thickness of a filter for deep roentgen treatments. Experimentation with various metals showed that the most favorable results were obtained with an aluminum filter 3 mm. thick and with a zinc filter 0.5 mm. thick.

To obtain an equal dosage on the skin with aluminum and zinc filters the exposure in the case of zinc must be three to three and one half times as long as with aluminum but at depth of 8 to 10 cm. the ratio is reduced to . . . At this depth when using the thicker zinc filter by doubling the strength of the rays, the same dose can be received on the skin as with the thinner aluminum filter. The advantage is that a dosage which with an aluminum filter would reach the erythema limit may be doubled by using a zinc filter. The authors prefer the zinc filter to any other. W. A. B. LOCKMAN

Case, J. T. Roentgen Treatment of Deep-seated Cancer. *Physica & Surg.* 9:5 XXVII, 44

Case states that in general it must be admitted that the X-ray treatment of deep-seated carcinoma has not up to the present time gratified the fond hope with which the discovery of this method was so fervently greeted.

In superficial carcinoma where there is deep ulceration with involvement of the neighboring glands, etc., a very thorough-going preliminary pre-operative roentgenization should be administered. On the ninth or tenth day a radical operation should be performed followed later by another X-ray treatment. By combining roentgenization with surgical intervention one is most likely to insure good results.

Discussing the question as to whether operable carcinoma shall be treated by irradiation or operation, Case states that the result which have thus far followed roentgentherapy of deep-seated malignant neoplasms do not warrant the belief that roentgentherapy affords a means of cure of these deep-seated lesions. In the light of our present knowledge it may be stated as an axiom that the X-ray method should never replace or in any way interfere with the surgical treatment of cancer.

In looking over the literature of competent authors it is seen that in about 25 to 30 per cent of the cases of uterine carcinoma, the results of roentgentherapy are very satisfactory from a palliative standpoint but as yet Case has not seen an instance of definitely proven cure of pelvic cancer following the application of roentgentherapy.

In mammary carcinoma good palliative results are nearly always the rule.

The good palliative results which have followed the X-ray treatment of recurrences and inoperable cases warrant the adoption of post-operative X-ray treatment as a routine in malignant cases.

The treatment should be applied as soon as possible after operation and as thoroughly as though the disease was still present in its entirety.

Case a technique in operable cases is to submit the patient eight or ten days before operation to cross-fire filtered rays in full dose in as many areas

as possible. Ten days after operation the patient is again submitted to a further series of treatments administered as though the tumor were still present. HOLLIS L. POTTER.

Hanford, C. W. Some Radium Physics. *Chicago U. R. and* 9:6 XXVIII, 43

Therapeutic tests that the high aim of the radio-therapist should be to direct the radium rays to the deep tissues where the disease is located with the least injury to the healthy structures and that in many instances where results have not been obtained from the application, failure may be traced to lack of knowledge of certain physical facts that had not been observed by the operator. A number of examples are given, such as where the use of radium has been supposed to constitute a given amount of radium element is tested after repeated failure and found to contain only a very small amount, thereby inadequate for the purpose. Methods are reviewed which if carefully observed will save the operator from such errors. W. S. NEWCOMB

Wood, F. C. and Prime, F. J. The Action of Radium on Transplanted Tumors of Animals. *J. Surg. Path.* 9:5 LXV, 75

The operations, based chiefly on clinical reports, of the therapeutic value of radium in the treatment of malignant growths have differed greatly. Whether the β - or the γ rays are the most efficient in treating tumors, or whether both should be employed, remains still undecided. For these reasons the authors carried out a number of experiments in the Columbia University to determine the biologic action of radium, using animal tumors as an index of the lethal effect. Rat and mouse tumors of various types were used among them the Ehrlich fibroblast mouse sarcoma and the Flucker-Jobling rat carcinoma. They were treated either after removal from the host or in situ, strict asepsis being observed. After exposure to the β - and γ rays, portions of the treated tumor as well as untreated fragments were inoculated with animals of the same strain. X-rays were not used.

These results are claimed by the authors from their experiments.

Three factors only are important in the action of radium on tumors: time of exposure, amount of the radium element, and distance between the radium and the tumor tissue.

1. The removal of the β -rays diminishes the effect of the radium but the effect of the γ rays is in accordance with the same general law which governs the β -rays.

2. Sublethal exposures hinder the growth of tumor cells for some time, while still shorter treatments seem to stimulate the cellular activities.

3. The facts derived from the experiments regarding the quantity of radium element and the time of exposure necessary for a given distance may be applied, with reasonable accuracy to human malignancies.

nant tumors. These experiments show that when only pure γ rays are used the necessary exposure is eight times as long as that required when the γ and hard β -rays combined are employed but as the latter are largely absorbed by the soft tissue the γ rays alone must be used for all deep work.

5 The effect of radium radiations on tumor-cells *in vitro* is less marked than on isolated cellular elements. This explains the fact that an exposure which will destroy a small metastatic nodule in man is quite ineffective in the case of a well circumscribed primary carcinoma.

H. L. E. I. TSLER

Quigley D. T. Therapeutic Effects of Radium.
J. L. M. 1915 95 (53)

Quigley thinks that in ordinary cases of cancer such as cancer of the breast etc. the best plan is to operate when operation is possible and use radium as an after-treatment to kill out such cells as may be missed by the knife and thereby lessen the chances for recurrence. He believes the great future for radium is as a post-operative treatment. The question with relation to radium in cancer is not Will radium supplant surgery in these cases? but Will our surgical results be bettered by using radium in conjunction with surgery?

H. L. E. I. TSLER

McConnell A. A. A New Medium for Pyelography
M. d. Press & Cure 96 of 136

For some years collargol, a colloidal silver preparation has been the medium most used for pyelography and although other substances have been tried as iodid of silver none have proved so generally satisfactory.

Since the war however collargol has become most unprocureable and McConnell in seeking a substitute in the English and American markets, failed to find anything but silver iodide which in his hands did not give as satisfactory results. He therefore consulted Professor Caldwell of the Royal College of Surgeons Ireland asking him for a salt opaque to X rays, harmless to the kidney, and capable of being injected through a ureteral catheter. Professor Caldwell was able to meet this request and supplied him with an entirely new bismuth compound to which the provisional name skiol is given. This is a non irritating substance, has the consistency of milk and is washed out of the renal pelvis by the urine before precipitation takes place. McConnell uses a 10 per cent solution and has obtained better pictures than any he has obtained with collargol. It has not caused irritation in any of his patients. Moreover he found that it disappeared from the pelvis more rapidly than collargol. Collargol has been found to remain in the renal pelvis from one to several weeks while in some cases in which skiol was used radiographs taken one or two days after the injection showed no shadow.

The technique is as follows. The patient is placed on the roentgen table the ureteral catheter is

introduced up to the renal pelvis, the X ray plate is fixed and preparations made to take a picture. The skiol solution is then allowed to flow into the ureteral catheter by gravity from a container which is held not more than 12 inches above the table. The kidney until the patient announces that some pain is felt in the kidney. At that instant the injection is stopped and the roentgenogram is taken. Then the fluid is allowed to run out and the catheter is removed.

D. VID. C. STR.

MILITARY SURGERY

Mott F. W. The Effects of High Explosives upon the Central Nervous System. *Lancet Lond* 1915 33

The author describes three groups of cases in which the nervous system was injured by explosives: (1) immediate death from a missile (2) injuries from high explosives which cause wounds but are not fatal (3) injuries of the central nervous system without visible injury. To the latter group must be added those cases which develop functional neuroses and psychoses.

The third group of cases is the one specially dealt with in this paper. Several theories are elaborated as to the possible causation of these intangible injuries to the nervous system: (1) Increased pressure in the cerebrospinal fluid may be the causative factor in these injuries. (2) Nerve-cells in a state of exhaustion are much more susceptible to shock than nerve-cells in the normal state. This fact may account for sudden death from the explosion of a shell without physical injury. (3) The sudden change in atmospheric pressure brought about by the explosion of a shell may result in the freeing of gas bubbles in the nervous tissues causing a similar condition to that found in caisson disease.

These theories are merely advanced by the author in a preliminary way and the discussion is to be continued.

J. H. SKILES

Vincent B. and Greenough R. B. Gunshot Wounds of the Soft Parts. *Boston M. C. S. J.* 1916 clxix 135

Vincent and Greenough at the American Ambulance, at Neuilly sur Seine report 318 cases of injuries of soft parts by missiles such as shrapnel balls, rifle bullets or shell fragments. The wounds were of every kind. In crated penetrating perforating or wide surface abrasions. When received at the American Ambulance a majority of the cases were from twenty four to seventy two hours old and were with few exceptions septic. On entering the hospital the patient was given a general anesthetic. The operation was devoted primarily to cleaning the wound and making free drainage. The wounds were enlarged as much as the extent of the infection required. The crushed edges of the wound and all the necrotic tissue were excised. All foreign material was removed. While in par-

ticular search was made at this time for missiles, for fear of spreading the infection to uncontaminated tissues, they were often discovered and removed. Pieces of clothing were often found just beyond or wrapped around the missile. When pieces remained in the tissues the course of sepsis was always prolonged. The use of rubber tissue for wicks and as a protective covering of raw surfaces prevented the gauze dressings from adhering to the wounds and saved the patients much suffering. Some of the most septic wounds were given continuous irrigations of sodium-hypochlorite solution, others had wet dressings that were frequently changed. Secondary sutures were done with good result in cases with extensive granulating surfaces.

The means of localization most frequently employed were the fluoroscope, X-ray plates and the Bergonier electromagnet. The magnet was operated with an alternating current in such a way that the shell fragment was put into rapid vibration. By placing a hand on the skin between the magnet and the foreign body the place of maximum vibration was noted and an incision made at that point. The method could be applied to missiles in the soft parts only and not too distant from the skin. The extraction of a missile was often facilitated by the use of an ordinary electromagnet. A metal probe with its outer end resting against the magnet was inserted into the wound till it touched the piece of metal. The magnetized probe would in turn attract the missile which was withdrawn with the probe from the wound. This method was employed successfully by Cushing in removing fragments of shell from the brain and by Blake on a piece of shell buried deep in the pleural cavity.

For routine work the fluoroscope proved the most rapid, accurate and economical means of localizing lodged missiles.

In certain cases where the fragments were small and numerous or because of an absence of symptoms, the missiles were left *situ*. A. H. Hixson

Weinberg, M. Bacteriological and Experimental Research on Gas Gangrene. *Lancet* Lond., p. 6, col. 6.

The work reported was first undertaken in the British Hospital at Versailles, September 1914, during the battle of the Marne, and was conducted later in a number of hospitals, both French and British. The majority of surgeons seemed to have a confused idea of the nature of gas gangrene at the beginning of the war and the tendency seemed to be to diagnose the condition every time a bad wound became infiltrated rapidly with gas. Two forms of gas gangrene are described (1) the classic and (2) the toxic form.

In describing the classic form the author gives the details of a case as follows: A soldier was admitted to the hospital twenty-four hours after being wounded. The foot and two-thirds of the leg were very much discolored, the discharge emitted a putrid odor. The leg and thigh were swollen as

far as the junction of the middle and upper third, the veins were distended, the skin browned, and there was crepitation on palpation around the wound. The temperature was 105°F. A few hours later crepitation extended over the entire leg and thigh and large blebs containing dark fluid were scattered here and there on the surface. The temperature rose to 104°F. Amputation was done in the middle of the thigh, the gangrene spread to the body and neck and death occurred at the end of the second day. Dyspnea was marked two hours before the end.

The development of some cases of this classical form was not always as rapid as in the foregoing case because the microbe chiefly responsible was of low degree of pathogenicity and in such mild cases radical surgery often saved the patient.

The toxic form is characterized by extensive edema sufficient in some cases to mask the gas infiltration. This form is illustrated by the following case: A patient admitted to a French hospital forty hours after he was wounded, having been exposed twenty-four hours between the French and German lines, after the receipt of the injury. There was a wound in the middle third of the forearm, crepitation around the wound was slight but extensive edema was present up to the middle of the arm and the veins were prominent. In spite of free incisions and irrigation with oxygen peroxide the edema extended to the shoulder and chest and death occurred twenty-four hours later without the appearance of much crepitation. There was a putrid odor which was not necessarily a symptom of the case and it bore no relation to its gravity since it might have been due to organisms of a few pathogenesis which were present.

The author exhibited some microphotographs of culture fields from cases which showed a variety of organisms, including bacilli perfringens, staphylococci streptococci and diplococci also bacillus sporogenes.

It seemed that gas gangrene was not due to any specific micro-organism. There is great difficulty in distinguishing bacillus perfringens from vibrio septique (malignant edema) and the toxins must be tested with antitoxic serum. Bacillus perfringens produces a large quantity of gas while vibrio septique produces less. A bacillus oedematis had also been found in some cases, the toxins from which when injected subcutaneously in guinea pigs produced a rapidly extending edema. This microbe was frequently associated with bacilli sporogenes. Weinberg emphasizes his belief that there is no flora peculiar to gas gangrene. A new microbe bacillus fallax, causing gas gangrene has lately been discovered, when and by whom is not stated. Some of the organisms found in the flora of gas gangrene emanate from the air others are of intestinal origin. Attempts to make bacterocultures have not been successful and they were rarely positive in the septic form of the disease. The very rapid course of gas gangrene in men and animals is thought to be

due to individual susceptibility. Careful observation and experiment have shown that gangrene of a limb is not always the result of gas-producing organisms but complete obliteration of the vessel may arise from non gas-producing organisms. It is interesting to note that gangrene of a limb following stoppage of the blood supply affords favorable conditions for the growth of gas-producing microbes.

To prevent gas gangrene wounds should be treated early and radically. The diminution in the number of cases occurring now as compared to the earlier period of the war is due to the well developed transport facilities which enable the relief corps to remove the wounded from the fighting front to a casualty hospital in a few hours. The wounds should be opened as widely as possible at once. Large projectiles and particles of clothing having been removed the wound should be irrigated with weak antiseptics and the irrigation should be often repeated. Good results are also obtained by the use of superheated air and intravenous injections of sal arsan. Injection of polyvalent serum drawn from all the organisms concerned was also considered helpful.

Moylman B. The Treatment of Gunshot Wounds. *B. M. J.* 9: 333

The treatment of gunshot wounds in the present war has become greatly complicated by several factors: (1) The wounded soldier usually lies for many hours or even days before he can be removed to the field hospital. (2) The modern high velocity projectile causes explosive destruction of tissue resulting in a large deep ragged wound which is always infected. (3) The battlefields have been so intensely cultivated that the ground contains many virulent organisms with which the bodies and clothing of the men are sure to become contaminated. (4) The hygiene of the soldier is necessarily very poor. In some instances clothing has been worn continuously for several months. This results in a filthy condition of the person which together with his general run down condition naturally leads to contamination of the wound.

The treatment of a wound therefore usually has to do with the combating of infection. A wound which is treated early may be excised or treated with some strong antiseptic but these early wounds are in the minority.

The treatment of an infected wound should be very thorough, the entire field being thoroughly cleansed and adequate drainage secured. Many antiseptic solutions have been tried the one which has given the most satisfactory results being Dakin's solution. Dakin's solution is made from bleaching powder forming calcium hypochlorite. It is a very effective antiseptic and does not apparently injure the tissues. Continuous application of the fluid to the wound is secured by continuous irrigation or by keeping gauze wicks soaked by immersing the ends in a dish of the solution. Sufficient drainage should be insured.

No gauze dressings or impermeable material should be placed over the wound as a close covering tends to dam up the secretion.

The hypotonic salt solution of Wright is highly recommended to induce lymphatic drainage. Morrison and Hullock have advised the use of a solution of magnesium sulphate in place of sodium chloride. Out-door treatment and plenty of fresh air in work wonders in hastening the recovery.

The use of a cines is still a matter of controversy but there are undoubtedly selected cases in which they do much good. J. H. SALT

Carrel Dehelly and Dumas. Secondary Closing of Wounds. *B. M. J.* 9: 336

The authors presented a paper at the Paris Academy of Medicine in January on the results of the early closing of war wounds that have been treated with the sodium hypochlorite solution prepared after the Dakin formula. They concluded that the secondary closure of wounds in from four to ten days is a general method of great utility.

Free incision of wounds alone formerly for exploration the removal of foreign matter and the use of drainage act as a drawback since they prolong the treatment and cause an undue amount of irritation. The latter kills the parts between the muscles, aponeurosis and skin which ends in adhesions and contractions thereby hindering function. To avoid this treatment by the Dakin solution permits the surgeon to bring the anatomical surfaces of a wound together by layers in the secondary closing of the wound just as he does in a primary operation. When brought together early connective tissue has not had time to form unduly it is reduced to a thin sheet which does not seriously interfere with muscular movements.

The authors open up all wounds primarily enough to admit of careful exploration cleansing and hemostasis. The hypochlorite solution is instilled constantly for several days by the technique already recommended by them in previous reports. As soon as the daily bacteriological examinations indicate the disappearance of bacteria the wound is closed usually in four to ten days. In those wounds that remain uninfected the tissues are unaltered in the course of the antiseptic treatment and the authors find that the wounds thus treated unite by first intention as is observed in operative wounds. The tissues should always be brought into exact apposition with adhesive strips 2.5 to 5 cm broad. If the skin becomes adherent to the subjacent structures and granulation tissue has filled the intervening space the skin is loosened from the edges of the wound the granulations curetted and the parts including the skin are then brought into apposition with sutures. This procedure hastens the rate of recovery avoids stiffness and atrophic changes.

McQuinn and M. Bazy believe that good surgical technique and irrigation are of more importance than the employment of sodium hypochlorite as an antiseptic. L. A. L. CARD

Bérard, L., and Lumière, A. Some Elementary Rules Relative to the Treatment of Suppurating Wounds in War (Quelques préceptes élémentaires relatifs au traitement des plaies de guerre suppurées) *Rev de chir* 19 6, xxiv 445

The authors call attention to the difference in the condition of projectile wounds in the recent period of the European campaign, where the fighting was in the trenches and that of the early period when the war was one of movement and projectile wounds were mostly uninfected.

The suggestions which the authors formulate in the care and treatment of suppurating wounds are (1) the removal as quickly as possible of all foreign bodies (2) the draining as early as possible of infected tracts, and the discharging of purulent collections by large incisions and very large drains (3) the treating of all wounds antiseptically using hypochlorites preferably especially the mixture of chloride of lime and boric acid (4) the frequent changing of dressings and preventing the adhesion of pieces of the dressings to the wounds (5) never to uselessly injure wounds (6) to use humid dressings only occasionally in particular cases renewing them quite frequently A. Goss.

Dalton, F. J. A. Sodium Hypochlorite in the Treatment of Septic Wounds. *B. u. M. J.* 9 6 1, 26.

Dalton on the British hospital ship *Rew* investigating the value of sodium hypochlorite in the treatment of septic wounds, reports a series of 57 cases. The results obtained were uniformly excellent and there was an absolute unanimity among the members of the medical staff in the hospital ship in the preference for hypochlorite solution in the irrigation of infected wounds. Wounds were enlarged, counteropenings made, bone fragments and foreign bodies removed etc. and thorough irrigation instituted with large quantities of hypochlorite solution. Rubber tubes were then inserted and gauze strips packed into all parts of the wound. The ends of the rubber tubes were brought out through the dressings that the hypochlorite solution might subsequently be renewed by means of a syringe. Fresh hypochlorite solution was applied in this way every two hours in the severe cases. In the worst cases the gauze strips were removed after twenty-four hours, in slight wounds they were left in three or four days, the wounds cleaning up with simply spraying fresh solution into the tubes.

Dalton points out the following advantages observed in the employment of the sodium hypochlorite solution when properly prepared according to the Dakin formula (1) The simplicity and cheapness of preparation of the antiseptic. (2) Being non-toxic and non-irritating to the tissues it may be used without ill effects in large quantities over long periods of time. (3) The deodorant action of the solution is remarkable. (4) The rapidity with which sloughs separate and clean granulation tissue is formed. (5) The infrequency of dressing required. (6) The

fact that injections of the hypochlorite solution into the rubber tubes used in the dressings may with safety be entrusted to very imperfectly trained or derbies without fear of ill results, once the case has been adequately dealt with by the surgeon.

A. H. HIXSON

Health of Armies in Peace and War. *Lancet* Lond., 9 6 ix 57

The annual report of the Surgeon General U. S. A. for 1904 gives us a valuable means of comparing the health of an army during peace with that of the armies in Europe. Although the army is small in comparison with the armies engaged in the gigantic struggle abroad it is sufficiently large to give valuable data.

Of the 88,000 men died of tuberculosis 15 each from pneumonia and chronic heart disease, 10 from cancer—ratios which correspond with those of other armies during years of peace. The influence of vaccination against smallpox and typhoid fever is still shown. Among the 88,000 men there were 7 cases of smallpox with 1 death and 3 cases of typhoid fever with no death.

The principal causes of admission to sick report were alcoholism and venereal disease although these were showing marked diminution in the last decade.

The Paris correspondent of the *Law* in a recent letter writes on the sick rate of the French army at the front and shows that the most serious infectious diseases of civil life such as scarlet fever and diphtheria, as well as mumps and less important ailments, are not so prevalent in the French army during peace. Typhoid has been more frequent but less fatal. No reference is made to the various pedal ailments of the present war—shell shock, soldier's heart, trench foot—and they may be intentionally omitted. The inference seems to be justified that the health of the French army has not been adversely influenced by the act of campaigning. Doctor Moisse of Berlin, a thorax of a well-known work on disease and social position has recently pointed out that diabetes mellitus and acute nephritis, often of the hemorrhagic form, are more frequent in the youthful combatants. The health of armies in peace and war has been conserved by the rules of sanitary science in all civilized countries. The devastations incident to cholera, cerebrospinal meningitis, typhus, typhoid, yellow fever and malaria are now practically unknown. The sanitary service of the military establishments today is rendered efficient by drilling the medical personnel in the duties of health officers. It is easier and less expensive to prevent disease than to treat it or to arrest its spread. In this regard the Sanitary Service of the British Army has accomplished a great deal in the present war. Every division of the army has a sanitary section consisting of 26 men (not including army service corps men) viz. one officer and 5 non-commissioned officers and men. The officer is generally a medical officer of health

or one who holds a diploma in public health service or as a bacteriologist some are sanitary engineers and even architects.

A large number of the non-commissioned officers are sanitary inspectors some hold sanitary diplomas others are plumbers carpenters schoolmasters graduates in honors from Oxford Cambridge and other universities solicitors chemists, and representatives of all professions and trades. In this varied personnel it is not difficult to provide each section with a sufficient number of disinfectors interpreters carpenters cooks builders for the special and varied services in the field. The work performed by these sections includes the bathing of troops by thousands disinfection of the men for vermin after enteric cerebrospinal fever and other infectious diseases. Their further duties embrace disinfection of all clothing and blankets purification of water the drainage of farms and billets giving instruction for the erection of destructors or incinerators ablution tanks grease traps urine pits filters fly traps and the installation of every kind of structure or appliance that appertains to sanitation in the field.

After great battles, when the casualties are so great in numbers that the ambulances cannot deal with them the personnel of the sanitary companies is called upon to assist in the care of the injured. This body of expert workers has rendered the Royal Army Medical Corps officers valuable assistance in many ways especially in watching over the health and sanitation of the soldiers.

Aside from the work of the medical corps and sanitary sections in warding off disease great assistance has been derived from auxiliary bodies like the Red Cross. Through its assistance the mortality among the wounded has been very much reduced since its organization by Henri Dunant a half century ago. L. A. LAURE.

SURGICAL PATHOLOGY

Razetti L.: Operative Mortality (La mortalidad operatoria). *Gu. med. de Caracas* 1906 vol 17.

The author reports the results of 310 operations performed during a period of 22 months. The cases were divided into the following groups: head neck thorax abdomen genito-urinary apparatus perineum and rectum extremities.

Of 310 patients operated upon 30 died a mortality of 6.6 per cent. The general mortality in the surgical clinic was divided into two classes the pathological mortality and the operator mortality or those due to accidents or complications derived directly from the operation itself.

Of the 10 deaths 16 were pathologic and 14 operator or a pathologic mortality of 5.16 per cent and an operator mortality of 4.51 per cent.

The cases occurred in a general hospital the cases were not selected and some of the cases were in an advanced stage or their general condition on admission was very unsatisfactory.

RAOUL L. VILLAS.

Apert E.: Urticaria and Pseudo-Appendicitis. *M. d. med.* 1906 vol 105.

The acute forms of urticaria and sometimes also the chronic may give rise to an actual pseudo-peritoneal syndrome akin to that of purpura and polymorphous erythema possibly simulating appendicitis. Our present knowledge of the pathogenesis of urticaria enables us to understand what happens in such cases.

Since the works of Richet Arthus Leane Vidal and Joltrain it has been known that urticaria is an anaphylactic phenomenon and that the cutaneous troubles are only the outward and visible manifestations of sudden changes in the blood of what Vidal calls a *hémoclasie* or of a splitting up of the blood. The pseudoperitoneal phenomena testify to the existence of this state. The absence of the local signs of acute appendicitis the absence of rigidity of the abdominal wall and of localized skin hyperesthesia should prevent any confusion between an attack of appendicitis and the pseudoperitoneal attack associated with urticaria.

W. A. BRIDGES.

Gaucher: Unrecognized Syphilitic Lesions Surgically Operated as Cancers or as Local Tuberculous. (*Des lésions syphilitiques mal interprétées comme tumeurs*) *Ann. ot. rhin. laryng.* 1906 vol 15.

Thoracically the differences between syphilitic tuberculous and cancerous lesions appear to be so well established that in practice there should hardly be an error. Nevertheless the diagnosis is sometimes very difficult or at least it is very inaccurately made in a number of cases by surgeons who are experienced and well informed. Errors are oftenest observed in chancres gummatous infiltrations and in osseous and articular lesions.

The confusion of syphilis with local tuberculosis has very grave consequences particularly when it is a question of osseous or articular lesions. The author has frequently directed attention to the similarity of the suppurative osteitis and the osteo-arthritis of hereditary tertiary syphilis and tuberculous osteitis and arthropathies. Suppuration is not and cannot be admitted to be a distinct characteristic of tuberculosis. Hereditary osseous syphilis can be suppurative as well as osseous tuberculosis.

Not alone in the matter of hereditary syphilis are errors made but also in the white tumors in adults which result from acquired syphilis and which are frequently treated as white tuberculous tumors and operated as such.

The author mentions several cases which have come under his notice which corroborate his contentions. He therefore thinks that in all osseous or articular lesions which are apparently of tuberculous origin the Wassermann reaction should be looked for and mercurial treatment tried before surgery is resorted to.

W. A. BRIDGES.

HOSPITAL, MEDICOLEGAL, AND MEDICAL EDUCATION

The Duties of Medical Practitioners in Cases of Criminal Abortion *Brit M J* 9 6 1 306

The duties of medical practitioners in cases of criminal abortions are discussed in the original article. The question as to how far a medical man, who obtains in his professional capacity knowledge of the commission of a criminal offence, is in duty bound as a citizen to give information to the police authorities and so set the criminal law in action, is one which should be of great interest to the medical profession.

Probably the most frequent occurrence in which an opportunity of this kind might arise, is that of a medical man called in to attend a woman upon whom an illegal operation has been performed and in such a case under the decisions of the English Court cited in the article it is safe to say that the doctor is under no obligation to and indeed should not divulge the information which he has obtained in his professional capacity as it is of the highest importance that professional confidence should be respected and held inviolate. Quoting from an English case I doubt very much whether a doctor called in to assist a woman in procuring an abortion, for that in itself is a crime but for the purpose of attending her and giving her medical advice could be justified in reporting the facts to the public prosecutor. There might be cases when it is the obvious duty of a medical man to speak out and it would be monstrous thing for a medical man to screen a person going to him with a wound which it might be supposed had been inflicted in the course of a deadly struggle. The above is a quotation of Lord Brampton's remarks before the Royal College of Physicians of London in 1896.

In 1914 the English Courts had to deal with a case of an alleged illegal operation on a woman on whom three successive doctors had been attending. None of these doctors had given information to the police and there was consequently no evidence upon which to convict the prisoner who was

charged with having performed the illegal operation. The court in discussing the failure of the attending physician to report the matter stated: "No one would wish to see disturbed the confidential relations which exist between the medical man and his patient but there are cases, and it appears to me that this is one where the desire to preserve that confidence must be subordinated to the duty which is imposed on every good citizen to assist in the investigation of a crime. A time such as is here imputed to this man may be the moral duty of the medical man in cases where the patient is not dying or not likely to recover to communicate with the authorities when he sees good reason to believe that criminal offence has been committed."

The trend of the above discussion will be noted to be somewhat contrary to the previously cited, and holds that medical men are under the same moral duty as their brethren in all cases where they become aware of the commission of a crime to report it to the authorities. There are, however, different opinions when it comes to the attention of the British Medical Association caused it to appoint a committee to confer with the Lord Chief Justice upon this important question. This duty was received by the Lord Chief Justice on May 1, 1915 and the summary of the resolutions passed by the Royal College of Physicians of London in consequence of said interview is as follows: That a medical practitioner is not justified in disclosing information obtained in the course of professional attendance upon a woman who has her consent but that when he is convinced that a criminal abortion has been performed on his patient he should give her especially when she is likely to die, the information which may be taken as evidence against the person who has performed the operation provided always that her chances of recovery are not thereby prejudiced and that in the event of her refusal to make a statement he is under no legal obligation to talk for the sake of that the consent of the patient dying he should refuse to give a certificate of the cause of death and should communicate with the coroner.

JOS. A. CASTAGNOLA.

GYNECOLOGY

UTERUS

Goodwin, R. T.: Lacerated Cervix. *T. St. J. Med.* 910 xl 543

The author reviews the anatomy of the cervix, gives the most frequent symptoms of lacerations of the cervix, the results produced thereby, and concludes by discussing the operative treatment.

Lacerations of the cervix are very common. The chief cause of cervical tears is meddling obstetrics, for example, want of care or judgment in the use of forceps, premature rupture of the bag of waters, the injudicious use of the drugs ergot and pituitrin, mechanical dilatation of the cervix, and roughness in performing podalic version.

The symptoms are not pathognomonic and are due to the lesions caused by the laceration. The most constant of these secondary conditions are subinvolution of the uterus, endometritis, and uterine displacements, and the symptoms usually described as being due to lacerations of the cervix are in reality caused by one or all of these complications. Backache, bearing down in the pelvis, vertical headache, leucorrhoea, menorrhagia, metrorrhagia, sterility, and abortion are the most frequent of these symptoms.

The results of the lacerations are either immediate or remote. Of the immediate results the most frequently observed are hemorrhage, sepsis, and vesicovaginal fistula. The principal remote results are subinvolution of the uterus, chronic endometritis, uterine displacements due to subinvolution or to contractions of cicatricial tissue in the cellular structures behind the uterus, chronic tubal and ovarian disease, and cancer.

As a large number of lacerations require no treatment whatever, it is important to have a clear and definite idea as to what class of cases require operative interference.

The following rules have been formulated for this purpose:

1. Operate upon all lacerations which are complicated with induration and hypertrophy of the cervical tissues, eversion of the intracervical mucous membrane, cystic degeneration, and erosion.

2. Operate upon all lacerations which are responsible for subinvolution of the uterus, endometritis, and uterine displacements.

3. Operate upon all lacerations which are associated with a sensitive plug of scar tissue in the angle of the wound.

Any grave pelvic disease is a contra-indication for operative interference in laceration of the cervix. There is always considerable dragging upon the uterus during an operation upon the cervix, and

these manipulations may cause a fatal peritonitis by breaking up of adhesions. RALPH H. KULS.

Percy, J. F.: The Problem of Heat as a Method of Treatment in Inoperable Uterine Carcinoma. *T. St. J. Med.* 910 xl 543

There are three stages to be recognized in the development of cautery treatment of carcinoma of the uterus: (1) that in which it is used merely to stop hemorrhage and limit offensive discharge; (2) in the galvanocautery excision of the cervix, uteri developed by the late Dr. John Byrne of Brooklyn. (In this technique a degree of heat sufficient to cut the tissues was used); (3) in the dissemination of a coagulating degree of heat through the widest area possible of the cancer mass, with no attempt at immediate excision of the parts (Percy).

The technique of Byrne was not designed for advanced inoperable cancer in which the uterovaginal junction is fixed with extensive malignant and inflammatory infiltration of both broad ligaments and the perimetrium. As classified today, Byrne operated only in the first steps of cervical cancer involvement. He deplored the use of the cold steel knife in cervical cancer and forty-four years ago referred to it as a comparatively fruitless procedure at best. This is just as true today — without the preliminary use of heat — as it was in his day. The cases treated by Byrne with galvanocautery excision of the cervix were the type of cases which would be considered suitable for the Reis-Wertheim treatment of today.

The author has the following to say as to the future of the heat treatment. The stage of operability with my present technique is easily overestimated and I confidently expect that if the promise which I see in my work is realized in the further development of the use of heat in cancer, the stage of operability will be without limit in strictly pelvic cancer. I would not have you believe, however, that the ideal is mere operability. Back of it all is the hope and promise of results never before obtained by any method so far developed in that disease, which has always stood as a synonym for incurable pelvic cancer. In conclusion permit me to re-emphasize the following points:

1. The Percy technique so-called is not a cautery operation. I remove nothing. The tissues following the application of moderately low degrees of heat are literally coagulated and slowly dissolve. It usually takes two weeks for a healthy granulating surface to appear beneath the gradually dissolving mass of inert cancer debris.

3 "The operation of Byrne was a high galvanocautery incision of the cervix. There could be but little penetration of heat. Byrne recognized this when he advised that the surface left after the removal of the gross mass be sealed over with the cautery knife in order to get all the heat penetration possible. But Byrne never thought of applying heat to the degree of obtaining penetration sufficient to render movable the fixed tissues in the pelvic basin. If the fixed tissues are malignant and inflammatory are not made freely movable as they are normally the heat penetration has not been sufficient and, therefore, is ineffective.

3 "To coagulate a large mass of uterine cancer equires from thirty to sixty minutes, and if the broad ligaments still remain still fixed an additional ten minutes.

4. In my effort to emphasize the importance of avoiding the burning temperatures, I fear that I have led many surgeons to the opposite extreme.

I said that they are trying to destroy the activity of an inoperable mass of cancer with temperatures so low that days, rather than hours, would be required to make the heat effective. Byrne fried his tissues. I broiled or pasteurized them. The Byrne technique was based on the use of heat as a acute process. Mine is not acute, but chronic, both as to time and degree. Heat more heat and yet more heat but heat, not fire broiling nor frying nor roasting but curdling pasteurization, not desiccation coagulation, not carbonization.

In its practical application, the whole technique can be summed up in one statement. Do not carbonize the tissues. For in the degree that this is done in that degree is heat penetration inhibited and heat penetration is the vitally essential thing. A gentle simmering sound only should be heard when the ear is placed near the vaginal water-cooled speculum. This simmering sound is produced by a temperature above 45° C (113° F). It probably ranges from 83 to 95° C (180 to 200° F). Heat in the cancer operable or inoperable or as preliminary to the use of the cold steel knife has, with its present development come to stay. It offers more in the way of cure in the early case than any other treatment so far devised. In the late case it promises success from suffering with prolongation of life that is most hopeful.

But more than all else we have not yet fully learned the technique of most effectively destroying cancer in the accessible regions of the body by heat. When we read another chapter will have been written in the history of man's contest with his physical ills that will compare very favorably with anything so far accomplished along the lines of scientific endeavor.

Ramsohoff J. and J. L. Radtke. Treatment of Uterine Fibroids. *Lancet-Cl* 9655 6

The authors believe that radium is the method of choice in the treatment of complicated terine fibroids as the treatment is safe and in the usual

use the symptomatic are almost certain. It should not be used where there is reasonable doubt of the diagnosis, or where the fibroid is complicated by infections of the tubes and ovaries.

Operation should also be the method of choice when pressure symptoms are so acute as to demand immediate relief.

Radium treatment is superior to X-ray treatment because the radium is brought into intimate contact with the fibroid itself. It does not depend on penetration of the rays.

Five typical cases are cited. On particularly interesting case was that of fibroid in a woman past the menopause, occupying the entire pelvis and extending 2 inches above the umbilicus. Under treatment the multiple disappearance of the tumor as secured. Operation thus case would have been feasible because of the presence of a large nucleus of the tumor of the aorta.

Condit W. H. Compensatory Vascular Ectopia Menstruation Nematoma Menstrua Dent 157 102 157 102

The author reports the interesting case of a young woman who had bystectomy and bilateral salpingo-oophorectomy yet 18 months had the subjective symptoms and sensation which had characterized her previous menstrual periods and had hemorrhaging at some of her cutaneous tissues. Fifteen days after the operation the regular menstruation she had hemorrhaging to the nerve the use of splints treated over the left ninth intercostal space. It increased the size of a hen egg and there occurred considerable ecchymosis in the skin about the area. Four days after the tumor subsided in one half and soon the skin ecchymosis disappeared. No blood escaped from the tumor or skin. The process was repeated regularly every twenty-eight to thirty-four days for twenty-one months. At the time the tumor was which had gradually formed ruptured and he last consented to operation. Microscopic sections were negative for melanoma.

At the next regular period the left mammary gland was attacked in a similar manner but after one year the manifestations in this gland became less frequent and regular and at the end of two years it had returned to practically its normal appearance. The author now hoped that relief had come but she then had an extensive cutaneous hemorrhage into the extensor surface of both legs, accompanied by painful extreme ecchymosis from the thighs to the knees. Similar attacks occurred in one leg thirty-four days later and were repeated each month. The last attack occurred in July 1914 seven years and three months after the operation. It involved the posterior surface of the right leg from the gluteal fold to the ankle being most marked over the popliteal space.

The conclusion arrived at in this study is that menstrual abnormalities or irregularities are due to blood pressure changes of the individual together

with some atrophic or pathological changes in part or parts where the hemorrhage manifested itself. In the particular case reported the peculiar demonstrations were brought about by a failure of the individual physical economy to adapt or adjust itself to the change brought about in the blood pressure by removal of part or parts previously acting as the safety valve of this particular economy.

Lange S. Recent Results in the X-Ray Treatment of Menorrhagia, Dysmenorrhoea, and Uterine Myoma. *Am J Roentgenol* 9

Lange's paper is based upon 60 consecutive cases of menorrhagia, dysmenorrhoea and uterine fibroid treated by X-ray therapy. In every case a satisfactory result was achieved and artificial menopause apparently permanent occurring in every case in which it was desired, regardless of the age of the patient. These cases were referred from many different sources and while only ordinary care and skill were employed in their selection, malignancy had not developed in any case either during or following the treatment. So far as he has been able to follow the case there has been no recurrence of the menstruation after it has once stopped. In several cases there has been an occasional transient menstruation during the last month just following the menopause. After a lapse of ten months, however, abatement of the ovarian function has been complete and permanent. He has concluded to be a safe working rule that if never missed the treatment may be discontinued.

In this series of 60 cases, 3 were treated because of persistent menorrhagia. The ages of the patients varied from sixteen to fifty years. The minimum of X-ray radiation required to bring about permanent menopause was one treatment of 600 X in a woman forty-nine. The greatest amount given any patient was 600 X (eight treatment) which was required to abolish the ovarian function in a girl of twenty. Another patient of seventeen years of age required only 600 X to accomplish the same result. A woman of twenty-eight required 600 X (six treatment). A woman of thirty-two required 600 X. With increase in the age of the patients the amount of X-ray radiation required rapidly decreases.

The equipment consisted of a Coolidge tube backing up a spark gap of nine to nine and one-half inches and a filter consisting of 3 mm. of aluminum and a thick layer of soft lead. With target distance of six inches, 10 milliamperes are passed for 2.5 minutes (over 20 X) through each of four areas or about 100 X for each treatment.

Within a month Lange would give three or four treatment, but in a footnote concedes the possibility of an error in his knob reading and that other operators would use an interval of three weeks between treatments. (A caution the unskilled practitioner would follow it could be entirely.)

(D. J. R. B.)

Collins A. S. A. W. An Operation for Retrodisplacement of the Uterus. *Is.*

The uterus is held in a retroflexed position and ligaments are caught with a wire for pulling up with the median line and the uterus is held in a normal position.

A ligament is then placed in the position of the uterus and the uterus is then held in a normal position. The uterus is then held in a normal position and the ligament is then placed in the position of the uterus and the uterus is then held in a normal position.

A ligament is then placed in the position of the uterus and the uterus is then held in a normal position. The uterus is then held in a normal position and the ligament is then placed in the position of the uterus and the uterus is then held in a normal position.

It is a muscle-to-muscle attachment and is possible to pull down the uterus and the uterus is then held in a normal position. The uterus is then held in a normal position and the ligament is then placed in the position of the uterus and the uterus is then held in a normal position.

A bladder or other organ is then placed in the position of the uterus and the uterus is then held in a normal position.

The uterus remains mobile.

(F. Ward L. C.)

Handfield Jones M. Clinical Aspect of the Double Uterus in Its Relation to Diagnosis and Treatment. *Lancet* 1914

The paper is based on the report of 10 cases of this condition 5 of which are under the author's observation. The cases are selected to illustrate certain clinical points. Among them were: 1. Case in which septum intervened between the second and third uterus occurred after delivery of a child from the third uterus. 2. Case in which the fetal sacs were removed from the uterus of the patient safely carried to term a single pregnancy in the second uterus. 3. Case of hamman-Rich in a double uterus. 4. Case illustrating the possibility of delivery by the unimpregnated uterus of a double uterus. 5. Case in which the unimpregnated uterus was safely delivered of the way of the pregnant portion and delivered. 6. Case in which death occurred from sepsis and hemorrhage following an attempt to lift the septum separating the two uteri both of which were pregnant after the first uterus had been safely delivered. 7. Case in which a pregnancy of 10 to 11 months on the left of a double uterus after

the other uterus had been emptied by curettage in the early months (8) a case in which a double vagina was discovered by the patient herself and (9) a case in which pregnancy proceeded safely to term after the condition had been demonstrated by an exploratory laparotomy in the early months of pregnancy C D HARRIS

Gallant A. E. The Removal of the Troublesome Useless Uterus. 4 1 11 5 9 6 ch, 455

Eliminating hysterectomies for (1) life-destroying disease and (2) for conditions detrimental to health or dangerous to life, the author goes on to the consideration of (3) removal of the uterus because of conditions the source and cause of health-destroying discomfort—troublesome because they were the cause of intractable suffering—useless because they were either absolutely relatively or practically incapable of performing the one sole function of the uterus—reproduction. In 2 women between 57 and 73 years, who had ceased to menstruate, the senile uteri were removed because of prolapsed bladder with or without rectocele or descent of the uterus or intestines, in 7 cases uterosacral ligament retrofixation, 4 cases chronic pyometria and ovarian sarcoma (?) one case. The second group included 1 woman whose ages ranged from 37 to 47 years, and who were still menstruating. Four had passed the approximate age for the menopause from 2 to 11 years while the other 7 still had in prospect from one to five years longer to flow normally. The average range of fertility was from one to seven children, the most recent birth seven months previous to operation, the average length of sterility was between six and seven years.

The third group included 7 suffering women between 30 and 34 years, in the full tide of reproductive activity, who had not been benefited by local and general treatment or by conservative operations.

Gallant, when deciding to operate or not to operate was influenced largely, by (1) the severity of the symptoms, (2) the effect on the general health and (3) the environment. Excessive nervousness was the one predominating complaint in all but one instance. Dysmenorrhea came next in order of frequency usually of a severe type lasting throughout the flow and compelling the sufferer to lie down for a few hours or go to bed for one, two or even three days of each period. Backache was a very common symptom, located by placing the hands over the sacral region, variously described as come and go pain, dragging, tearing, bearing down, falling, and present all the time during the monthlies, not so bad between, etc., but to each one very trying and very real. Headache, suboccipital was present in over half the cases, and of a truly torturing variety relieved only by some sort of dope. Ilio-abdominal pain, when not of appendicular origin was of a dragging, tearing, burning character and referable

(tension on the round ligaments or enlargement or adhesions of the tubes and ovaries, distinguishable from the appendix only by actual palpation. Dyspareunia was present whenever the vagina was raw or the uterosacral ligament immobilized the uterus.

Dysuria with frequent painful urination was nearly always associated with a demonstrable trigonitis, an acid vaginitis, and acid urine of high specific gravity.

The conditions calling for operation were prolapsed bladder with or without prolapse of the uterus and rectum, 1 case retroversion, 7 cases uterine fixation, 16 cases hypertrophied uterus, 5 cases anteversion, 4 cases lacerated cervix, 6 cases perineum, 1 case diseased ovaries and tubes, 6 cases persistent vaginitis, 6 cases with gonorrhea, 3 cases visceropeliosis cases.

The operative measures employed were vaginal hysterectomy 9 times, with salpingo-oophorectomy 1 case, complete excision of vagina, 3 cases partial excision, 4 cases supravaginal, 4 cases with ovaries and tubes, case belowinovaginal pain cases abdominal pain 2 cases anterior colporrhaphy 2 times perineorrhaphy 6 times appendectomy 4 times uterine drainage, times drainage through the cervical stump, times conservative (?) amputation of cervix, 2 times resection of sigmoid 1 case. This last patient died on the fifth day after operation, presumably from rupture of the slit of the resectum brought about by her (conscious if not) voiding into the bed. One other died 8 days after complete loss of the vagina from hypostatic pneumonia.

In conclusion Gallant states his belief that removal of the troublesome useless uterus is not only justifiable but the most rational procedure in the following conditions:

1. In senile women, complete denudation and closure of the vaginal canal is the one sure and permanent means of curing hernial vaginas.

2. Well-nourished women who have ceased to menstruate and who have passed or are approaching the approximate age when the menses should cease hysterectomy and partial colectomy will prove beneficial and still provide for marital relations.

3. Menstruating women under thirty-five years, after every means to conserve childbearing function have been exhausted when the conditions cause ill of semi-invalidism when they prevent her from working and earning a livelihood when they seriously interfere with her duties to her husband and children and condemn her to a life of unalloyed suffering, then and then only as a last resort, should the uterus be removed.

4. Whenever the pelvic conditions are associated with a troublesome, colicky appendix, or simple or exophthalmic goiter they should be removed.

5. Whenever combined with visceropeliosis a cure cannot be expected unless the patient is fitted with an appropriate corset.

area filled with delicate fibrous tissue, fibroblast and new blood vessels. Along the circumference of these primary fibroblasts which have penetrated into the surrounding lime-staining tissue reveals a marked lime absorption (Moschcowitz).

ADNEXAL AND PERIUTERINE CONDITIONS

Moschcowitz, E: The Relation of Angiogenesis to Ossification Based upon the Study of Five Cases of Calcification and Ossification of the Ovary. *Bull. Johns Hopkins Hosp.* 1916, vol. 21.

Within a comparatively short time the author has been able to study in the pathological laboratory of the Beth Israel Hospital three cases of calcification and two of ossification of the ovary. The lesions were studied particularly from a morphological viewpoint. The process in each instance involved a corpus albicans. The specimens represented an apparently continuous series in which four stages were recognizable: (1) an early discrete multiple deposit within a healed corpus luteum; (2) a definitely circumscribed deposit of amorphous lime within a corpus albicans; (3) the formation of primary Haversian canals which is accomplished by the genesis of an active mesoblastic tissue both upon the surface and within the interior of such a circumscribed lime deposit. (This mesoblastic tissue is derived from the adjacent blood vessels of the ovary, and the predominant activity is the development of new blood vessels associated with this

activity; the development of osteoblasts from the mesenchymal cells); (4) true bone formation with maturation of all the elements described above, together with eccentric deposition of bone plates around the primary Haversian canals and the formation of marrow.

Moschcowitz states that the development of new blood vessels affords the keynote to the interpretation, in terms of cellular ontogeny, of the process of ossification and that the histological constituents which enter into the formation of new blood vessels are the progenitors of all the histological components of osseous tissue. In other words, that blood vessels, osteoblasts, bone cells and marrow (in part at least) are merely differentiations of the mesenchymal cell unit.

To his mind the author's specimens furnish strong corroboration of the adaptive or mesenchymal theory of angiogenesis, and to the theory of the non-specificity of endothelium. Ossification, he believes, does not occur without preliminary calcification, and calcification occurs only in dead tissues, and there is no explanation for regarding bony structures within the ovary as blastomata.

(F. I. B. L.)

but syphilis if present will exert an influence of its own upon coexistent diseases. Moreover latent syphilis prevails more in women than in men.

The course of syphilis in men differs in many points from that in women. To cite but one of the differences the relative frequency of testes and paresis in the two sexes is well known.

Syphilis of the internal genitalia in women presents a number of problems as yet unsolved. The question of infection by the spirocheta of a syphilitic man is discussed, also the possibility of differences in the strains of spirochetæ which might have a predilection for one part or the other of the female genital tract. There is finally the question whether certain parts of the genitalia possess a sort of relative immunity.

Primary chancre of the vagina is rare probably because of certain histologic and biologic characteristics of the vagina. The typical signs of disease of a mucous membrane like parient-like induration persist as a rule only for a short time. Under ordinary circumstances spontaneous resorption occurs after about two weeks. The absence of definite symptoms such as pain or vaginal discharge and the insignificance of any remaining scar probably result in many cases in failure or even inability to correctly diagnose this lesion.

Secondary syphilitic lesions of the vagina are very rare. They occur either in the form of macules or papules the latter variety seems to be relatively more frequent. They have no symptomatology of their own and therefore are discovered only accidentally during an examination with the speculum.

Tertiary luetic manifestations of the vagina are also extremely rare. They represent as a rule the continuation of secondary lesions in the vulva, uterus or adjoining organs. The isolated submucous gumma breaks down early and appears in the form of a more or less characteristic ulcer. The more destructive processes which eventually lead to the formation of fistula and strictures almost always originate in structures surrounding the vagina. Tertiary lesions of the vagina do not exhibit characteristic symptoms such as pain or discharge.

Primary chancre of the cervix represents the best known and most common type of syphilitic affections of the female internal genitalia. Its frequency has probably been overestimated. Statistics based on a large number of observations have never shown a frequency of over 15 per cent of all primary chancres found on the genitalia. It must however be admitted that in a considerable number of cases its presence on the vaginal portion of the cervix is overlooked.

Primary chancre of the cervix does not give rise to any noteworthy clinical symptoms. Therefore as a rule a search for it is made only after the appearance of the secondary exanthema. Under normal conditions the primary lesion heals with such rapidity that its existence in a large percentage of

cases can only be surmised from certain findings which in themselves are not characteristic.

Not even during its existence does the primary chancre of the cervix truly characterize its pathognomonic aspect on account of its rapid and varied evolution from an unroofed inflammation to an ulcer which in turn either heals quickly or transforms into an inoperable carcinoma.

Concerning the absence of palpal swelling but especially the difficulty of ascertaining the characteristic induration of its base a description looking somewhat like an abscess of the cervix is not infrequently met with. The spirocheta pallida is never found in it and it is followed by a typical secondary exanthema.

Eight personal observations have been cited by the authors to the few cases found in the literature of a secondary lesion of the cervix. Syphilis manifested itself upon the cervix in the form of macules, papules and ulcerations. These forms probably represent three successive stages in the development of a lesion caused by scattered accumulation of the spirocheta pallida in the squamous mucosa of the cervix. The parasite can readily be recovered from the secretion of any of the three forms and thus explain the great infectiousness of secondary lesions. Wassermann is positive in this stage. Macules and papules have no symptomatology of their own while ulcers may give rise to a profuse yellowish discharge. Occasionally a peculiar puffiness of the fornices may be present. The leucoplasic appearance of macules, the characteristic form of the papules and the typical yellowish color of the ulceration render diagnosis comparatively easy. Secondaries in other parts of the body form a valuable aid. Cervical lesions as a rule heal quickly and may disappear without leaving any traces. Specific treatment energetically applied brings about resolution in a very short time.

Actual knowledge concerning syphilitic lesions of the uterine body is extremely meager. Primary and secondary manifestations have not yet been observed in the uterus. A few instances of gumma in the uterine wall have been recorded. An isolated observation by Hoffmann proves the possibility of gummatous changes in the endometrium. This infrequency of tertiary lesions is a matter of surprise for the uterus more than any other internal organ of the body is exposed to direct infection. Spirochetæ may reach the uterine cavity from the vagina or lesions of the cervix. It is certain that an actively syphilitic mother invariably infects the fetus. In every pregnant syphilitic woman spirochetæ must be present in the endometrium. Unless syphilitic lesions of the uterus have been overlooked in the past we are forced to assume a relative immunity on the part of the uterus.

It seems possible that the tubes may be the seat of luetic lesions but the pathological and clinical material on record is yet too incomplete to permit of positive assertion. Spirochetæ have never been found in the tubes of syphilitic women.

Various changes in the ovaries (simple enlargement syphilitic oophoritis, tertiary sclerosis of the ovary ovarian gumma) have been described as typical expressions of the secondary and tertiary stages of luetic infections, but in no instance with the possible exception of H. S. Mann's case, has positive proof been furnished that such alterations are actually due to a local luetic process.

The fact that in some syphilitic patients either an amenorrhea or more commonly a metrorrhagia, disappears after specific medication cannot be accepted as evidence of a syphilitic ovarian lesion. Spirochetes have as yet not been demonstrated in the ovaries of adults.

Syphilis of the pelvic cellular tissue appears in the form of a diffuse gummatous infiltration which secondarily involves the pelvic peritoneum. To the few cases on record the authors have added personal observation. In almost all instances a wrong diagnosis of malignancy has been made. In their own case the positive outcome of the Wassermann reaction together with other unmistakable signs of tertiary syphilis about the outer genitals aided in arriving at the correct diagnosis. Specific treatment produces amazingly quick improvement of an apparently hopeless condition.

Syphilis may be the causative factor of disturbed menstrual function for various reasons. Impairment of general health and disorder in the harmonious synergism of all endocrine glands through the affection of one may in the course of a luetic infection interfere with normal ovarian activity. Therefore, in syphilitic patients specific medication may correct a menorrhagia or metrorrhagia which has proved refractory to the customary modes of treatment. Such prompt therapeutic effect, however, does not permit of a diagnosis of luetic processes in the uterus or in the ovaries, because uterine lesions probably never, and syphilitic ovarian lesions, if actually existing, are but rarely responsible for abnormal uterine hemorrhages.

The Wassermann reaction is found positive in a very large percentage of patients suffering from metrorrhagias. This is not surprising. Luetic women through the common complication with gonorrhea and as the result of frequent abortions are particularly prone to develop gynecologic anomalies in which irregular uterine hemorrhages represent a predominant symptom.

The authors recommend a trial with specific therapy before radical treatment is decided upon for all cases in which a uterine hemorrhage is not definitely explained by local findings.

Normal cervical secretions may contain spirochetes during the secondary stage even though there are no specific lesions about the genitalia. This has been definitely proved by the authors by actual observation. The search for spirochetes may become as important a part of our diagnostic technique as is the stain for gonococci. The prognosis as to the danger from infection as well as the time of cure may depend upon such an examination.

As regards the uterus and more particularly the cervix convincing proof of the interrelations of syphilis and cancer are meager and it is necessary for the present at least, to rely chiefly on the analogy with other regions of the body. The following four possibilities suggest themselves.

1. An iteration of all tissues of the body caused directly or indirectly by the syphilitic virus—*Gonorrhea* *mitis* *g* of Neisser—whereby the defensive apparatus of the organism is weakened.

2. Any part of the body which in the past has been the seat of a syphilitic lesion becomes a *locus in quo* *istius* wherein cancer may develop.

3. Leucoplakia may represent the connecting link between syphilis and cancer.

4. The direct transition of syphilitic into carcinomatous tissue.

Microscopic sections are produced to illustrate the probable mode of such transformation. Unless arrested in time by antiluetic treatment, atypical cell proliferation such as is stimulated by the syphilitic lesion may lead to carcinoma.

While actual and well established facts regarding syphilis of the female genital organs are comparatively few in number in contrast to the many theories and the volume of literature on this subject yet enough is known to compel and hold the interest of the gynecologist.

Syphilis may cause organic lesions in all parts of the genital tract such as ulcerations and tumorizations. The gynecologist will be able to properly interpret and treat such lesions only if he is familiar with the local pathology of syphilis. He may also meet with functional disturbances within the genital sphere or explainable by any local findings, which may be due directly or indirectly to the influence of syphilis.

There are close analogies between the genital organs in the male and the female from a purely developmental and anatomical point of view. The fact that the ovaries correspond to the testicles, the tube to the epididymis, the uterus to the prostate has seemed to many writers sufficient to base deductions as to the pathology of syphilitic lesions in the female upon their knowledge of luetic lesions in the male. Such reasoning is faulty. Syphilis in many respects affects woman in a manner essentially different from man. After all, there is nothing in man to compare with disturbances of menstrual function which so often confront the gynecologist.

Gynecology has in the past profited by the pioneer work of dermatology in the realm of syphilis. It is now time that the gynecologist should contribute his full share. There are still many mooted questions, such as syphilis without primary lesion or the pathology of local lesions in the female genital tract which the gynecologist is amply fitted to solve.

He should also fall in line with the representatives of other specialties in advancing the problem of the relationship between cancer and previous syphilitic lesions in the same locality.

Familiarity with syphilis lesions in the genital tract must needs prove of eminent practical value to the gynecologist in view of the frequent confusion in the diagnosis of cancer and syphilitic ulceration, or gummata. That occasionally a patient is subjected to a serious radical operation which will have been cured by antiluetic treatment there can be no doubt.

A more intimate interest in the problems of syphilis of the internal female genitalia will advance gynecology both in its theory and in its practice.

MISCELLANEOUS

Coffey R. C. Surgical Treatment of Gonorrheal Tube Infection with a Quarantine Pack.
S. G. M. (Oct. 13)

The author emphasizes the importance of differentiating gonorrheal from pyogenic tube infection, for in the former the tube once sealed rarely functions, while in the latter pyogenic infection most tubes may be restored to function by proper drainage. The pack is made by laying wicks all the way across the pelvis in a complete wall the wicks extending to the bottom of the pelvis and protruding through the abdominal wound. Above this pack of gauze wicks four thicknesses of gutta percha tissue in the form of a large sheet is used to protect the intestine from contact with the gauze.

During the past eight years more than fifty cases of gonorrheal tube infection have been operated upon in the very acute stage with no mortality. In four of these the operation was performed so early that the tube had not sealed but a considerable quantity of pus could be squeezed out of the tube. The quarantine pack was placed, attacked, cut short, and in no instance has the patient had trouble since. In two other cases where the tubes were firmly sealed the tubes were ligated and a stump left. In both instances it was necessary to do a second operation to remove the stumps. In all other cases excision of the uterine end was practiced, followed by the placing of the quarantine pack. In all cases the attack was cut short at

and in none of this group of cases has a second operation been necessary.

The author's conclusions are: 1. Acute violent infection are best treated by early and radical operation.

2. If the tubes have not firmly sealed, the patient should be quarantined with a pack and allowed to remain unharmed. If they are firmly sealed they should be excised and hysterectomy and ovaries isolated from the intestine by a quarantine pack.

The author believes that many more tube infections will be saved by this method than by the old conservative method and that the usual sequel following gonorrheal tube infection will be markedly decreased.

Leeuwen G. A. Van. Some Remarks Regarding Useless, Therefore Undesirable Operations. *Quelques remarques à propos de opérations inutiles (ou indésirables)*. *J. h. m. s. d. b. j. n.* 1907. 333.

Many hysterical women in whom the genital apparatus is absolutely normal consult gynecologists for pains in the lower abdomen which they refer to the uterus or adnexa. In many such the indicated diagnosis is—no genital anomaly, hysteria.

In examining such women who have come to the gynecological clinic in Amsterdam Van Leeuwen found in a great number a cicatrix of a former appendicectomy. He found that the result of such operation was favorable in 40 per cent of cases but unfavorable in 60 per cent. The unfavorable results were generally in cases of chronic appendicitis.

Diagnosis of chronic appendicitis is difficult especially in women yet it is often made without sufficient reason. It is confounded very often with hysterical pains and anomalies. The operation which is done on these hysterical subjects is naturally insufficient. It is even harmful because since operation has failed to relieve them of imaginary pain they will now believe that there is something abnormal in their lower abdomen.

Such operations based on wrong diagnosis are not only damaging to the patient but to medical science.

W. A. BRON.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Van Slyke, L. and Vinograd Villichur. A Quantitative Test of the Abderhalden Reaction. *Am J Obst N Y* 9 6 1041 90

Owing to the great uncertainty which has been associated with the Abderhalden reaction the authors have worked in the hope of providing a quantitative method sufficiently accurate, simple and specific for proteolysis to make the results definite and free from subjective influence. They confined themselves to study of pregnant with normal serum. They utilized placenta prepared in three different ways.

As a standard method for measurement of serum protease the ammonium nitrogen determination seemed to them particularly promising for the following reasons. First it is quantitative and permits accurate results with a small amount of material. Second, it is specific for proteolysis. The change of the non-ammonium nitrogen of proteins into ammonium nitrogen is characteristic of protein digestion and the extent of this change affords a direct and quantitative measure of the extent to which protein digestion occurs. The method since its publication in 1910 has been used successfully in studies of protein digestion by various investigators.

As nearly as possible the same amount of placental tissue was used in every case. The utmost care was taken to avoid bacterial contamination, and the technique was controlled by means of repeated cultures with negative result. The chemical manipulations were simple, clear-cut, and quantitative. Duplicate controls always gave closely agreeing results.

Practically every serum, whether from a pregnant or non-pregnant individual showed some definitely measurable degree of digestion when incubated with placental tissue. The range of individual variation in proteolytic activity was wide. The result with normal sera cover in each case a range which includes most of the result from pregnant sera. After years' work using the utmost care, the authors found that the individual variations of both pregnant and non-pregnant sera make the results from both overlap so completely as to render the utilization of the reaction even with a quantitative technique absolutely impracticable for either a positive or negative diagnosis even of pregnancy.

C. H. D. VII.

Evans, D. J. Eclampsia. *Cad M Ass J* 9 6 VI, 0.

The author is of the opinion that true eclampsia is, on the whole, a rather rare complication of pregnancy and that a preponderant proportion of cases

diagnosed as eclampsia are really cases of renal insufficiency or nephritis in other words that in the larger proportion of cases the toxemia is due primarily to defective kidneys, while in the remainder the hepatic type the renal involvement is purely secondary. That it is possible to make a diagnosis of true eclampsia during life is thus open to question.

As a general rule, toxemia occurring late in pregnancy is attended with a marked increase in the general blood-pressure. In all cases of pregnancy presenting signs or symptoms of toxemia, the blood pressure should be systematically observed. A rising blood pressure associated with the symptoms headache, constipation, redness, epigastric pain, disturbed vision, albuminuria, etc. are indicative of danger and a pressure of 5 mm. may be considered as the danger limit.

As regards treatment every individual case must be studied and no single method of treatment is applicable to all.

In the presence of evident symptoms of toxemia in the later months of pregnancy associated with albuminuria and casts and an increased blood pressure, eliminative and sedative treatment is indicated. One must rely on milk diet, hot baths, the copious use of fluids and purgatives, together with rest in bed to bring about improvement. If there be no improvement indicated by the subsidence of the albuminuria, redness of blood pressure and disappearance of the general symptoms of toxemia, then labor should be induced. Venesection, sweating, the employment of morphia and chloral in moderate doses, with purgation and the free use of fluids, constitute the treatment of a case of actual convulsions. In cases at or near term active surgical methods of delivery may be undertaken, but only to save the life of the child as such operations, unless attended with considerable hemorrhage, seem to have but little influence in relieving the condition of the mother. EDWARD L. COYNE.

Diel, H. E. Eclampsia; Studies Concerning Its Causes, Nature, and Treatment. *N Eng M Gaz* 9 6 II, 7

As a general average eclampsia occurs in 0.3 to 0.6 per cent of all cases of confinement, 20 per cent coming antepartum, 60 per cent during labor and 20 per cent puerperal. The general predisposing causes seem to be primarily hereditary contracted pelvis, multiple pregnancy, previous renal or hepatic disease, and an unstable nervous equilibrium. Properly speaking eclampsia is but one, of the most severe as well, of the toxemias of pregnancy.

The author reviews the various theories as to the

cause of eclampsia and on July 1 that all cases probably do not have the same origin.

At present and until the cause be specially known the treatment is still but an a matter of routine.

First however there are the preventive measures. Symptom suggestive of impending eclampsia are headache, nausea, vomiting, seeing spots before the eyes with blurred vision, epigastric pain, insomnia or an abnormal desire to sleep, two things, edema, high blood pressure and albuminuria. When such symptoms are present, dietary measures should be taken—especially avoiding fritters and food rich in cellulose, also attention must be given to the eliminative channels. If these do not suffice, premature induction of labor is decidedly called for.

After convulsions have occurred there are two methods of treatment: (1) to deliver the patient once (2) delivery in case but attempting to control convulsions by the administration of morphine or chloral, birth and vivisection.

Remove toxic material by any rational means possible, relieving the same by saline intravenously or by colonic irrigations. Assist labor when it is developing or when the patient's condition does not improve.

If actual operative measures are needed, provided there be no dilatation of the cervix, the choice of methods rests between abdominal caesarean section, vaginal caesarean section and instrumental dilatation of the cervix. Vaginal caesarean section seems to offer the best chance for the mother in that it seems to involve the least shock and the least chance of sepsis. C. D. H. Livi.

Rand F H Indications for the Advantages of the High Incision in Caesarean Section J M S I M I 96 1170

The author gives the following indications for caesarean section:

Absolute indications i.e. conditions which admit of no other means of delivery: (1) contracted pelvis, as a flat pelvis where the true conjugate is less than 7 cm. and the child normal in size (2) neoplasms of the pelvis, uterus, adnexa, cervix, vagina, rectum, if sufficient to cause obstruction to the birth canal so that a normal birth is prevented (3) additional indications: cicatrices of the vagina, or cervix, some cases of ventral fixation, ruptured uterus, tonically contracted uterus, accidental hemorrhage (4) eclampsia—by this method of treatment the maternal mortality has been reduced nearly one half (5) placenta previa is thus best treated as it offers the best chance for both mother and child (6) condition of the fetus—one with a non-moulding head, impacted breech or face or prolapse of the cord where infection has been a hindrance.

Relative indications These are cases where caesarean section vies with forceps delivery, podalic version, pubiotomy, accouchement force, etc. Such cases include pelvic deformity, certain cases of

placenta previa, tonically contracted of the uterus, and in multiple cases, for morbid conditions where the fetus is alone in the interest of the child or to save the mother's life.

Relative indications (1) when attempts at delivery have been made from below (2) when it is possible that vaginal examination has been made with disastrous precautions.

Operative (1) Choice of time to operate. It is best to wait until labor has begun to be uterine, but not too late. However, in large perineal operations, the operation is an emergency, perineal. A high incision in the uterus is indicated in a living birth following reasons: (1) the abdominal opening is smaller than in the low type of incision (2) abdominal and uterine wound are separated by contraction and involution of the uterus which lessens the chance of adhesions (3) uterine incision is made through the part of the organ away from the lower blood vessels which lessens the danger of hemorrhage (4) incision is made in a portion of the uterus less likely to rupture in future pregnancies (5) there is less escape of intestines and omentum which lessens the shock and post-operative disturbances (6) there is less probability of subsequent hernia. C. D. H. Livi.

Bell R G Caesarean Section in a Pitman's Cottage B I M J 96 1195

The author reports a caesarean section performed under unusual difficulties in a case of contracted pelvis. The two previous labors had ended in the sacrifice of the children. Operation was successful in this instance a living child was delivered and the patient had a smooth convalescent puerperium. Exception might be taken to the opinion expressed by the author that many major abdominal operations could be done quite as well at the patient's home as in the hospital. Certainly with the history of the case in hand transportation to the hospital could have been effected long before the time of the operation the need for which was evident. PETER F WILLIAMS.

Tweedy E. H. The Lower Uterine Segment Its Origin and Boundaries. Lan & Lond 96 505

It requires only a very minute portion of the upper portion of the cervix to suffice for the growth of the lower uterine segment. We must think of the cervix as growing large rapidly rather than of its being rapidly stretched. These changes in the growth of the cervix result from stimulation by direct pressure exercised by the ovum during the latter half of pregnancy and during labor. To understand the progress of the growth of the lower uterine segment it is important to keep in mind certain established anatomical and physiological features. The endoperitoneal tissue forms an important diaphragm for the pelvis. Its fibers are inserted into the muscle bundles of the uterus and may be considered the main structural elements of the

latter. The diaphragm is held in tension by the uterine muscle. It supports the uterus, prevents descent of the contents of the abdomen and constitutes a barrier which effectively protects the cervix from pressure. The os internum opens at an early period of pregnancy and this relation corresponds with Hegar's early sign of pregnancy. Consequent on this opening the uterus and abdominal contents sag downward and the fornices become somewhat shallow. The uterine muscle-fibers are put out of tension by the opening of the os, with consequent contraction and retraction of these fibers and the upward movement of the diaphragm with its attached blood-vessels and ureter. This upward movement produces a still wider opening of the diaphragm, permitting the growing ovum to pass through it and allowing the latter to exercise direct pressure on the structures immediately beneath. Bearing these facts in mind we must conclude that the cervix is not an elastic structure, but, on the other hand, that it has a power of extraordinarily rapid growth when stimulated by continuous pressure. The similarity in the growth of the cervix to that of the growth of the lower uterine segment is very apparent, and we have no difficulty in following its subsequent development into the part known as the lower uterine segment. The ring of Mueller must be considered the undilated portion of the cervix which has as yet not been subjected to direct pressure and Bandl's retraction ring must consist of the structures which go to form the internal os. C. D. HAYES.

LYNN, F. C. The Systolic Blood Pressure in Pregnancy; Observations on Five Thousand Consecutive Cases in the Pregnancy Clinic of the Boston Lying In Hospital. *J. Am. M. Ass.* 1916, 196, 935.

In 80 per cent of pregnant women, the blood-pressure ranges from 100 to 130.

In 9 per cent, the blood-pressure may be below 100 one or more times. A blood-pressure below 90 does not mean that the patient will have shock unaccompanied by hemorrhage at confinement.

In 11 per cent of cases, the blood-pressure may be above 130 one or more times. Age, nationality and parity seem to have some influence on blood pressure. High blood-pressure in the young is more frequently a sign of toxemia than in those over 30.

Elevated blood-pressure is more commonly an index of toxemia than is albuminuria, and it is apt to be an earlier sign. The degree of elevation points more surely to the likelihood of toxemia than does the degree of albuminuria. Both, however, are of the utmost importance.

Isolated cases of elevated blood-pressure unaccompanied by albuminuria or evidences of toxemia occurred not infrequently. Usually they responded to free catharsis. Some pressures remained elevated in spite of treatment and apparently were normal during pregnancy at least for the patients who exhibited them.

A progressively rising blood-pressure, often from a low level, even though it never reaches the arbitrary danger point, should be regarded with apprehension as a most valuable sign of approaching toxemia. Toxemia is much more common with a blood-pressure above 130 than it is below that point.

Most cases of eclampsia occurred with pressure of 60 or more. Eclampsia may however occur with a moderately elevated blood-pressure.

All toxemias developed both albuminuria and elevated blood-pressure.

While the incidence of eclampsia in this series is about the same as the figures usually given, it is significant that two-thirds of the patients who developed convulsions absolutely neglected advice and refused to return to the clinic. Had these patients been discharged against advice during pregnancy for disobeying instructions, very favorable statistics would have been obtained. The hospital feels that it would have been most unjust to the ignorant foreigners, who constitute the vast majority of its patients, to desert them when they most needed skilled hospital care. With proper co-operation from the patients and eliminating the fulminating cases which develop in a few hours, there is no doubt that eclampsia would be practically preventable disease. EDWARD L. C. WELLS.

LABOR AND ITS COMPLICATIONS

WICHMANN, S. E. The High Forceps Operation (Zur Klinik der hohen Zangoperation). *Arch. und Arb. Stockholm*, 9, 6. *Kirurgi N. p.* and No. 2, p. 3.

The author in a very detailed and comprehensive article deals with the clinical data obtained in 900 high forceps operations in the obstetrical clinic of the University of Helsingfors from the beginning of the year 800 to the middle of 94. A short summary of each case is given. The matter is so diffuse and extensive that only an outline of the points discussed by the author can be presented in an abstract.

Under the heading of material Wichmann discusses choice of the cases, distribution of the material according to differences of maternal pelvis, size of the children, the manner of presentation of head in pelvis, indications calling for high forceps operation, age of the mothers and number of labors.

Under prognosis of high forceps operation, the following points are considered:

1. For the mother: (1) mortality, (2) injuries, (3) post partum hemorrhages, (4) morbidity, (5) late results.

2. For the child: (1) mortality, (2) as regards the pelvis and weight of child, (3) age of mother and number of previous births, (4) indication for operation, (5) mobility or fixation of head, (6) causes of death of the children, (7) injuries, late results.

The technique of the high forceps operation by various operators is discussed. Finally the value of the high forceps operation as regards position of the operation in the therapy of the contracted pelvis.

and significance of the resistance of soft parts as regards prognosis for mothers and children in high forceps operations. The article is accompanied by an extensive bibliography. W. A. BRENNAN

Mundell J. J. Pituitrin in Labor. *Am J Obstet* N. Y. 9 6 lxxiii 304

The author has reviewed the rather extensive literature which has accumulated on this subject during the six years this extract has been used in obstetrics. He has collected reports of 3,952 cases in which it has been used and gives a table showing the unfavorable results which have been reported by various writers. There were deaths due to rupture of the uterus, but in each case the records show that these fatal cases were due to the misuse of pituitrin. He finds a fetal mortality of 21 in 3,952 cases and a maternal mortality of 1.

This study shows the need of careful analysis of all the factors in the case before reporting the good or bad effects of such a powerful extract as pituitrin. C. H. DAVIS

Skell A. J. Analgesia and Anesthesia in Obstetric Practice. *J Am M A* 19 1 lxix 9

In labors not distinctly abnormal morphine is used during the first stage and only when the labor is expected to last at least four hours longer. The author's indications for morphine during the first stage are:

1. A rigid hypersensitive os.
2. Evidence of considerable pain with a probable first stage of several hours, as in most primiparae.
3. The presence of nagging but ineffectual pains which irritate and exhaust the patient out of proportion to results.

Accordingly many patients particularly primiparae get a single hypodermic of one sixth grain of morphine.

At the beginning of the second stage or if the patient suffers severely shortly before dilatation is completed the use of gas is begun. Intermittent administration is made at first that is during the pain only and with small amounts as 30 gallons of nitrous oxide to 15 gallons of oxygen. As the head approaches the pelvic floor and finally strikes the perineum the nitrous oxide is gradually increased in volume to 50 or 60 gallons and the intervals between administrations are shortened. This gradual increase of the volume of the gas given is controlled by the patient's statement of pain or comfort during uterine contraction. As the perineum begins distending and the most painful stage of labor arrives the gas is given still more continuously until, at the time of crowning from 70 to 80 gallons of nitrous oxide are given practically continuously. When the head is born the nitrous oxide is at once discontinued and the patient sharply revived by a few inhalations of pure oxygen.

If the woman is a primipara with a rigid inelastic perineum and lacerations seem inevitable the utmost possible relaxation is secured by switching to ether

and pushing to complete unconsciousness at the moment the head crowns the perineum.

The author enters a vigorous protest against the advice at present being so freely given that anyone may use gas in labor cases with perfect safety. Gas is a powerful therapeutic agent with infinite possibilities for harm at the hands of incompetent or careless users. The statement has been made that gas in the hands of an expert is a safe anesthetic but the most dangerous anesthetic if given by a novice. This is far too strong a statement to make concerning analgesia. Even here however some knowledge and experience are necessary to secure both safety and satisfaction from its use. Moreover the temptation to follow a gas analgesia labor with a gas anesthesia for repair is so obvious that all those who expect to adopt this method should spend sufficient time in special study of the agents they are to use so that they can direct its administration. This does not mean that a doctor must equip himself as a gas expert. The skill necessary for its use in labor can be acquired in a short time but free use of gas by the absolutely inexperienced will surely lead to tragedies. EDWARD I. CORNELI

MISCELLANEOUS

Francis, L. M. Treatment of Ophthalmia Neonatorum. *B Jale M J* 19 6 lxxv 344

The author not only discusses the treatment of ophthalmia neonatorum but also those features in its management which are of interest to the general practitioner. The article may be summed up as follows:

1. Not all ophthalmias of the newborn are gonorrhoeal. 30 per cent are due to other organisms as the staphylococcus streptococcus etc.

2. There are two classes of ophthalmias: those primary infections occurring at the time of birth and those where the infection occurs secondarily from extravaginal sources.

3. Early diagnosis is imperative. All new cases of ophthalmia must be regarded with suspicion until proven to be of a benign nature. Smears should be made early.

4. In unilateral infection the other eye should be protected and the attendants warned of the danger.

5. Because of the frequent serious corneal involvement gonorrhoeal ophthalmia should be under the care of the ophthalmologist.

6. Careful and intelligent nursing is as important as medical advice in these cases. C. D. HOLMES

Barnett C. J. Treatment of Gonorrhoeal Ophthalmia. *M J Med Rec* 19 6 lxxvii 239.

The author has used cresatin in a number of cases of gonorrhoeal ophthalmia and finds it an excellent drug. Cresatin is a phenol derivative of very powerful germicidal properties, entirely free from the corrosive destructive action of the ordinary phenols.

The duration of gonorrhoeal ophthalmia under

this method of treatment is twenty four to forty eight hours after the first application. In most cases one application was found sufficient. In one case more than two such treatments given. Gonococci were rarely found after the first application where they did so appear a second application effectively disposed of them.

The technique is as follows. A 25 per cent solution of cresatin in alcohol is used. The conjunctival sac must first be cleared of secretion by means of a stream of warm physiological saline or saturated boric acid solution preferably through an undrained. This is followed by the instillation of a drop or two of a one per cent solution of boric acid or cocaine to prevent the slight irritation of the next step. A small cotton swab used to apply drop of cresatin to the mucosa of the conjunctival sac. It is imperative to cover the entire surface of the conjunctiva in this application. The after-treatment consists in keeping the conjunctival sac free from pus and the repetition of the application should occur as demanded. RALPH H. KIMM

Hannah, C. R. J. J. ries the Infant Prodced Birth. *T. St J Med* 9 6 21 539

The author discusses the various causes for birth injuries, and gives the histories of four cases of long and difficult labor followed by injuries to the infants.

It is in cases of contracted pelvis that the infants suffer most. Here the use of the forceps produces a depressed fracture, concussion of the brain or an intracranial hemorrhage, any one of which may cause permanent pathological change which in later life may explain paralysis, headache, epilepsy and other existing maladies. Usually these injuries are the result of the scientific application of the mechanics of delivery. Brute force is substituted for proper and thoughtful manipulations. Prolonged and hard labor pains, which prevent a change in the fetal blood, are frequently found in cases of generally contracted pelvis, and in cases with rigid and unyielding perineum.

In conclusion the author emphasizes the following points:

That neglect of frequent observance of the fetal heart-sounds cost the life of many child.

That a slow irregular fetal heart beat or excessively fast one signifies fetal danger.

That the presence of mephitic or sea-green meconium in the liquor amnii in cephalic presentation may mean compression and failure to recognize this fact hazards the life of the fetus.

That placental may cause tetanic contractions of the uterus, and if so an interference in the placental blood may be prevented which would produce hypercalcemia.

That an irregular and slow fetal heart or an excessively fast one or the presence of meconium in the liquor amnii are symptoms which indicate that the fetus must be delivered or it will probably die.

That if an attempt to deliver is made it should first be made certain that the child can be delivered alive. That it will probably live and second that the mother will not be injured.

That an internal hernial mass using internal pressure should be removed early or pathological destruction of the nervous system will take place which may use deformities, imbecility, epilepsy and other forms of degeneracy. RALPH H. KIMM

Davis, L. P. Syphilis in Its Relation to Obstetrics. *J. Am Gynec Soc* Wash DC 9 6 51 3

Davis believes that the most positive diagnosis of syphilis in the parturient may be derived from the fact that it is recognized by examining the parasites found in the blood of the umbilical vein and the oncotri of the umbilical cord. This gives an opportunity for examination suspected cases without poisoning mother or child or causing interference with the parasites are never found in the mother but occasionally the chorion. When found the placenta they are the rule and in the blood of these cases. Should the retention of the placenta be careful they will probably be destroyed by the blood of the mother.

Syphilis may be diagnosed in the placenta when gummatous placental lesions or marked or growth of the placenta of the placenta is present. Similarly the comparison of the placenta of the child is as a whole in syphilis the proportion is 4 to 1 at the marked increase in size of the placental placenta. Where the mother is syphilitic although the child is not yet approached as found in the mother or to per cent of cases. In her both parent syphilis the placenta shows some of their presence in per cent. Syphilis is transmitted from mother to mother through the leucocytes of the umbilical vein or through the red cells of the blood. So far as fetal effect by syphilis concerned the placental lesion is much less important than as previously supposed.

The syphilitic are found abundantly in the organs of the syphilitic fetus and represent three fifths of all macerated fetuses.

Where the syphilitic can be found in the blood of either parent or in tissues removed from lesions, the diagnosis is positive. Searching for the parasites, the fetus must be kept in mind that bichloride of mercury 5,000 causes the parasites disappear from tissues, and hence one must be taken into antiseptic precautions destroy the possibility of diagnosis.

Syphilis may form antigen in the milk, which protect against infection. The mother is then especially well prepared to receive offspring which may be and probably is, syphilitic. Should the child be syphilitic and the mother about to nurse.

Syphilitic nurse should be secured for the child but if the mother be syphilitic and the child healthy, the child should be artificially fed. In doubtful cases, it is best to procure a healthy wet nurse.

The majority of writers today believe that Colles' law is no longer valid in view of our present knowledge. The condition known as latent syphilis in the mother, the antigens which her breast milk contains and the belief that the fetus conveys syphilis to the mother are proof against the validity of Colles' law.

Treatment may destroy spirochætae but unfortunately toxins produced by the parasites may still poison the patient.

The Wassermann reaction cannot be relied upon for a positive diagnosis of syphilis. Pregnant patients having diseases caused by protozoa or tuberculosis malignant growths scarlatina pneumonia and eclampsia may give a positive Wassermann reaction when syphilis is absent. It has frequently been observed that a patient having a negative Wassermann reaction is greatly benefited by antisyphilitic treatment.

Noguchi's vaccine known as lumen is useful in preventing the development of tertiary syphilis. It has not been especially successful with pregnant women.

The frequency of syphilis among parturient women is difficult to estimate. Fournier found that among married women in his clinic 70 per cent had syphilis before marriage and 20 per cent afterward. In the majority the first sign of the disease appears within six months after marriage. When history could be obtained it was found that the husband had become infected less than three years before marriage. The first three years after marriage is the most dangerous period of life for the woman so far as infection by syphilis is concerned. Both syphilitic men and women should receive continuous treatment for at least six years after marriage.

In parturient patients syphilis may cause lesion in the genital tract making post-neous birth difficult impossible. The mortality of syphilis of parturient women is estimated at 1 per cent largely from mixed infection. Fetal perinatal morbidity is much increased by syphilis and phenomena may be observed in the perinatal period.

It is commonly supposed that syphilis is a frequent cause of abortion but this is now being denied.

In the living newborn a diagnosis can be made by examining the umbilical cord and detecting characteristic parasites in the wall of the umbilical vein and connective tissue. In apparently healthy children spirochætae are often found at the umbilicus. The X-ray is especially valuable in this way in the newborn the steech reaction being an important symptom of the disease. Syphilis is a frequent cause of stillbirth and of stillborn infant in whom there may be no apparent sign of the disease. Children born with syphilis remain apparently healthy and develop disease at the joint the lymphatic the bones and the meninges as late as a year after birth. Birth defects are often attacked and the fetal character of the disease differentiates it from tuberculous disease at the knee joint which is unilateral. In these cases the venereal fluid may give a positive Wassermann test.

The percentage of syphilitic children is between 1 and 2 of the first year and a long incubation usually 1 to 2 years in 12 per cent.

As regards the frequency of syphilis in the newborn among the poor 1 child in 100 is an infant in whom syphilis is born among the poor in the United States 1 child in 3 per 1000 among the venereal gave a positive Wassermann reaction. Complications of the newborn are by many not considered a syphilitic but a streptococcal infection. The characteristic lesions are at the tip of the palms of the hand in the sole of the feet and in the peculiar staining of the tissues about the mouth and the anus.

Salvarsan treatment is useful for both mother and child in acute and chronic syphilis but it will not prevent the death of the child in stillbirth or toxemia. The majority of observers use salvarsan to a moderate and severe cases and rely upon mercury and iodine to complete a cure. In using salvarsan the urine should be repeatedly examined to observe the excretion of arsenic. Should this fall poisoning may result. Many prefer to treat the pregnant woman by hypodermic injection of a mercurial preparation.

GENITO-URINARY SURGERY

ADRENAL, KIDNEY AND URETER

Thomas, G. J. Clinical Review of 240 Cases of Non-surgical Infection of the Kidneys and Ureters. *Urol. & C. Gen. Res.* 9 6 XII, 17

The author analyzes 240 cases of renal infection which received urological treatment in the Mayo Clinic. Tuberculosis and infection secondary to calculus or urinary obstructions are excluded. Frequency of urination is the earliest and most frequent symptom, 76 per cent. Cystitis, however, was noted in only 6 per cent of the cases. Renal pain was the initial symptom in 37 per cent and hematuria in only 7 per cent although present at some time in 4 per cent. Ninety-five cases had bacteriologic examination and 63 per cent of these were colon infections. Thomas argues that the original offending organisms probably lessen the resistance of the kidney so that the colon bacillus which is constantly passing through the kidney becomes pathogenic. The majority of infections are bilateral and should be considered so until proven otherwise by pyelography and cultural examination. Contamination is frequent usually from poorly sterilized ureteral catheters or the use of an unsterile lubricant.

In treatment a careful search for foci of infection, such as tonsils, teeth, abscesses, furunculosis, bone infections, etc. should be made before urologic treatment is instituted. Of local treatment lavage of the kidney pelvis and ureters every four or five days was most frequently used. Lavage with 0.5 to 3 per cent silver nitrate. Of 150 cases which were followed in 50 per cent the condition remained stationary, improved in 46 per cent, and cured in 18 per cent. Of the 38 cases cured, 6 had autogenous vaccine only, 6 vaccine and urinary antiseptics only, 4 urinary antiseptics only, 2 pelvic lavage, and 2 vaccines and lavage whereas, 3 cases had urinary antiseptics, vaccines, and lavage. Three cases received no treatment, were operated upon and one had bladder lavage only. FRANK HIGMAN

Crabtree, E. G. A Method of Demonstrating Bacteria in Urine by Means of the Centrifuge; the Relative Value of Examinations by Culture or Stained Sediment. *Surg. Gynec. & Obst.* 916 XIII, 1

The author calls attention to certain unavoidable errors in the diagnosis of urinary infection where the clinician relies entirely upon cultural evidence. These errors are due to four factors:

1. The tendency of some common bacteria like the colon bacillus when recurring in mixed infections to overgrow other perhaps more significant bacteria.

This occurrence is most troublesome in infections with phosphate calculi and in sections of the kidney where a colon pyelitis already exists.

2. The tendency of chromogenic bacteria to obscure their more significant growths in culture.

3. The possibility of formalin treatment of small quantities of urine being washed off formalin sterilized catheter sufficient to inhibit growth in culture.

4. Routine culture fails to demonstrate the more rare bacterial infections because of suitable cultural conditions and media.

He calls attention to the value of staining as a control to cultural examinations of urines as a means of avoiding the above. By his method of eliminating pus from centrifuged sediment large numbers of bacterial tubercle bacilli when present are demonstrated. Sufficient evidence as to the nature of the organisms is obtained by stained over examinations to indicate proper cultural examinations as readily recognized infections by the number of bacteria.

Schmidt, L. E. The Role of Urine Stasis in Etiology of Pyogenic Kidney. *Lancet* 9 6 CIV, 9

Urine stasis is probably the most factor in establishing renal infection. It is recognized that if lowered resistance of present urine stasis may account for changes in the kidney and the sequelae. Bacterial invasion may take place by the ureters or their lymph-channels. Provided that an infectious focus exists in the or the immediate neighborhood. Recurrences have undoubtedly demonstrated the existence of a lymph-channel between the bladder by way of the ureter and thus out is the author the most important source of renal infection.

Owing to predisposing factors existing such as periods of congestion of their genital system superinduced by menstruation, pregnancy, labor the possibility of the establishment of infections of the kidney is greater than in the male. Schmidt believes that this type of infection though some statistics state the contrary is frequently met with in the female sex.

Owing to the close relation of the infection to the kidney by lymphatic circulation sections of the kidney are easily accounted for generally occur on the basis of intestinal

and stasis. In the etiology of urine stasis congenital renal anomalies of formation or location (horseshoe kidney, dysplasias with anomalous vessels favoring stone formation, polycystic kidney, etc.) play an important rôle. Schmidt has observed that many of these conditions are the nucleus for later occurring renal infections. In 11 cases of congenital polycystic kidney, which came to operation, 9 were complicated with infections. The same is true of hydronephrosis in the vast majority of which infection sooner or later necessitates operative interference.

Operative injuries of the ureter obstructive conditions connected with advanced renal neoplasms, parasitic growths of the kidney and concretions of the upper urinary tract are cited as other and frequent sources for renal stasis and consecutive renal infection. In looking over his operative records the author found that urine stasis in the pelvis of the kidney was an important factor in infections of the kidney, that in fully four fifths of his cases the colon bacillus could be demonstrated as the infecting agent and that but a small percentage of cases are ascending in character.

Owing to the fact that obstructive conditions of the urethra are more prevalent in males, consecutive infectious changes of the upper urinary tract are less frequent in women than in men, a fact that is borne out by the author's statistical compilation of his own material.

The reverse is true of urine stasis due to pathological conditions in the bony pelvis causing pressure on the ureters, which are by far more common in the female sex. The greater frequency of renal infections in the male as evidenced by the author's statistics on his own work is explained on the basis of the preponderance of more favorable conditions for general infections in that sex.

The author concludes his very instructive article by insisting upon early operative relief for the great majority of cases of renal infection as a sequel to urine stasis. A more expectant régime may yield good results in the frequent cases of colon infection consecutive to congestion while in renal infections due to the more common pus-producing organisms may a timely surgical measures are fraught with satisfactory results.

Danziger, F. An Unusual Case of Kidney Ripping by a Grenade Splinter. *Arch. f. klin. u. exp. Med.* 1914, 11, 160.

Danziger gives a short clinical report of a very interesting and unusual case of ripping of a kidney by a splinter from a grenade. On operation the kidney was found to be completely torn in two pieces, the ureter which was also torn from the bladder being attached to the smaller piece. The renal cavity was cleaned out and tamponed, the ureter removed and the vessels in the vicinity ligated. The peritoneum was not injured. After a temporary tampon with drawn and the clot of the torn

kidney united and sutured. The hemorrhage was slight and there were no complications. Recovery was uneventful.

W. A. B. R. 1914.

Stutzin and Gundelfinger. War Injuries of the Urogenital System. *Chirurg. u. gynec. Wochenschr.* 1914, 39, 22.

Stutzin, who writes from the German Red Cross Hospital at Constantinople, discusses the most frequent type of injuries of the genito-urinary system occurring in war. He gives the details of the clinical history in ten cases of this kind observed by him. He points out the difficulty of carrying out the complicated diagnostic and operative technique required in such cases at the front, but says that cystoscopy is possible and necessary in the field.

Injuries of the bladder are the most frequent type observed. Where the healing is tardy, incision and drainage must be resorted to.

In the case of ureteral fistulae occurring from wounds without spontaneous healing, nephrectomy is called for. Sectioning of the bladder is generally the rule in the case of urethral injuries. Plastic operations are often required on the genital organs and, when necessary, the scrotal skin is best utilized. The after-treatment of all cases operated upon for urogenital injuries must be carefully watched.

W. A. B. R. 1914.

Kakels, M. S. Large Congenital Hydronephrosis in an Infant Six Weeks of Age. *Arch. f. klin. u. exp. Med.* 1914, 11, 527.

Kakels reports this case on account of its rarity, the youth of the patient, the large size of the hydronephrosis, its rapid progress, and its successful removal by transperitoneal nephrectomy.

The infant was six weeks old, ventricose from birth, and since birth a gradual and increasing swelling of the abdomen had been noted. On examination the whole abdomen was found to be greatly distended with the swelling bulging from under the costal borders on both sides and to the right flank, an elongated mass was felt with fluctuation. The diagnosis lay between a malignant and non-malignant growth of the kidney and, as corroborated by the X-ray plate, such that it was a retroperitoneal growth.

On account of its large size, the growth was extirpated transperitoneally through the anterior abdominal route and 300 cc. of straw-colored, urinitic fluid was removed. The sac showed that it was continuous with a greatly enlarged kidney three times its normal size, made up entirely of distended pelvises of globular form and not pear-shaped. There was neither structure nor dilatation of the ureter but from its bluish, faint and at an anomalous position the author ascribed these factors the biological element in the causation of the hydronephrosis.

L. C. R. 1914.

Ramsdoff, J.: Unilateral Haematuria Surg. Gynec. & Obst., 9 6 xiii, 75.

Ramsdoff presents a case of pancreatic cyst, with what he believes to be the unique symptom of haematuria. The tumor was in the left upper quadrant projecting into the loin, distinctly fluctuating and of slow growth. When first seen it was nearly as large as an adult head. Cystoscopic examination showed a bloody stream of urine issuing from the left ureteral orifice. Indigocarmine injection demonstrated equal function on the part of the two kidneys.

Ureteral catheterization and radiographing of the renal pelvis was refrained from on account of the weakened condition of the patient at the time of examination. The barium injection of the rectum showed the colon normal.

Exploration of the left kidney by lumbar incision revealed a somewhat larger kidney than normal. A diagnosis was made of cystic sarcoma of the left kidney. Lumbar exposure of the kidney showed it to be normal. Median incision then displayed the cyst of the pancreas, projecting between the colon and the stomach, with the spleen six or eight times its normal size. The pressure of the pancreatic cyst on the renal and splenic vein had produced the haematuria and the enlargement of the spleen. The haematuria disappeared after the operation.

So far as the author knows, the case is unique, since a search of the relevant literature has failed to show another case.

The pancreatic matter of the cysts was demonstrated by the presence of the three pancreatic ferments: alkaline phosphatase, amylase, and lipase. There were also present little masses of asphoned fat.

Macedo, C.: The Periods of Amelioration in Renal Tuberculosis (Los periodos de mejora en la tuberculosis renal) *Cris. med. Lima* 9 6, xiii, 33.

From clinical histories the author deduces that during the long periods of arrest or apparent cure of renal tuberculosis, some symptoms improve and even disappear while others persist, revealing the existence of the primitive pathologic state of the kidney.

The symptoms diminishing in intensity or disappearing are: (1) lumbar pain, (2) frequency of micturition, and (3) haematuria.

The clinical signs which persist are: (1) polyuria, (2) albuminuria, (3) pyuria, and (4) bacillus tuberculosis.

Cystoscopic examinations have proved to the author that—(1) acute cystitis of a tubercular origin may develop into a chronic state, with a normal functioning of the urinary bladder, (2) cicatrices of advanced tubercular lesions may be observed, (3) in such conditions characteristic cystoscopic aspects are met with.

Renal tuberculosis starts insidiously and develops without being discovered by the patient or the

attending physician, then it confines itself to lesions of the renal parenchyma, latent tuberculosis.

When the patient has reached the stage of acute tuberculosis, producing symptoms alarming to the patient and permitting of a diagnosis, the tuberculous process is sufficiently advanced to force the abandoning of all hope for a spontaneous cure or medical treatment; the end-result is the destruction of the kidney. Although renal tuberculosis and long living are incompatible, the only salvation of life in such cases rests with the surgeon, nephrectomy being the only treatment available with the understanding that all depends on the condition of the other kidney and the general condition of the patient. RIVER L. VIO.

Simmonds, M.: Danger of Pyelography (Ueber die Gefahr der Pyelographie) *Menschen med. IV. Ausdr.* 9 6 xiii, 79.

In a case in which Simmonds made a pyelographic investigation on so doubtful kidney symptoms, the patient died on the third day following. In this case 5 cm of 5 per cent Iargol solution were injected into the right kidney pelvis. He died with some other reported cases of death following collargol solution injections.

From the autopsy made in his case it is clear that Simmonds had collargol poisoning, not the cause of death but that death resulted from a streptococcus septic infection. There were apparent pyemias in the rete by which the streptococci had found a mode of entrance into the blood stream. While it is not clear what part the injection may have played in the passage of the microbes, yet a 5 per cent solution was evidently not bactericidal.

Among the dangers of pyelography therefore must be reckoned on that is usually ignored, i.e., septic infection. The surgeon must take special precautions to avoid injuries to the kidney tissues by the infusion, and if the bladder, lower urinary passages are found to contain infective microbes it is better to abstain from pyelography.

W. A. BRENNAN

Grossi, V.: Clinical Considerations of Ambard's Constant (*Applicazioni cliniche della costante di Ambard*) *Ped. Roma* 9 6 xiii, sec. III, 4.

Grossi has made an extensive study of the clinical result obtained by himself and others in the application of Ambard's constant. His own experience is based on 51 complete clinical cases in which the constant was observed 77 times. He concludes that Ambard's urosecretory constant is like various other methods of value in examining the renal function, indicating the global alteration of the function of the kidney and that it can in its extreme limits confirm a lethal prognosis or cause more caution in making an operative intervention. It is superior to the calorimetric method in cases where catheterization of the ureters is impossible.

In regard to the numerical limitations imposed by

Chevaasu, Grossi believes that they have no absolute value and that the interpretation of the constant ought to be made in each individual case according to the clinical criteria and the various causative factors: azotemia, ureic concentration, daily ureic elimination.

In 5 patients dying from renal insufficiency the azotemia was always higher than 1 gram in one case it reached 5.2 gr per 1000 in one case for some few days before death it fell to 0.3 gr. Three cases in which the azotemia was above 1 gr were operated upon successfully and recovered 1 died four months later.

The ureic concentration in cases of death was always below 10 per 1000. The daily elimination was still less and was associated with oliguria. In 2 patients dying from hematogenous infection of the kidney the constant and its factors were almost normal.

From the surgical point of view great value should be attached to the ureic concentration and to the daily elimination which correspond in reality to Albarran's two-hour examination of the global urine and to Cathelin's analogous procedures.

The significance and pathogenesis of the azotemia and of the constant are very far from being clear. In their present state Grossi thinks that we must consider them as simply signs to which it is necessary to attach great importance perhaps just as much as to the albumin contents of the urine.

Wechselmann: Intravenous Injections of Lactose Without Reaction: Sclayer's Kidney Test (Ueber reaktionslos verlaufende intravenöse Milchsückerinjektionen). *Beri kl. Wochenschr.* 916 III, 84.

Wechselmann has been using the lactose test for some years past and in many thousands of cases. His experience is that it is very reliable when the lactose is pure and furnishes a dependable index of the kidney functioning. The ill effects which some have found after the use of lactose are explainable as due to the presence of impurities.

W. A. BAEY

Wyman M H: The Phenolsulphonephthalein Estimation of Renal Function in a Thousand Cases. *J. So. C. M. A.* 96 VII 84.

The majority of the 1,000 tests were done on surgical patients at the Columbia (S. C.) Hospital as a part of the routine examination.

An output of 50 per cent or over comes only from normal kidneys.

A 60 per cent output may be temporarily observed in cases where there are at the same time evidences of kidney disease: albumin or casts but if the latter do not clear up quickly the output soon begins to decrease.

When a sound kidney is compensating unusually well for its diseased fellow we may find a 60 per cent excretion together with albumin and pus.

But in 25 per cent of cases evidence of kidney disease is accompanied by an excretion below 60 per cent.

From the prognostic viewpoint the important thing is whether the curve rises or falls. A man may be regarded as a good surgical risk with an output of but 20 per cent provided the curve has risen and is stationary. I. I. CARD

Hunner G L: Ureteral Stricture Excluding Cases Due to Tuberculosis and Calculus. Report of Fifty Cases. *J. Am. Med. A.* St. Louis 96 April.

In discussing stricture of the ureter the author is dealing only with the narrowing of the ureteral lumen due to intrinsic disease of the ureter.

The report of cases is further limited by excluding strictures due to tuberculous disease and those strictures immediately surrounding a stone.

Thus limited inflammatory stricture is a far more common disease than is generally believed the author's cases up to November 1915 numbering 50 as contrasted with 49 nephrectomies for tuberculosis and 30 operations for stone in the ureter.

The author recognizes congenital narrowing as an etiological factor in the disease but thinks its importance has been greatly overestimated and does not classify any of his cases as due to this cause.

Other causes are gonorrheal infection probably traveling up the lymphatics from the bladder and pyelonephritic infections which others have considered as infecting the ureter by way of the urine stream. The author thinks it more probable that the ureteral wall involvement is synchronous with the pyelonephritic infection and like it has a blood or lymph stream origin.

Ureteral stricture from the ordinary pyogenic cystic infections is extremely rare. Traumatic cases follow operations childbearing and other sources of injury to the ureteral wall.

The author thinks that by far the greatest source of ureteral stricture is some distant focus of disease such as infected tonsils sinuses teeth or disease of the gastro-intestinal tract.

In such cases the disease settles in the ureteral walls and causes the narrowing which in many cases is followed by dilatation and later by infection of the urinary tract.

The symptoms of ureteral stricture are for the most part due to the obstruction and are identical with the symptoms of stone in the ureter. Some patients complain only of a more or less constant dull aching pain in the lumbar region. Others have this constant dull pain with acute exacerbations of pain in the kidney region and the pain is often reflected down the ureter. There may be bladder and rectal tenesmus. Such attacks may require morphia, and either the pain or the morphia may bring about severe nausea and vomiting.

If infection be present the above symptom are likely to be more severe and are accompanied by chills high temperature and profound prostration.

The congestions incident to exposure getting the feet wet, catching cold, and those due to the menstrual period are likely to cause partial or complete temporary closure of the inflammatory area and thus bring about a severe attack of renal pain. Spontaneous local pain at the stricture site is complained of in some cases.

The diagnosis is made on the history, the urine examination, and the physical findings. As above stated the history is that of tone in the ureter or of pyelitis. The urine may be quite negative but it usually contains a few red blood corpuscles or a few leucocytes and it may contain both in small or large numbers. Particularly after severe renal colic, the urine may be smoky with blood or if infection be present it may be turbid with pus and bacteria.

The observation that the urine may be quite negative in these cases is a most important one from the diagnostic standpoint. Too often with a negative X-ray and with normal urine it is concluded that the urinary tract is not involved and renal catheterization and the obtaining of a pyelo-ureterogram are neglected. The patient is operated upon for appendicitis, or some form of exploratory laparotomy is done and the victim continues to suffer or to find partial relief in expectant methods of treatment.

If the stricture be located in or near the bladder wall, it may be palpated as a definite thickening indistinguishable from the dilatation usually surrounding a stone, and cystoscopy in such case often shows redness and edema about the ureteral orifice.

If with the above history and urinary and physical findings one is unable by X-ray and a wax-tipped catheter to locate stone in the ureter, probable diagnosis of stricture is justified.

Repeated obstruction to the renal catheter at a certain distance from the bladder is further evidence of stricture.

By melting pure beeswax and making a wax spindle on the renal catheter, the short distance back of its tip one can appreciate the obstruction to this spindle as it meets the stricture and a more certain diagnostic feature is the hang of this spindle on the stricture area as the catheter is withdrawn.

Additional corroborative evidence of stricture is the presence of hydronephrosis although a measurable increase in kidney and ureter content may be absent even after years of recurrent renal attacks.

The trauma of catheterization is often followed by a severe renal attack and in the infected cases by a typical pyelitis attack. In suspected ureteral stone or stricture a large catheter or preferably a large catheter with wax bulb dilator should be passed to dilate sufficiently to avoid this edematous closure of the lumen after examination.

The author has seen several cases in which the fluid content of the kidney pelvis was less than

normal. These are usually cases with a prolonged infection which has resulted in contraction of kidney pelvis in spite of the mechanical obstruction lower down causing symptoms. A pyelo-ureterogram in such cases shows the site of the ureter stricture and a slightly dilated ureter above the point.

The author takes definite issue with the prevalent opinion that dilatation of the kidney pelvis and ureter are due to infection. Many of his cases with sterile urine and no history of previous infection have the dilated ureter and pelvis.

Of 44 cases with urine report, 16 were sterile of these 6 have notes on the kidney content of these were approximately normal, measuring respectively 8 and 12 ccm. 7 had a hydronephrosis ranging from 15 to 30 ccm. and one excepted with clear urine measured 385 ccm.

Of 18 infected cases, 5 were measured 4 being normal or less than normal size and the pelvis 11 cases averaging 130 ccm. In this series of cases the average duration of symptoms in the six cases was two and a half years, and in the infected cases four years.

The ideal treatment for stricture of the ureter is dilatation from the vesical approach. Dilatation results in relieving the patient's symptoms and shrinkage of the distended pelvis and ureter. Infection be present dilatation is supplemented by renal lavage although it is probable that in many cases would clear up without the lavage simply giving the urine free drainage. In the infrequent cases of long duration with immense sacculated kidneys one may be unable to clear up the infection but after dilatation of the stricture the kidney pelvis shrinks markedly the urine becomes more clear and in some cases entirely clear even for the bacteria and microscopic pus, and the patient is restored to approximately normal health. These facts are of vital importance to those path with bilateral stricture. In the cases with one lateral stricture and with immense hydronephrotic pyonephrotic kidney conservatism often calls for the extirpation of the kidney. This was done six times in the author's cases.

In cases that cannot be dilated by the vesical approach the author advises extraperitoneal exposure of the ureter and retrograde dilatation. This was done on 8 of his 50 cases, with excellent results in 6. Two of his early cases failed to obtain complete relief probably because of insufficient dilatation.

Bilateral stricture was demonstrated in 12 of 50 cases. It is probable that systematic examination would have shown a larger percentage of bilateral cases, as some of these 12 had symptoms on one side only and the other side was accidentally found to have stricture in the course of a check test or after relief of symptoms on one side the patient returned later with symptoms in the other kidney and these were found due to stricture the corresponding ureter.

BLADDER, URETHRA AND PENIS

Woodall G W. Some Problems in the X Ray
Diagnosis of Urinary Calculi. *11th Y M J*
9 6 1961 17

According to Woodall the X ray is but one of three indispensable means of diagnosis in cases of suspected urinary calculi. The other two are (1) a careful history and physical examination (2) a cystoscopic exploration and study of the urinary findings from the bladder and kidney.

He groups the cases from a roentgenologic viewpoint into three classes:

1. The X ray findings may be positive and easily confirmed by cystoscopic and other data.
2. The X ray findings may be negative and very misleading unless subordinated to other available positive data. Negative cases may suddenly become positive due probably to some change in the composition of the calculi.

3. Apparently positive X ray findings may prove to be erroneous when checked by cystoscopy and other means of diagnosis.

Several case histories are given to illustrate each group.

Woodall considers the X ray to be the most valuable single factor in the diagnosis of urinary calculi and to be of indispensable service when used in conjunction with a carefully taken history and an exhaustive study of the clinical aspects of the case. Used alone however without proper confirmation by such means as mentioned it may lead to serious error almost as often as it would furnish a correct diagnosis.

DAVID K. B. W.

Kelly H A., and Neill W.: Cauterization and
Fulguration of Bladder Tumors. *J. Am. A. S.*
1 19 61 72

The author reports two cases in which cauterization and fulguration were done for bladder tumors.

The first case a female aged 41 had been twice operated upon for papilloma of the bladder five and four years previous, respectively. Two years previous cystoscopy had revealed an ulceration 26 mm in diameter on the posterior wall. There was a similar area on the vertex 18 mm in diameter. Repeated fulgurations covering a period of eighteen months cleared up numerous tumor masses. At present the bladder is normal except for two small recurrent areas about 4 and 2 mm in diameter about the right ureteral orifice.

In the second case a female aged 38 the cystoscopy revealed a large papilloma attached to and filling the anterior surface of the bladder. Cystoscopy showed a growth 1.5 cm in diameter attached to the posterior wall and three large cauliflower growths on the anterior wall protruding into the urethra and including the left ureteral orifice. Nine tumors in all were removed. There was a recurrence two years later the size of a cherry near the left ureteral orifice but after fulguration there was no recurrence.

The author advocates the use of the Kelly's advantage being that it facilitates seeing and treating the pedicle at the tumor thereby shortening the period of treatment. There are two slightly diverging needles for fulguration. With the open type the curved little handle platinum knife is used. It is hooked around the pedicle and when heat is brought to bear through the pedicle.

Freund H. Experience with Mikka Operation
for Ectopia of the Bladder. *Urology*
1961 18 104

In a very comprehensive paper the author reviews a number of original operations for ectopia of the bladder and their merits and demerits. The author states that the Mikka operation is the most reliable and has the advantage of these procedures in that it is essentially an open operation and is not under the handling group of the ectopia. In the Mikka operation the bladder is brought into the normal position and the pedicle is removed. In the Mikka operation the peritoneum is not torn and the bladder is not damaged. In the Mikka operation the bladder is not damaged. In the Mikka operation the bladder is not damaged.

The technique of the Mikka operation is described especially the Mikka operation. The operation consists essentially in utilizing the cecum as a bladder and the appendix as a ureter. The modifications which have been suggested to avoid an ascending infection are referred to. The Mikka method including the author's case.

The only serious obstacles which might prevent the Mikka operation from being carried out are (1) the fact that the appendix may have been removed previously or (2) in cases where the appendix as the result of inflammatory processes may have become so altered as to be valueless. Furthermore (3) the cecum may be fixed normally or by inflammatory adhesions. Freund describes some means of obviating these complications. Against the disadvantages there are numerous decided advantages.

In summarizing his experience Freund concludes: (1) Age should be considered one should not operate on a child under five without serious reason. (2) A period of from six to eight weeks should elapse between the two steps of the operation (1) the preparation of the cecum and appendix and (2) the removal of the exstrophied bladder. (3) Ureteral catheterization and analysis of the specimens prior to operation is important. (4) If pyelonephritis of both sides already exists, operation is not advised. Although in several cases the operation has been a failure yet Freund is of the opinion that this is due to the fact that it was not carried out properly.

operator, but that in these cases there were two or three different operators. He further thinks that the results obtained in the cured cases are such as to lead to the belief that the Makkas operation is the operation of choice in bladder ectopia.

W. A. BRENZ

MacKenzie, D. W.: Double Urethra with Operation: Review of Literature. *Surg. Gynec. & Obst.* 9 6, xiv, 344.

The case reported from the genito-urinary service of the Bellevue Hospital was that of a young man 6 years of age who was admitted to the service in November 1904.

The patient had been troubled with enuresis nocturna at times since a child had always passed urine from two openings, one in the normal position on the glans penis and one in the frenum. About 1903 a small lump appeared on the center of the ventral surface of the penis. It was cut down upon and a stone one-half inch in diameter removed from the urethra. The sinus still remained. About six months later a perineal section was performed. This opening also refused to close.

Physical examination showed a well-developed healthy young man 5 feet 10 inches in height weighing 150 pounds. Urinary meatus normal in size and position. Sinuses, three in number: one at the frenum, one about 1.5 inches from the frenum on the ventral surface of the penis, and one in the perineum.

Rectal examination showed no abnormalities. X-ray of the urinary tract was negative for stone. Cystoscopic examination revealed a normal bladder with a small sacule into which the right ureter opened. The phenolsulphophthalein output was normal.

Exploration with probes and sounds revealed the existence of a urethra apparently normal except for a slight stricture in the bulb admitting a 6 F. sound. Of the three fistulae the posterior perineal one opened into the membranous urethra just behind the stricture. The other two, the frenum and near the scrotum, opened into a common passage which readily took a 16 F. sound and entered the urethra in the bulb just in front of the stricture.

The perineal sinus was excised and its opening to the membranous urethra closed. The subperineal canal was slit from the frenum to the bulb. It was found to be lined with normal mucous membrane and surrounded with its companion urethra by a common corpus spongiosum. It was extirpated completely from the bulb forward. The wound healed by primary intention, and the patient left the hospital passing all his urine through the normal passage.

The male urethra originates from two genetically distinct portions of the embryo, the prostatic and membranous portions resulting from therogenital sinus, while the remaining portion originates at a later period from the folds of the genital ridge or tubercle.

There are two important points to be settled according to Lebrun (1): Is the abnormal canal a urethra or merely some diverticular or canalicular excretory formation? (2) Granted it is a true urethra, how is its formation to be explained?

MacKenzie's conclusions after studying a large number of cases are briefly as follows:

The occurrence of more or less complete duplication of the male urethra, involving the canal from the bulb to the meatus, cannot be doubted, as a large number of well-authenticated instances of several degrees of the anomaly have been recorded. Accessory canals have been described as being about equal in size to the normal urethra and freely communicating with it in the bulb as in Meisels and the author's case. In other cases one passage was smaller than the fellow with which it connected in the bulb-de-sac. Perfectly authentic cases of accessory urethras extending to the bladder have also been reported.

The pathogenesis of the urethral duplication meets with difficulties. A number of explanations have been suggested, the most probable theory referring to the formation of double urethra to anomalies of the epibulbar urethral tract in the embryo.

GENITAL ORGANS

Smith, E. O.: Anatomy and Pathology of Seminal Vesicles. *U. S. Nat. Case Rep.* 91/70.

The author's report is based on a study of large amount of post-mortem material and out many points of practical value to the genito-urinary surgeon.

In his series Smith found the greatest variation in size and position of the vesicles and that that a great difference from the midline varies in different individuals and in the same individual according to the degree of distention of the bladder. Most of the vesicles, their upper pole overlap the ureter when it enters the bladder; it thus follows that bronchitis inflammation of the vesicles at this point may constitute the ureter, make ureteral catheterization difficult or impossible and by back pressure lower the resistance of the kidney to infection.

The main blood supply of the vesicle enters at the upper and lower poles, consequently careful ligation should be done at these points in removing the vesicle. The peritoneum occasionally was found to extend well down onto the vesicle and the dissection of the peritoneum at this point should be borne in mind in operating in this vicinity.

From the clinical standpoint the most important feature of the vesicle examined by Smith was the presence of multiple sharp angulations in the tubule offering very poor natural drainage. Thus shows that massage of the vesicles to be effective should void trauma and that satisfactory surgical drainage can only be secured by multiple incisions. In seeking for source of focal infections the vesicle should never be overlooked.

Calculi were not found in any of the vesicles examined by the author and from his experience he does not believe that because a vesicle is nodular it is necessarily tuberculous. H. L. SAXTORPH

Plaggemeier H. W. Tuberculosis of the Seminal Vesical and Epididymis. *L. A. C. C. T. R.* 1916 34

Tuberculous infection in the genito-urinary tract is as a rule secondary to a focus elsewhere in the body usually in the lungs intestines or bones. Primary tuberculosis of the genital tract has been demonstrated by a number of observers.

Guiley in 183 cases of urogenital tuberculosis found 10 cases involving the prostate and seminal vesicles alone. Saxtorph in a series of 70 cases noted 9 such occurrences. Walker found that the disease was stated to be primary in genito-urinary organs in 52 out of 144 cases but he found in experimental infections that the lungs were nearly always involved and showed the most advanced process.

Generally speaking genital tuberculosis is rare before the fourth month the percentage increasing to a maximum in the third and fourth decade.

In early life both sides are often affected but after 12 the majority of cases are unilateral. In Barney's series of 153 cases of epididymal tuberculosis 35 per cent were right 35 per cent left and 30 per cent bilateral.

The great mass of evidence points to the epididymis as the most common seat of primary infection in the genital tract. Cabot says: We should recognize that urinary tuberculosis is primary in the kidney and genital tuberculosis primary in the epididymis. Walker found in 270 cases that the kidney was first involved in 184 the epididymis in 80 the prostate in 6 and the seminal vesicles in 1. Keyes holds that the weight of evidence goes to show that in many if not all cases the prostate or vesicle is tuberculous before the epididymis becomes so. There is much authentic evidence that the epididymis is in most cases affected first.

Whether the normal seminal vesicle can harbor the cast-off tubercle bacilli without being affected or whether its secretion has a deleterious influence upon these organisms is as yet an unsolved problem.

Considering the rarity of primary infection of the seminal vesicle and the developmental analogy of the seminal vesicle and the urinary bladder the method of attack upon the kidney in bladder tuberculosis suggests the same rule in the vesicles and epididymis.

Much argument and many experiments have been put forth to prove extension of infection in each direction via the vas some holding that extension can take place only in the direction of the current and others that a reserved prostatitis is produced by irritation. Ascension by the subperitoneal lymphatics and the blood stream helps to explain the passage of the disease upward without general involvement of the vas. Ascension seems to be the rule descension the exception.

When tuberculosis involves the epididymis above epididymectomy should be performed. If both epididymes are involved double epididymectomy is indicated. Masculinity is not impaired and sterility has usually already taken place.

It is questionable if or whenotomy ever is indicated. When both epididymes and testes are involved it is better to incise and drain. The removal of a massively involved vas is advisable at all is best done by the high operation of Cabot. Removal of the epididymis and contiguous portion of the vas has had a signal effect on the process in the vesicles, the infection receding and the vesicles becoming fibrous.

If the process is confined to the vesicle vesiculectomy as advocated by Young is a splendid operation but if the prostate also is involved it should not be performed.

The prognosis of primary tuberculosis of the genitalia in children is usually good there seeming to be a limitation of tubercular processes in all organs in children except the meninges. In later life the tendency to wider involvement is a strong argument for radical operation.

Hygienic and climatic treatment both pre and post-operative is of importance. The author favors the Corbus idea of active immunization before operation.

The conclusions reached in the report of the Massachusetts General Hospital is that until ten years has elapsed no patient can be said to be cured of tuberculosis.

In conclusion genital tuberculosis in the male is a grave affection and except in the case of children operation affords the best means of cure.

The primary focus being removed the survival of the patient depends on the ability of his body to immunize itself against the disease. H. G. FLUKE.

Staley R. W. Treatment of Non-tuberculous Inflammations of the Seminal Duct. *L. A. C. C. T. R.* 1916 31

Surgical treatment of acute epididymitis has received considerable attention in recent years.

Epididymotomy is a simple operation and can be done in the office under local anesthesia. Pain is relieved promptly and resolution takes place more rapidly than by the expectant plan of treatment. Mild cases usually resolve fairly promptly under palliative treatment. The more severe cases justify epididymotomy. Relapsing epididymitis not dependent upon prostatic seminal vesicles or posterior urethral infection are most successfully treated by total extirpation of the affected epididymis.

Acute deferentitis usually yields to palliative treatment and rarely demands surgery except when abscess formation takes place in which case drainage should promptly be instituted.

The inaccessibility of the seminal vesicles and prostate has prevented more frequent use of surgical measures in acute conditions of these organs.

On this account palliative measures must suffice in the milder cases, and surgery be reserved for cases of well-defined abscess. Fuller incision or that of Young and Squer will be necessary to reach the vesicles, while a slight modification of lateral lithotomy will be sufficient in the case of prostatic abscess.

Non-operative treatment of acute prostatitis and vesiculitis includes rest in bed, application of heat by means of the psychrophore, restricted diet, antipyretic. All urethral manipulations should be omitted except catheterization when retention occurs. After acute symptoms subside massage is indicated and in the declining stage dilatations of the posterior urethra are of definite value.

Irrigations of the vas, ampulla, and vesicle with argyrol or protargol by Hefield a method is expressed in those cases where much debris is expressed by massage. In perivesiculitis with impotence not improved by massage or irrigations through the vas, a carefully performed vesiculectomy sometimes will restore the sexual function.

Gonorrheal arthritis is relieved in many instances by non-surgical measures, but vesiculectomy or vesiculectomy may be necessary for permanent relief in some cases. Vaccines, bacterial derivatives, and phytocogens have been generally disappointing.

His conclusions are Epididymotomy represents a decided advance in the treatment of acute epididymitis. Dilatation, massage, and irrigation will benefit and control the majority of cases of prostatic vesiculitis. Irrigation of the vesicle through the vas in properly selected cases is curative. Vaccines have some brilliant successes in their credit, and should still have a place in the treatment of these disorders.

H. G. HARRIS.

Silverberg, M. The Prognosis of Prostatitis. *Calif St J Med* 96 14 60.

There are two methods of determining the condition of the prostatic gland: (1) its palpation through the rectum and (2) the gross and microscopic examination of the fluid expressed from the gland. He states that the palpation of the diseased gland may be misleading in that it may be perfectly smooth and of uniform consistency but is usually slightly more sensitive to touch than the normal prostate. Irregularities in the size and shape of the gland are relatively common and are hard to interpret. In the microscopic examination of the expressed secretion the presence or absence of pus cells and their relation to the number of lecithin bodies present should be noted. These findings are subject to the following errors: (1) the distribution of the pathological elements may be uneven and the material used in the examination may be from the normal portion of the gland likewise the marked involvement of a small focus may furnish enough pus to diffuse throughout the entire specimen and the error would be made of diagnosing a diffuse disease of the gland whereas in reality there is

present only a small focus of disease. The third factor in determining the prognosis is the reaction of the patient to the various treatments.

The author states that these conditions sometimes clear up without treatment but usually do not. Most of the cases persist with marked obstinacy. He states that after a given method of treatment has been used for a few weeks if the patient does not improve the method should be changed either in whole or in part and this plan should be persisted in until a method suitable for that particular case is obtained. The author summarizes as follows:

It is desirable that prostatitis be cured in every case but treatment frequently fails or is otherwise unsatisfactory.

The outlook is an important matter to the individual as well as from the standpoint of social hygiene prophylaxis.

3. The probable issue is suggested by the history, clinical findings, and by closely following the effects of treatment.

4. There is really no scientific method of establishing prognosis, though bacteriology may avail here.

5. The duration of treatment is uncertain.

V. D. LEVINE 1847

McCarthy, J. P. Some Features of Importance in the Diagnosis and Prognosis of Urogenital Tuberculosis. *Surg Gyn & Obst* 96 31 330.

The author calls attention to the importance in urogenital tuberculosis, of investigating the deep urethra as well as the bladder. He comments on the frequency (hitherto insufficiently emphasized) of the associated involvement of the reticular structures even in the presence of unilateral renal tuberculosis.

Attention is also called to the fallacy of operative procedure such as epididymectomy etc without the most careful inspection of the posterior urethra.

The author feels that while it is generally recognized by urological surgeons that operative intervention such as nephrectomy etc for tuberculosis should be regarded merely as the preliminary step in the treatment of a constitutionally tuberculous subject, altogether too little emphasis is accorded this fact in operative clinics as well as the hospital care of such cases.

Finally he emphasizes the supreme importance of universal take care of the surgical tuberculous, non-operative and post-operative subject, from the economic and humanitarian standpoint.

MISCELLANEOUS

Hanzlik, P. J. Hexamethylenamine as a Urat Solvent and Diuretic, and Its Effect on the Reaction of Urine. *J Lab & Clin Med* 96 13

The author exhaustively reviews the literature in order to find the truth about the alleged urate and uric acid solvent properties of hexamethylenamine.

e. The chemistry and behavior of various so-
lved urate solvents indicate only very slight
degrees of success under the conditions existing in
the body.

Urate or uric acid solubility depends largely on the
free of reaction (hydrogen ion concentration)
the concentration of fluids and there is no
evidence to show that hexamethylenamine has
any particular influence in this respect.

Recent and reliable evidence shows definitely
that therapeutic doses of the drug impart to the
urine no demonstrable uric acid or urate solvent
properties. Excessive doses impart only slight and
clinically negligible solvent effects. A greater
effect would be obtained at a much lower cost
than any of the common alkaline diuretics.

There is no evidence that hexamethylenamine can
dissolve urate calculi.

No substance has yet been discovered which
could form either soluble or easily oxidizable com-
pounds with uric acid, under the conditions obtain-
ing in the body.

F. E. C. ARDRE.

Rebel, A. J.: Genito-Urinary Symptoms Arising
from Anal Rectal and Colonic Diseases, and
Vice Versa. *J. Am. Med. Ass.* 96: 171, 1908.

Iterative conditions in and about the anal region
such as fissures, chancres, chancroids and perianal
hemas are reflexly the cause of frequent and pain-
ful micturition. In acute proctitis or acute dysen-

tery and in the presence of inflamed and ulcerated
hemorrhoids there is sometimes reflex dysuria and
vesical tenesmus due solely to an irritable rectal
condition. Cancer of the rectum is usually so in-
sidious in its growth that an anuria may be one of the
first symptoms of the disease. A syphilitic stricture
of the rectum is also apt to be quite insidious in its
formation and may give rise to scarcely any rectal
symptoms even though it has developed a consider-
able degree of obstruction of the bowel.

Abnormalities in the urine resulting from colonic
conditions solely are occasionally met with. Trans-
parietal infection through the lymphatics from the
intestine may be the cause of a cystitis. An en-
largement of the inguinal glands occurs with chancre
of the anus. Urethral stricture, polypsi in the
urethra especially of the deep urethra or its adnexa,
phimosis, stones in the bladder, gonorrhea in women,
and enlargement of the prostate gland are some of
the more common reflex causes of anal itching. On
the other hand, the author states that he has seen a
very severe scrotal and perineal pruritus caused by
leucorrhea entirely within the anal canal.

Neoplastic growths of the bladder, prostate and
seminal vesicles may give rise to rectal symptoms
such as are common in the early stages of rectal
cancer. In consequence of abscess formation from
disease or injury to the genito-urinary tract a
fistulous tract opening into the rectum is very
liable to result.

EAR

Verhoeff, F. H. Rosacea Keratitis and Certain Other Forms of Marginal Keratitis, Neuropathic in Origin; Treatment by Pericorneal Neurotomy. *Arch. Ophth.*, 9 6 xl 144.

Not generally known is the fact that with acute coryza and gastro-intestinal disturbances, herpetic lesions limited to the periphery of the cornea and of a highly distinctive character may occur.

The author contends that as they are uniformly located 1.5 mm. from the limbus this shows that they occur at the terminations of the conjunctival nerves in the cornea, and lesions situated 3 or 4 mm. from the limbus are explained by assuming that some nerve branches extend unusually far.

Since it is generally accepted that facial herpes is neuropathic in origin, it is regarded as altogether probable that these peripheral corneal lesions are likewise so, and the author's explanation of neuropathic keratitis in general is that impulses from the affected ganglion cells pass backward along the ordinary sensory nerves to the nerve terminations in the cornea where they produce by electrolytic dissociation, toxic substances injurious to the tissues.

Rosacea keratitis is also regarded as a form of neuropathic keratitis, and acting on the above theory the author does a partial peritomy to interrupt the injurious impulses, with the result that in fifteen cases operated on during the past year he has secured prompt healing in all, with no recurrences.

Rosacea of the skin, being regarded as an angioneurotic condition due to some abnormal constituent of the blood, he correlates with the corneal lesions by assuming that the same deleterious agent acts on the ciliary ganglion and through this on the skin and cornea. S. S. HOWE.

Dehobues, T. L. Treatment of Gonococcal Conjunctivitis by Autogonococcal Serum (Tratamiento de la conjuntivitis blenorragica por el suero antigonococcal). *Rev. d. med. y cir. de la U. de* 9 6 xli 99.

The author reports 8 cases successfully treated. The first hypodermic injection of the serum consisted of .ccm. Subsequent injections of .3 ccm. were made every three or four days. After the fifteenth day of treatment no gonococci were found in the secretions. Corneal ulceration was found in one case, but was slight and yielded to special treatment. There were no phenomena of anaphylaxis and no nervous symptoms.

W. A. BREYER.

Smith, S. M. Aural Complications of Influenza. *Therap. Gaz.* 9 6 xl, 65.

Otitic influenza like other inflammatory changes due to the bacillus of influenza is distinguished by the intensity, rapidity and virulence of action frequently involving the mastoid and other adjacent structures, with absence of the usual symptoms. The initial observable inflammatory process is a severe myringitis, hemorrhagic in character with spontaneous rupture of the membrana tympani in forty-eight hours. Early free incision of the membrana tympani with rest and general eliminative treatment are the best prophylactic measures.

ELLEN J. PATTERSON.

Packard, F. R. Report of a Case of Acute Mastoiditis, with Influential Meningitis; Treatment by Operation on the Mastoid and Anti-Influenza Serum. *T. Am. Otol. Soc.* Washington 9 6 xl v.

The patient a young girl eleven years old, following severe chills developed what was apparently a grippy attack and an acute otitis media in her right ear. The author incised the membrana tympani and evacuated some pus and the next day she had distinct symptoms of a mastoid involvement, accompanied by some ataxia, marked Kernig sign, photophobia and muscular rigidity of the neck. The mastoid was opened and at the same time lumbar puncture was performed. The fluid withdrawn from the spinal column showed an influenzal bacilli. Fletner anti-influenza serum was injected into the spinal column. Several such injections, each of which was followed by marked improvement in the patient's condition, were used in the course of the week subsequent to the mastoid operation and the development of the meningeal symptoms. The child's mastoid wound did well, the meningeal symptoms practically subsided and marked drowsiness developed with a recurrence of the symptoms of meningeal irritation. The diagnosis of abscess of the temporosphenoidal lobe was made and the cranium opened and pus evacuated. The child when made an uninterrupted recovery.

Dench, E. B. Acute Mastoiditis with Unusual Symptoms Indicative of Intracranial Involvement; Operation; Recovery. *T. Am. Otol. Soc.*, Washington 9 6 May.

The patient, a young woman aged 7 was operated upon for mastoiditis on the eighth day after the inception of an acute otitis media. The

mastoiditis was found to be of the hemorrhagic variety. Convalescence was slow and six weeks after the operation the patient was again admitted to the hospital suffering from severe headache general neurathenic symptoms and mental depression. At this time there appeared also an abducent paralysis upon the affected side. There was no evidence of any labyrinthine involvement and no aphasia. The spinal fluid was negative and the ophthalmoscopic examination showed each ocular fundus normal.

On account of the severe headache a large area of dura was exposed in the middle cranial fossa and the dura stripped up from the floor of the middle fossa as far as the apex of the petrous pyramid. No extradural collection of pus was found and no collection of pus was found in the old mastoid. The patient made a complete recovery. The headache immediately disappeared and the abducent paralysis disappeared. A rubber tube drain had been inserted deep in the middle cranial fossa at this operation. Three days after the operation swelling of each optic papilla was noted—more marked upon the operated side. The rubber tube drain was removed and the patient rapidly disappeared.

While the case presents many of the symptoms first described by Gradenigo it differs from them in that in these cases some purulent focus has usually been found at the time of operation, the presence of which explained the symptoms. In this particular case no such focus was found. It seems probable to the author that the cause of the unusual symptoms was a low grade of inflammation spreading along the dura to the apex of the petrous pyramid as an area of dura in the middle fossa was exposed at the time of the mastoid operation. This meningeal inflammation probably caused a certain amount of pressure upon the gasserian ganglion and also upon the sixth nerve causing the severe neuralgic pain in the head and the paralysis of the sixth nerve.

Dench E. B. *Obscure Cases of Mastoid Involvement*. *A. J. S. J. p. 100, 1915.*

This report does not deal with cases where the diagnosis is so evident that it can be made by a glance at the patient but rather with those cases in which the development of the inflammatory process is so insidious and the symptoms so slight that a diagnosis is made with the greatest difficulty.

The author reports several cases in which the middle-ear condition had cleared up or was rapidly clearing up but in which the inflammatory process in the mastoid was rapidly progressing as was demonstrated by the operation. From such cases the author draws the conclusion that the actual cessation of discharge is no absolute indication that the mastoid is healthy. Such being the case the

author attempts to show how one can tell in a given case of a late aural suppuration that there will probably be serious mastoid involvement or how one can tell in a given case that any involvement has entirely disappeared when the middle ear has completely recovered.

The following diagnostic signs are mentioned:
1. As to the site of the inflammatory process the author states that inflammations confined to the lower part of the tympanic cavity are much less liable to be followed by serious mastoid infection than cases in which the upper part of the cavity is involved.

As to the duration of the discharge the author believes that middle ear involvement which does not resolve entirely at the end of two weeks is one of mastoid involvement sufficiently extensive to demand at least exploratory operation.

Concerning tenderness on pressure over the mastoid the author states that tenderness at the beginning does not mean much but tenderness after the fourth or fifth day is of great significance and he adds that tenderness over the antrum is of more significance than tenderness over the tip.

The nature of the discharge is of importance. A streptococcus infection is more likely to result in mastoid infection requiring operation than is a staphylococcus infection.

The sign upon which the author places most reliance is a narrowing of the external auditory meatus near the drum.

Another important nasal sign is an actual shortening of the external meatus a condition in which the entire drum membrane appears nearer to the entrance of the canal than under normal conditions.

The above signs acquire additional importance where the opposite canal is normal in caliber and length. Concerning the swelling of the canal caused by furunculosis the author notes that this narrowing is more superficial than the narrowing due to mastoid involvement. When in doubt the author opens the mastoid.

8. Roentgenograms are mentioned as of great assistance.

9. The general symptoms mentioned as of diagnostic importance are persistent headache and sleeplessness.

As to temperature and the differential blood count the author is not much influenced by their absence.

In closing the author cites a case illustrative of the diagnostic importance of recurring attacks of acute otitis in pointing to mastoid involvement. The author feels that this sign needs more careful consideration as he argues that these attacks would not recur unless a purulent focus existed somewhere in the deeper structures of the middle ear.

ORR M. ROTT

SURGERY OF THE NOSE THROAT AND MOUTH

NOSE

Veney, C. A. The Diagnosis and Treatment of Inflammatory Affections of the Nasal Accessory Sinuses. *Northwest Med.* 9 6, xv 73.

After alluding to the importance of sinus disease as a causative factor in many gastro-intestinal affections, as well as to the sinus affecting other portions of the body the author considers the sinuses collectively and mentions the well known symptoms of headache, tenderness, nasal obstruction and discharge, dizziness and vertigo as well as prostrata and neurasthenic symptoms in general.

As to diagnostic methods the author mentions transillumination as one of the best aids. Other aids, as the pharyngoscope, X-ray puncturing and irrigation of the antrum and the application of suction to the nose are favorably commented upon.

As to treatment of the acute condition, the author mentions the necessity of securing adequate drainage and ventilation, and this is secured by shrinking the nasal mucosa by the application of weak solution of cocaine instead of adrenalin, as the latter is apt to produce a secondary swollen condition greater than was primarily present. After the membrane has been shrunk, the author describes with a normal saline solution or with mild alkaline solution followed by an application of a 25 per cent solution of argyrol and a oil spray. The patient is instructed to douche his nose freely with hot normal saline solution every hour or two and to take deep inhalations every two or three hours of compound tincture of benzoin and menthol, four ounces of the former and one drachm of the latter, two table-spoonsful being used in one-half pint of boiling water. General treatment with calomel, saline aspirin and phenacetin is recommended.

The indication for the treatment of the chronic cases is likewise drainage whether obtained by the correction of obstructing septal deformities or by petrosphenoidal turbinates. After drainage has been obtained irrigations are advised and when these prove futile operative interference is justified. The author has little faith in the beneficial influence of autogenous vaccines. Otto M. Rott

Gatwood, W. E. Carcinomata of the Nasopharynx. *J Am Med Ass.* 9 4, 141 499

From a review of the literature the following points are gleaned:

Carcinomata of the nasopharynx are characterized by a rather long latent period and most of them originate in the vault or on the posterior wall. They are more prone to ulcerate and lead to epistaxis than other malignant tumors of this region. Extension

may take place in four ways: (1) by the inferior or pharyngeal route (2) by lateral prolongation (3) by the anterior or nasal route (4) by the posterior or cranial route.

Carcinomata of the nasopharynx very rarely produce visceral metastases but as a rule they give earlier adenopathy than other tumors of this region. About 60 per cent of the carcinomata in this organ occur in individuals between 4 and 60 years of age but they have been noticed in children as young as 3, 6 and 10 years of age. Otto M. Rott

Molina De Saut Remo A. H. Migraine. *N Y J* 10 6 498

Migraine is a nasal organ lesion. It is produced upon the upper part of the nasal cavity by swelling of the mucosa of the middle turbinate impeding gas to a certain high position of the nasal septum. It is distinct from the local circulation and exists in the paranasal sinuses. The treatment indicated is thorough complete submucous resection of the nasal septum with care to avoid perforation. J. P. Rarue

Callison J. G. Papilloma of the Nose. *La J* 10 6 1 53

The (short) report of a case of true papillary fibroid in a colored woman aged 4, who had been of 10 years duration and previously operated upon. When first seen by the author the left nostril was filled with a growth which presented dry, dark, and wrinkled appearance. The nasal cavity was so completely filled with the growth that a snare could not be passed round it much less the site of origin determined. To effect removal, the growth was removed by the use of the low forceps and thus its origin from the lower border and external surface of the middle turbinate was determined. Microscopical examination revealed the nature of the growth. Of particular interest was the appearance of the epithelial cells which retained their columnar character even to the surface. Other features of interest in the histological sections were the intense purulent infiltration of the epithelium and its absence from the connective-tissue stroma, the pus-cells in places collecting in to groups and forming cystlike spaces.

The growth had a tendency to recur so in order to eradicate as thoroughly possible the base of origin and hence to prevent the danger of malignant change the author intends performing a Caldwell-Luc operation, followed by a radical Moshé operation. After this careful cauterization of the tissues with a chemical substance such as trichloroacetic acid will be made. Otto M. Rott

Dabney V: Deaths Attributable to Intranasal Operations and Other Instrumentation *Surg Gynec & Obst* 916 xiii 324.

Deaths following cauterization of the nasal mucosa diagnostic puncture and irrigation or mere perforation of the antrum of Highmore are not to be expected but it is surprising that more deaths do not follow probing of sinuses resecting the septum or removing the middle turbinate in part or in its entirety. Polyp removal is more dangerous than believed for the same reasons as they indicate deep-seated disease and periostitis. Infection is accounted for by the virulence of the bacteria opening wide spaces for absorption of toxins trauma and continuity of tissue. The lymphatics rarely transmit infection which travels by the blood stream or by actual continuity as a rule. Cocaine was not responsible for any deaths though adrenalin was. Numerous authors are cited to show that adrenalin with light chloroform anesthesia is peculiarly dangerous even with light etherization it is thought risky. Deaths due to adrenalin were 4 to hæmorrhage 3 to packing nose for epistaxis 1 to puncture or injection of air or fluids into the antrum of Highmore 10 to probing and irrigating frontal sinus 3 to polyp removal 9 to ethmoid curettement 4 to turbinate operations 9.

In the author's personal case following resection of the lower edge of the inferior turbinate of one side the patient never recovered consciousness from the ether and died in three days from a cerebrospinal meningitis. It was probably a case of latent meningitis before operation. One death was due to exploration of the sphenoidal sinus 9 deaths resulted from resection of the septum. Deaths from invasion of the antrum of Highmore are due to reflex irritation of the vagus through the irritation of the second branch of the trigeminal which supplies the interior of the antrum. It is demonstrable that the interior of the nose is a zone of considerable danger for even the slightest instrumental interference and that adrenalin combined with a general anæsthetic especially when used for operative assistance is not to be lightly employed.

Blackburn W J: Submucous Resection of the Nasal Septum *J Ophth Otol Laryng* 91 xvi 8.

The universally gratifying results in a series of over a hundred operations for submucous resection of the septum leads the author to conclude that a deviated septum may be the underlying cause of many diseases of the nose throat and ear. By obstructing the nasal respiration the resistance of the tissues of the nose and throat are lowered and patients with deviated septa frequently develop ethmoiditis sinusitis suppurative otitis media mastoiditis with brain abscess laryngitis bronchitis chronic head deafness tinnitus aurium asthma hay fever or other neurotic conditions.

LITERATURE.

Sludce G: A Galvanocautery Operation for the Lower Turbinate *Laryngol* 916 xxi 66.

The pathological condition for which this technique is recommended is general swelling (hypertrophy or intumescence) of the soft parts covering the lower turbinates the clinical condition being for the most part nasal obstruction with or without eustachian tube irritation.

To the anteroposterior incision usually made in cauterization of the inferior turbinate the author has added (1) a straight one descending in front at an angle of 45 degrees from a point a little above the line of attachment of the body of the turbinate to meet tangent the anterior limit of the anteroposterior incision and then descending below it to the level of the free margin of the vestibule almost to the mucocutaneous junction in the vestibule (2) two curved incisions on the body of the turbinate posteriorly which are made operating from the postnasal space by means of a specially curved cautery tip introduced through the mouth behind the soft palate. One curved incision is made above and one below each beginning 1 to 1.25 cm. in front of the posterior tip and extending backward to meet on the lateral wall just at the tip (3) the tip of the cautery is extended forward to a point which is to be the posterior end of the anteroposterior incision and carried backward over the tip to the junction of the curved incisions or even as far backward as the cartilage of the anterior lip of the mouth of the eustachian tube especially in those cases associated with tubal irritation.

For all this work the author uses an electrode which has no insulation upon it and which consists of the two upper wires which are united by a platinum-iridium tip. This permits the wires to be separated and spread apart as far as 1 cm. if desired which transforms the narrow tip into a V or U shaped end as desired. When this is used on the pull any tissue to be removed can be engaged in this loop and the current turned on, when it acts like a spokeshave.

The author has a definite order of procedure in this work which is as follows.

After anesthetizing the turbinate and soft palate the latter is forcibly drawn forward by the author's self retaining palate retractor. A large warm post nasal glass is used as a tongue depressor. The curved electrode is then introduced cold in a horizontal plane through the mouth into the pharynx. The glass is then slipped back into the postnasal position and the tip of the cautery is brought forward into the affected nostril put in place and the current turned on. First the lower curved incision is made near the posterior end of the anteroposterior incision and then the upper curved incision. This completes the work from the postnasal side. From in front the author introduces a straight tip to meet the middle posterior incision and carries this forward until he reaches the anterior end of the incision where he changes the direction of the tip placing it near the anterior tip of the middle tur-

binate, when it is drawn downward and forward to its prescribed lower limit. The tip used is so blunt that if it were once removed from the tissue it would burn itself out.

The author has employed this procedure in more than 1,000 cases extending over a period of seventeen years. Out of this number 3 cases required an anterior packing with Simpson's spatula to control bleeding. In none of the author's snare and scissors operations has the result been so satisfactory as with this method. The author has never seen the permanent drying or crusting mentioned by some men. This method is also applicable to snaring off the posterior end of the inferior turbinate.

Two cases are reported in which deafness, not responding to any of the operations for nasal obstruction, has responded to this method of cauterization especially when the posterior line extended to the anterior tip of the pharyngeal orifice of the eustachian tube.

OTTO M. ROSE

Kellogg, F. B. An Improved Submucous Operation.
J. Ophth. Otol. & Laryngol. 9 6, xiii, 5

The author makes his primary incision from high up in front of the deviation on the convex side down to and half way across the floor. Then elevating the membrane above and below the edge of the ridge until the mucous membrane of the convex side is free except along this edge he inserts the blades of a delicate pair of scissors one above and one below the ridge and trims off the edge of the ridge leaving it attached to the membrane. After elevating the membrane on the concave side he inserts a Bowman's saw under the dissection inside the membrane saws off the projecting spur in the plan of the septum removes the spur with forceps, and packs with strips of spunk.

ELMER J. PATTERSON

THROAT

Hays, H. A Simple Tonsil Operation Under Local Anesthesia. *Med. Rec.* 9 6 Jul 4 9.

Using Schleich infiltration anesthesia the author depresses the tongue firmly and separates the tonsil capsule from the anterior pillar working from below up with his double bladed knife. Then using his modified aneurism needle threaded with stout cord or suture, he threads the cord in the deepest part of the tonsil from below upward ties it and using the cord as a retractor completes the dissection with Hurd tonsil separator or his index finger.

ELMER J. PATTERSON

Shearer T. L. The Question of Age in Tonsillectomy.
J. Ophth. Otol. & Laryngol. 9 6, xiii, 205

Tonsillectomy is indicated in adults under 40 years, when the patient has hypertrophied or diseased tonsils or the tonsils are the focus of infection of pathological conditions remote from the tonsil. It is indicated also in malignant disease of the tonsil irrespective of age followed by radium radiation of the wound.

Tonsillectomy is contra indicated in any adult suffering from arteriosclerosis, and adults over 45 are treated satisfactorily by the electrocautery.

ELMER J. PATTERSON

Friedberg, S. A. Removal of Tonsils and Adenoids in Diphtheria Carriers. *J. Am. M. Ass.* 9 6 Jul, 8

Several instances have been noted in which the local application of kaolin seemed to be without any effect on diphtheria bacilli. In view of the prompt disappearance of the bacilli in these cases after tonsillectomy and removal of adenoids the author makes a brief report of the results.

Six cases are reported five occurring in children. The tonsils were removed after all methods were used to rid the throat of diphtheria. In two days or less the cultures became negative.

In none of these patients did the operation have any different general effects than it has ordinarily. In all of the patients the Schick test gave negative results just before the operation. Six successive negative cultures were required before the patients were discharged.

The results obtained in this series indicate clearly that in persistent carriers it may be necessary to remove the tonsils and adenoid tissue if it is desired to terminate the carrier condition promptly.

The bacteriologic examination should be made with care as it is well known that applications of medicinal agents may destroy the bacilli on the surface while leaving unaffected those in the crypts of the tonsils and the folds of the adenoid tissue.

As to the time the operation should be performed it is perhaps advisable to wait from two to three weeks after the clinical recovery of the patient. In the case of the chronic carrier no time limit is necessary.

EDWARD L. COMELL

MOUTH

Durante, L. Tuberculosis of the Tongue. *A. Surg. Pathol.* 9 6 Jul, 43

In addition to reporting 5 cases of tuberculosis of the tongue, the author gives a very complete bibliography of the literature upon this unusual disease. He has been able to collect about 350 cases, some of which, however, have been recorded without anatomico-clinical details. The reason for the relative infrequency of the lesions on the tongue, an organ which comes in contact with almost all tuberculous infecting material, is due probably to two factors: (1) to the particular structure of the lingual mucosa which resists the direct penetration of the bacillus tuberculosis and (2) to the natural resistance which all striated muscle presents to the lodgment of the bacilli. Almost all of the cases cited occurred between the twentieth and fiftieth year, a condition has been recorded as occurring in infancy, the age in which tuberculous lesions are so common and widespread. From these considerations the author concludes that the tuberculous process in the tongue

is assisted by such lesions as trauma of the mucosa by pipe stems, by carious teeth by toxic glossitis etc., and that as these causes are more frequent in men than in women lingual tuberculosis is to be expected more frequently in men. Statistics bear out this contention as Chvostek reports one man to every four men and Delavan records nine in twenty three.

While theoretically tuberculosis may be localized in the tongue by the blood vessels by the lymphatics by direct infection, or by extension from surrounding organs practically it is impossible to determine the exact method of infection. Many of the cases reported in the literature as primary tuberculosis were not controlled by autopsy so that the term must be accepted in the clinical sense only. The theoretical possibility of a primary tuberculosis of the tongue is practically confirmed by two cases which the author collected in which the patients died from other causes and careful post mortem examination gave no evidence of tuberculous infection in other organs. In the majority of cases the localization was secondary to a tuberculous process elsewhere in the body. From the histologic examination of the tissue removed from the living patients reported by the author and from the statistics collected by him the indications all seem to point to a hematogenous infection as the most common in method of infection of the tongue by tuberculosis.

The anatomical forms of the disease do not represent a distinct anatomical entity but diverse forms of the same evolutionary process depending upon the virulence of the bacilli the local resistance of the tissues, and the systemic resistance of the patient, are found in various cases and in various parts of the tongue in the same case. The beginning is always characterized by new formation of tuberculous nodules which may be localized separately in the dermis of the mucosa or in the lingual parenchyma. From this initial localization of the tuberculous process two clinically different types may originate. The first presents itself initially as a plaque of gray color somewhat elevated above the surrounding mucosa hard to the touch and without inflammatory reaction. It resembles cutaneous lupus and is very often accompanied by lupous lesions of the buccal mucosa of the nose or of the skin of the face. This type is referred to as glossodermatitis tuberculo-fibrosa or should it ulcerate as glossodermatitis tuberculo-ulcerosa. When, on the other hand the parenchyma of the

tongue is primarily affected nodular tuberculosis may result or the lesions may become confluent or disseminated in various regions—disseminated milary tuberculosis of the tongue. The second type in any of its various forms may maintain its individuality for months or years simulating either a neoplastic lesion or the localization of tertiary lues. The typical tuberculous ulcer has irregular margins and is soft and reddened with a soft yellow base. It may appear in any region of the tongue but with more frequency on the margin and the tip. The adenitis which accompanies it is often bilateral and lightly painful to pressure. Usually there is not much difficulty in finding the bacilli in tuberculous glossitis although undiluted case has been reported with the bacilli being found.

The symptoms vary considerably with the stage of evolution of the disease. The initial period is marked with few or no subjective symptoms. When the ulcerative form develops there is abundant irritation and some pain due mostly to the passage of food. The pain may limit the mobility of the tongue. In the ulcerative type which is complicated by secondary infection there is usually painful general adenopathy but in the closed form of lingual tuberculosis it is often absent.

Diagnosis in the early stage of the process presents great difficulty. Mistaken for pythelomatous neoplasms amputations of the tongue with radical removal of the glands of the neck have been done for tuberculous glossitis. Mercurial treatment has been employed in 180 reported cases showing the frequency with which it has been mistaken for tertiary lues. There are no sure criteria of differentiation and it is always well in case of doubt to employ the microscopic examination of the tissue of the lesion. This can usually be done by frozen sections during the operation as was done in each of the cases reported by the author.

The prognosis is favorable when the tuberculosis of the tongue presents itself as a primary and unique lesion. It is generally unfavorable when the lingual lesion is a late localization secondary to a broncho-pulmonary process.

The treatment of election which has been avoided by previous authors has been operative when the tuberculous lesion of the tongue was single and circumscribed. In the multiple and diffuse lesions the treatment recommended has been local with the cautery.

Removal of bullets and other metallic foreign bodies. R. G. P. LAMOND. Bristol Med.-Chir. J. 9 5 xciii, 57.

Three cases of field surgery. G. MATRONOLA. Clin. chir. Milano, 9 6 N.

The principles of treatment and their application to wounds. C. F. M. SAUDY. Brit. M. J. 9 6 i, 367.

Secondary closing of wounds. CARRILL, DENTLEY, and DUMAS. Brit. M. J. 9 6 i, 363. [65]

Physical treatment for disabled soldiers. J. CAMUS. Lancet Lond. 9 6 cxc, 60.

The biologic conception of the curability of infected wounds. E. BERTARELLI. Gazz. d. osp. d. clin. Milano 19 6 lxxvii, 360.

Some elementary rules relative to the treatment of suppurating wounds in war. L. BIGNARD and A. LUMIERE. Rev. de chir. 9 6 xcii, 445. [66]

Sodium hypochlorite in the treatment of septic wounds. F. J. A. DALTO. Brit. M. J. 9 6 i, 366. [66]

The immediate cure of wounds made by hand bombs and grenades. L. DOMINGUE. Clin. chir. Milano, 9 6 N. 14.

Some notes on the treatment of the Turkish wounded from the Vues Canal. F. C. MADDER. Lancet Lond., 9 6 cxc, 63.

The ship surgeon. E. A. JOCKARD. Am. Med. 9 6 xl, 74.

The importance of general principles in military surgery. G. C. TURNER. Brit. M. J. 9 6 i, 40.

The case recording of wounds in war. A. W. SHERK. Clin. J. 9 6 xl, 60.

The rate of mortality in the British Army on years ago. A. CHURTON. Proc. Roy. Soc. Med. 9 6 Sect. History Med. 89.

Snowshoes for transportation of the wounded. Th. Muenchen. med. Wchnsch. 916 p. 30.

Health of armies in peace and war. Lancet, Lond., 9 6 cxc, 57. [66]

Preparations of the naval medical department for battle. A. FARRINGTON. M. Surgeon, 9 6 xcvi, 35.

Work in base hospital. W. RAMON. Brit. M. J. 9 6 i, 372.

War surgery experiences in field hospital. KAPFEN. Berl. klin. Wchnsch. 9 6 xcix, 38.

The American clean up of Serbia. G. A. LURIE. Am. J. Clin. Med. 9 6 xlii, 209.

Surgical Pathology

Some present-day problems in surgery. N. F. FALLOU. Boston M. & S. J. 19 6 cl xiv, 47.

Surgical problems considered from the standpoint of morbidity. E. H. OCHSNER. Illinois M. J. 916 xli, 6.

Operative mortality. L. RAETTL. Gaz. med. de Carcass., 9 6 xciii, 7. [67]

Urticaria and pseudo-appendicitis. L. APERT. Monde méd., 9 6 xvi, 63. [67]

The value of various diagnostic methods for the cerebrospinal fluid. H. NAKAMU. J. Cutan. Dis. 9 6, xciv, 70.

Morphologic alterations of the tube and ovary in the clinically distinct forms of the disease BLUM *Semin. gynec. med.* 1916 viii 39

Unrecognized syphilitic lesion surgically operated as cancer of the local tuberculosis CAULIER *Ann. d. mal. vén. Par.* 1916 vi 153 [67]

Surgery and syphilis. J. H. CAULIER *Illus. M. M. J.* 1916 xix 108

Hospital, Medicolegal and Medical Education

Medical experts in our courts C. F. BECKLEY *Paed. M. J.* 1916 lix 138

Liability for wrong diagnosis and treatment J. Am. M. Ass. 1916 lxxvii 764

Death from having chloroform administered by person neither physician nor trained nurse ROUHLIN *THE STATE [GA.]* 86 S. E. R. 45 J. Am. M. Ass. 1916 lxxvii 836

Breaking stitches and opening of wound not covered by a student in a woman (STOKLEY *THE FIDELITY & CASUALTY CO. OF N. Y. v. R. [ALA.]* 99 So. R. 64) J. Am. M. Ass. 1916 lxxvii 840

Malleable line—its medical and legal significance W. W. C. WYLLIE *South M. J.* 1916 vi 20

Sufficient evidence of malpractice in treatment of fracture WILKINSON *Br. M. J. [Mk.]* 54 N. W. R. 56 J. Am. M. Ass. 1916 lxxvii 836

The duties of medical practitioners in cases of criminal abortion. Brit. M. J. 1916 vi 206 [68]

Röntgen ray plates may be shown in jury cases (LUTTON *S. UTHA EXP. CO. [N. C.]* 86 S. E. R. 64) J. Am. M. Ass. 1916 lxxvii 838

Cephalic surgery S. C. BEACH, *Am. J. Clin. Med.* 1916 viii 36

Some medical and surgical experiences at Miraj Hospital W. J. WANLE and C. E. VAIL *Indian M. Gaz.* 1916 liii 9

GYNECOLOGY

Uterus

Cervical laceration D. I. ROSTER *J. Fla. M. Ass.* 1916 lii 266

Lacerated cervix R. T. G. DWIN *Texas St. J. Med.* 1916 xl 542 [69]

Intermediate trachelorrhaphy as a prophylactic against the pernicious effects sometimes caused by lacerations of the cervix. H. J. BOLDT *Am. J. Obst. & Gyn.* 1916 lxxviii 543

Some essential points in the treatment of carcinoma of the uterine cervix E. W. JONES *J. Lancet.* 1916 xxxvii, 160

The problem of heat as a method of treatment in inoperable uterine carcinoma J. F. PERRY *T. Am. Gynec. Soc. Washington* 1916 May [69]

Adenocarcinoma of the uterus and carcinomatous gallbladder H. J. BOLDT *Am. J. Obst. & Gyn.* 1916 lxxviii 543

A case of fibroid tumor of the uterus complicated by pregnancy myomectomy recovery R. B. HALL *Lancet-Clin.* 1916 cxvii 354

Uterine fibroids J. O. POLAK *Am. J. Obst. & Gyn.* 1916 lxxviii 509

Gangrenous interstitial fibroids L. C. B. LEWIS *Am. J. Obst. & Gyn.* 1916 lxxviii 488

Radium treatment of uterine fibroids J. and J. L. RABSONOFF *Lancet Clin.* 1916 cxvii 6 [70]

The meaning and mechanism of menstruation F. HARRIS *Clin. J.* 1916 xl 25 20

Compensatory (hilarious ectopic) menstruation xenomenia, memmen devil W. H. CONYER *Am. J. Obst. & Gyn.* 1916 lxxviii 38 [70]

Recent results in the X-ray treatment of menorrhagia dysmenorrhoea, and terine myoma S. LANGE *Am. J. Roentgenol.* 1916 lxxvii 7 [71]

Four uteri the seat of chronic inflammation H. J. BOLDT *Am. J. Obst. & Gyn.* 1916 lxxviii 54

Septic uterus L. S. JUDT *Am. J. Obst. & Gyn.* 1916 lxxviii 51

Procedentia uteri in a nullipara J. F. KEENAN *Brit. M. J.* 1916 liii 343

An operation for retrodisplacement of the uterus. A. S. W. C. LUTON *Am. J. Surg.* 1916 cxvii 9 [71]

Surgical treatment of retrodisplacements of the uterus. J. A. HILL *Texas M. J.* 1916 cxvii 354

Clinical sequel of the double uterus in its relation to diagnosis and treatment M. HANDFIELD JONES *Lancet, Lond.* 1916 cxvii 574 [71]

Uterus bicornis unicornis abscess in right cornu amputated in normal pregnancy in left cornu H. ARNOLD *Med. Rec.* 1916 lxxviii 510

Uterine surgery A. M. JUDD *Med. Times*, 1916 xlvii 78

The removal of the troublesome useless uterus. A. E. GALLANT *N. Y. M. J.* 1916 cxvii 485 [72]

Adnexal and Peritubal Conditions

Technique by which conservatism is made possible in diseases of the adnexa P. B. SALANTER *Am. J. Surg.* 1916 cxvii 90

The relation of angiogenesis to ossification based upon the study of five cases of calcification and ossification of the ovary F. M. SCHWARTZ *Bull. Johns Hopkins Hosp.* 1916 cxvii 7 [73]

Infection of ovarian dermoid cyst with typhoid bacillus A. L. O'SHEA *J. Am. M. Ass.* 1916 lxxviii 888 [74]

Fibrocyst of ovary with a purulent tubo-ovarian cyst on the opposite side H. J. BOLDT *Am. J. Obst. & Gyn.* 1916 lxxviii 54

Twisted ovarian cyst complicated with pregnancy simulating symptoms of renal calculus apparent corroboration by roentgen picture H. N. VENERBERG *Am. J. Obst. & Gyn.* 1916 lxxviii 486 [75]

The end results of resection of the ovaries for microcystic disease J. A. MCGILVER *Am. J. Obst. & Gyn.* 1916 lxxviii 435

Strangulated fallopian tube in ovary and intestine in infant G. ABELLO *J. Am. M. Ass.* 1916 lxxviii 83 [76]

Salpingitis secondary to appendicitis J. E. MOORE *Surg. Gynec. & Obst.* 1916 cxvii 77 [77]

External Genitalia

- Syphilis of the internal genital organs in the female. G. G. LORIMER and H. FARRINGTON. *T. Am. Gynec. Soc.* Washington, p. 6, May. [74]
 Uterovaginal fistula. H. SMITH. *Indian M. Gaz.* 1906, 11, 65.
 A case of pseudobemphrodes, with remarks on abnormal function of the endocrine glands. W. C. QUINBY. *Bull. Johns Hopkins Hosp.* 1906, xvi, 40.
 A case of relaxed sphincter with incontinence of urine cured by the Kelly operation. H. D. FARRIS. *Med. Rec.*, 1906, 1xxix, 538.

Miscellaneous

- Progress in gynecology. S. RUDENBERG. *Boston M. & S. J.* 1906, cxlii, 350.
 Morphine and scopalamine in gynecological surgery. W. F. MONTGOMERY. *Am. J. Obst.* N. Y., 1906, lxxviii, 439.
 Gangrene of the lower extremities after gynecological and obstetrical operations. A. STEIN. *Am. J. Obst.* N. Y., 1906, lxxviii, 517.
 Haemorrhagic pelvic peritonitis, hysterectomy. A. H. HARRISON. *Am. J. Obst.* N. Y., 1906, lxxviii, 533.
 Perineal repair with report of case. B. L. SOLE. *BACHTER, N. Eng. M. J.* 1906, xv, 307.

- Surgical treatment of gonorrhoeal infection with quarantine pack. R. C. C. RY. *Surg. Gynec. & Obst.* 1906, xxi, 28. [77]
 The relation of the mammae gland to nervousness and menstruation. E. B. B. O. J. M. Am. G. 1906, 55.
 Experimental researches on the mechanism of menstruation. H. VICARIO. *Ann. d. gynec. et d. obst.* Par. 1906, xlii, 104.
 Precocious menopause in virgin. A. IAR. *Arch. bras. d. med.* 1906, 387.
 A report of several cases of chorio-epithelioma following vesicular mole. C. LOCKER. *Lancet* Lond. 1906, cxc, 54.
 Borderline between operation and non operation in gynecology and obstetrics. KROVITZ. *Deutsche med. Wchnschr.* 1906, xlii, 435.
 The correlation between the olfactory and genital functions in the human female. J. A. HALL. *N. Y. Med. Press & Circ.* 1906, 61, 95.
 End results of the first 7 operative abdominal operations for pelvic disease in women. Standardization of the surgeon. G. P. LAROC. *Old Dominion J.* 1906, xlii, 60.
 Some remarks regarding useless (therefore) undesirable operations. G. A. VAN LEE. *Arch. mens. d. obst. et de gynec.* 1906, xv, 433. [77]

OBSTETRICS

Pregnancy and Its Complications

- Diagnosis of pregnancy by way of the urine. F. B. KERR. *J. Mo. St. M. Ass.* 1906, xlii.
 A urinary test for pregnancy. F. H. L. and C. H. WALKER. *N. Y. Med. J.* 1906, cxlii, 95.
 A quantitative test for the Abderhalden reaction. L. VAN SLYKE and V. KROGAN-VILCOUR. *Am. J. Obst.* N. Y., 1906, lxxviii, 500. [74]
 A case of ectopic gestation and appendicitis. F. M. NEILL. *Lancet*, Lond., 1906, cxc, 676.
 Ectopic gestation rupture operation recovery. S. GARTER. *Indian M. Gaz.* 1906, 11, 99.
 Ruptured interstitial ectopic pregnancy complicated by a large ovarian cyst. A. H. HARRISON. *Am. J. Obst.* N. Y., 1906, lxxviii, 534.
 Ruptured ectopic pregnancy simulating pelvic infection. A. H. HARRISON. *Am. J. Obst.* N. Y., 1906, lxxviii, 53.
 Extra-uterine pregnancy. A. P. HENDERSON. *Ellingwood Therap.* 1906, 8.
 Ruptured tubal pregnancy. H. M. TORRENTON. *Canad. M. Ass. J.* 1906, vi, 3.
 Interstitial gestation. M. C. W. DORRILL. *Rev. de gynec. et de chir. abdom.* Par. 1906, xlii, 405.
 Eclampsia. D. J. DYAR. *Canad. M. Ass. J.* 1906, vi, 34. [78]
 Eclampsia studies concerning its causes, nature and treatment. H. E. DUNN. *N. Eng. M. Gaz.* 1906, 11, 72. [78]
 Cesarean section. E. FIELD. *J. M. Soc. N. J.* 1906, xlii, 5.
 Vaginal cesarean section. A. STEIN. *Am. J. Obst.* N. Y., 1906, lxxviii, 535.
 Delivery by the natural passages following cesarean

- section report of 10 cases. J. T. WILLIAM. *Am. J. Obst.* N. Y., 1906, lxxviii, 45.
 Cesarean section—overdone. I. A. LEWIS. *Boston M. & S. J.* 1906, cxvii, 434.
 Modern indications for cesarean section. J. T. WILLIAM. *Boston M. & S. J.* 1906, cxvii, 450.
 Indications for the advantages of the high incision in cesarean section. F. H. RAAN. *J. M. St. M. Ass.* 1906, xlii, 76. [79]
 Cesarean section in Pluta. Octage. R. C. B. LL. *Brit. M. J.* 1906, 1, 9. [79]
 Segmental suprasympathetic cesarean section. F. ZARATE. *Semin. med.* 1906, xlii, 263.
 Cesarean section a consideration of indication, technique and time of operating. C. M. GALEX. *Boston M. & S. J.* 1906, cxvii, 44.
 The lower uterine segment its origin and boundaries. E. H. TWISS. *Lancet*, Lond. 1906, cxc, 465. [79]
 Abortion with expulsion of the placenta at the third month, full-term baby at nine months (probable twin pregnancy). H. ARRAVOW. *Med. Rec.* 1906, 1xxix, 530.
 A case of retention of a dead fetus. R. D. CANTANA. *Rev. de med. Barcel.* 1906, xlii, 97.
 Twin pregnancy in horn of bicornuate uterus with retention of the fetuses for twenty years. E. SCOTT and J. FOWLER. *Am. J. Obst.* N. Y., 1906, lxxviii, 570.
 A note on superfetation. A. KUTZ. *J. Tenn. M. J.* 1906, xlii, 304.
 Surgical treatment of placenta previa. E. L. BECK. *J. Arkansas M. Soc.* 1906, xli, 3.
 The prenatal problem and the influence which may or may not affect this period of the child's growth. M. WATZ. *Am. J. Obst.* N. Y., 1906, lxxviii, 416.

A case of meningeal hemorrhage observed in the course of pregnancy and labor followed by recovery. *LABR and BOURRET. Ann de gyn et obst Par* 1916 115.

The systolic blood-pressure in pregnancy observed on five thousand consecutive cases in the pregnant limbs of the Boston Lying in Hospital. *J C LEVIN. J Am M Ass* 1916 1915. [50]

Labor and Its Complications

Labor obstructed by ovarian cyst. *W SALL BURN. Brit M J* 1915 154.

Ovarian cyst obstructing labor. *H VERRAN. W Am J Obst N Y* 1916 1811 53.

Rupture of the uterus sustained during unrecognized until prolapse of the testicles ten eight hours later. *T H CHERRY. Med Rec* 1916 1815 56.

Chlorazene

(TRADE MARK)

(Para toluene sodium sulphochloramide)

DAKIN'S NEW ANTISEPTIC

This interesting antiseptic was introduced by Dr. H. D. Dakin, who was associated with Dr. Alexis Carrel at the temporary hospital No. 21 and the laboratories of the Rockefeller Foundation in Compiegne, France. Reports show this antiseptic to be used with great success in the military hospitals of Europe. (See British Medical Journal of January 29, 1916, Reprints on request.)

CHLORAZENE promises to be of great value in surgical practice. Read the following statements and it will be understood why this new antiseptic is regarded so favorably in Europe.

It is a white crystalline substance freely soluble in water.

It is extremely stable, i. e., in solid form it may be preserved indefinitely while aqueous solutions keep for relatively long time without marked decomposition.

It has no corrosive action, even in concentrated solutions. It neither precipitates nor coagulates proteins such as blood serum.

It is virtually non-toxic. Rabbits and guinea-pigs tolerate subcutaneous doses of grains 1 kilo (2 1/2 pounds) of body weight without symptoms except moderate local reaction. However it should not be used internally.

Its antiseptic action is intense. It is many times as antiseptic as phenol (equaling sodium hypochlorite) in this respect (molecule for molecule it is four times as germicidal as hypochlorite) while, according to Dakin, it is much less irritating than the latter substance, and may be used safely at concentration five to ten times as great.

It can be used freely and safely as an irrigant of infected wounds of deep lacerations, in treating compound fractures and in injuries and diseases of the mouth, uterus, bladder and ureters. Here most antiseptics cannot be employed in effective concentration on account of their toxic or caustic action.

In view of the success which has followed the use of this antiseptic in Europe, The Abbott Laboratories offer it to the medical profession of America under the name **CHLORAZENE-ABBOTT**.

LITERATURE ON REQUEST

Packages and Prices

CHLORAZENE is supplied in 4.4-grain tablets, in bottles of 100 at 60c. 1 pound 2-ounce bottles at 60c. Special packages for hospital use. Prices on request.

—but no
Pulmotor
was used!

The mistake of confusing PULMOTOR with the device that was used is natural.

In light years the name PULMOTOR has stamped itself indelibly upon public consciousness, through the press and through other channels of information in which the achievements of this apparatus of human life have been recorded.

Unhappily the newspaper running the article reproduced on this page referred to PULMOTOR the resuscitation device responsible for the painful injury inflicted on six persons by the bursting of an acid container.

Not only was no PULMOTOR used in this instance but had the PULMOTOR been used the accident could not have occurred.

The PULMOTOR employs no acid in its operation. Its action depends upon the force of compressed oxygen in an oxygen cylinder. It combines not only the assurance of no injury being done to the patient, largely because of its physiologically correct principle, but ensures the safety of the operators as well.

There but on the PULMOTOR—
genuine always bears the name DRAEGER

THE DRAEGER
OXYGEN APPARATUS CO
419 First Avenue Pittsburgh, Pa.

New Type "B" Pulmotor in operation. The only hand-operated resuscitation machine of scientific control.

BECAUSE in design and construction the GOODWIN CORSET follows true anatomical lines and scientific principles physicians recognize in it a most efficient mechanical aid in the treatment of both operable and nonoperable conditions. A leading orthopedist reports the case (see illustrations below) of a woman of 25 with congenital dislocation of the hip and extreme lordosis where in connection with orthopedic treatment he used a *rigid model Goodwin Corset*, in which two rigid steel braces replaced the ordinary boning in the middle of the back of the corset and with a heavy non-elastic band encircling the hips in place of the heavy and uncomfortable braces and jacket formerly worn, obtaining a marked improvement in pose of body and freedom of movement, so that the patient now enjoys health and comfort hitherto unknown, and is supporting herself as stenographer. Note the extreme degree of lordosis without the corset and correct pose of the corseted figure.

AMENORRHEA, DYSMENORRHEA AND SEVERE NERVOUS SYMPTOMS SUCCESSFULLY TREATED WITH LUTEIN—CORPUS LUTEUM

Extracts from case reports

"Miss L. M., May 21 1912 aged 22 complained of menorrhages and nervousness. The menstruation began at 13 and always been irregular, lapses of from two to eight months occurring. This patient was started on six grains of Lutein per day and after a few days began to show trace of menstruation which had not appeared for seven weeks. The dose was increased to 12 tablets daily when the flow became profuse and lasted in all five days when the uterus was discontinued. She stated that she had never had menstrual period similar to this before. —Dr. Curtis F. Burnam. The Journal A. M. A. August 31st, 1912 page 698.

In this last class, dysmenorrhea should be especially included. In my own practice I have observed a truly extraordinary manner the cure or relief of many such cases through the medium of this type of corpus luteum therapy. My best results have ever been gained in the administration of corpus luteum for the relief of the severe nervous symptoms attendant upon the menopause of both the physiological and artificial varieties and the functional amenorrhea of young women. —Dr. Adam P. Leighton, J. The American Journal of Obstetrics and Diseases of Women and Children November 1915 page 878.

The results referred to were obtained by the administration of Corpus Luteum of the BOW as presented in

We Ask Only Two Questions

before we buy any drug or chemical

"Is It Good Enough?"

And we ask that of our histologists, our
our drug-miller and even of the exper-
values on our laboratory staff. If all or none of them say
no—we reject it. If all of them say yes—and each of
them knows that to measure up to our inflexible standard
it must be strictly A.I.—then and then only we ask the
second question—What Is the Price

Quality Always Comes First

SHARP & DOHME

New York Post-Graduate

Medical School and Hospital

Winter Session 1916-1917

A dispensary service of 300,000 patients a year and furnishing clinical material for over 8,000 operations annually enables the New York Post-Graduate Medical School and Hospital to stand pre-eminent in the point of clinical material. The ample equipment and the fact that the Hospital and School are in the same buildings assure high efficiency.

The laboratories are organized for the teaching of essential scientific data in histology, bacteriology and pathology. Special laboratories have been created for the teaching of tropical medicine. Complete instruction in internal medicine, diseases of metabolism, X-Ray interpretation, special and applied therapeutics, surgery, general and special surgery on the cadaver and living, experimental research, clinical physiology and special instruction in the departments of the eye, ear, nose and throat are offered either in elementary or advanced work for both the general practitioner and the specialist.

THE GENERAL COURSE comprises daily clinical lectures and bedside instruction in—

Surgery	Dermatology	Genito-Urinary Diseases
Gynecology	Radiology	Orthopedic Surgery
Medicine	Diseases of the Rectum	Oral Surgery
Pediatrics	Neurology	Diseases of the Eye, Ear, Nose and Throat

SPECIAL COURSES to classes limited to small groups of matriculates are offered in the following departments:

Non-operative Gynecology	Bronchoscopy and Gastroscopy
Cystoscopy and Endoscopy	Refraction and Retinoscopy
Rectal Diseases	Neurology
Diseases of the Stomach	Anesthesia
Abdominal Diagnosis	Metabolism and Constitutional Diseases
Physical Diagnosis	Applied Therapeutics
Infant Feeding	Diseases of the Circulation
Intubation and Tracheotomy	Diagnosis and Treatment of Infectious Diseases
Radiology	

The fully equipped LABORATORIES give excellent opportunity for special and Advanced Courses and Research work in—

Hematology	Pathological Chemistry
Histology and Pathology	Serology and Vaccine Therapy
Bacteriology	Tropical Medicine

WATTERS CHLOROFORM CATGUT

Experience vs Experiment

*When considering the choice
of Catgut, remember that*

Watters were the first to preserve Catgut in Chloroform in 1904. Since then practically every man factors has followed our lead.

Watters were the first to employ a stable iodine compound to render catgut Antiseptic as well as Aseptic.

*It has taken others years to recognize
the wisdom of our pioneer work*

But Catgut put up in Chloroform is not CHLOROFORM
CATGUT

Manufacturers learn only by experience—we have had the experience

The McKesson Model F

For Nitrous Oxid and Oxygen

The McKesson Model F produces ideal gas-oxygen results in analgesia and anesthesia.

It is an ideal apparatus, with the gas flow automatically regulated by the patient's breathing, with an adjustable re-breathing bag and every other feature which would add to the accuracy safety and ease of administration.

The Model F is constructed so that the machine may be used with large or small tanks, and may be transformed from the portable type to the hospital unit, or office type in a few seconds.

Let us send you our catalog and other literature pertaining to the apparatus and gas-oxygen analgesia and anesthesia

Newer Blood Tests

for Rheumatism, Arthritis, Gout, Nephritis, Uremia and Diabetes

In diabetes it is desirable to determine the sugar content in the blood since this may be high while the glycosuria may be low owing to inefficient kidney function. In diabetes with acidosis the carbon dioxide determination is useful since any considerable increase indicates a grave condition.

For differential diagnosis between gout, arthritis and rheumatism the estimation of uric acid and non protein nitrogen in the blood is of assistance. In gout uric acid only is increased; in arthritis both the uric acid and the total non protein nitrogen are high while in rheumatism both are normal. More detailed information on request.

Sunrise Slumber The Teter Method for PAINLESS CHILDBIRTH

Almost all physicians and surgeons are familiar with the Teter Hospital Outfit. Doctor Teter recently perfected an Obstetrical Apparatus embodying the same principles as the Hospital Apparatus.

The Teter Gas-Oxygen Obstetrical Apparatus

is provided with

REGULATORS which must be used to reduce the high pressures of the gases and allow them to flow gently, steadily and evenly.

GAUGES which show the pressures to which the gases have been reduced.

VAPOR WARMER for heating the gases, thereby enabling the anesthetist to induce analgesia and anesthesia more quickly and gently. By using warm gases, saving of from one-third to one-half is made.

SIGHT-FEED of the gases through water, which shows the Doctor how much of each gas he is using.

REBREATHING BAG enables the patient to rebreath the gases, thereby reducing cost of same.

ETHER ATTACHMENT for delivering small percentages of ether for exceptional cases or for use in office practice.

PORTABLE. Special Instructions Unnecessary.

Described by Dr. Charles K. Teter, the recognized leading National Gas-Oxygen Anesthetist.

Hay Fever: Adrenalin

The suprarenal substance, in the form of its isolated active principle Adrenalin, is the chief reliance of a host of physicians. And well it justifies their confidence. Adrenalin effectually controls the nasal discharge. It cuts short the violent sneezing paroxysms. It aborts the annoying lachrimation. Nasal obstruction disappears under its use. Natural breathing is resumed. Distress gives way to comfort.

Adrenalin Chloride Solution

Adrenalin Chloride, 1 part; physiologic salt solution (with 0.5% Chlorotone), 1000 parts

Dilute with five to five times its volume of physiologic salt solution and spray into the nares and pharynx.

Ounc. glass-stoppered bottles.

Adrenalin Inhalant

Adrenalin Chloride, 1 part; an aromatized neutral oil base with 3% Chlorotone, 1000 parts

Administer full strength or dilute with three to four times its volume of olive oil, spraying into the nares and pharynx.

Ounc. glass-stoppered bottles.

The NEW GWATHMEY - GAS - OXYGEN - APPARATUS

Based on Latest Principles of Anesthesia

On pages 60 to 175 of Gwathmey's Anesthesia the Boothby and Cotton principles on anesthesia are set forth, underlying the Gwathmey Woolsey Gas-Oxygen Apparatus.

These principles have remained unshaken and are continuously gaining recognition because their application creates the conditions essential for surgeons and anesthetists.

The *new type* Gwathmey Apparatus is still another marked step in applied anesthesia. Every application has been discarded. Right Level Control takes the place of percentage scales. One simple control dial regulates both pressure and flow. Certain and instant control places uncertainty. Assurance of high a *two-thirds* in gas used has just been recorded.

PORTABLE—for Physicians

1866—1916

Golden Anniversary Announcement

To the Physicians and Surgeons
of the United States

We extend a cordial invitation to visit our New
Home when in Philadelphia

We shall exhibit, at the Meeting of the Clinical Congress of Surgeons, to be held at the Bellevue Stratford Hotel, many new instruments of novel design devised and used by operators in the various clinics.

For fifty years we have maintained the enviable reputation known the country over of making Superior Quality Surgical Instruments, Cautery Knives, Current Transformers and Appliances for the Correction of Deformities, also as dealers of furnishing the highest grade of electrically heated Office Sterilizers, Steel White Enamelled Office Furniture, Electrical Apparatus and Accessories.

CHARLES LENTZ & SONS

31 33 35 SO SEVENTEENTH ST. (Just above Chestnut St.)

Only five minute walk from the Bellevue St. & H. & P.

DR CHARLES GEIGER'S Electro-Operative Surgical Bone Instruments and Accessories

Used and recommended by Dr. John B. Murphy, Dr. Fred H. Albee, and Drs. W. J. and C. E. Mayo

This set of instruments is especially made for transplantations, dowel making and cranial work. Water is not required to keep the cutters from burning the bone, in using the Geiger machine, because of the slow speed. A few of the many advantages not found in other motor bone instruments are: Sterilization of the motor, slow speed, great power, simplicity of the chuck, and the firmness with which it can be held.

Dr Charles Geiger's Orthopedic and Fracture Extension Device

makes orthopedic and fracture work easy for the surgeon gives clear access and removes

obstruction while applying plaster to dressings to hip, back or any part of the limb. Perfect and continuous extension can be made on the smallest child as well as the largest man. The operating table is not in the way while applying dressings to the extremities as found in all other extension apparatus.

This device is portable, and can be quickly attached to any operating table.

DR CHARLES GEIGER,

St Joseph Mo., U S A.

During the Seventh Annual Session of the Clinical Congress of Surgeons At Philadelphia

WE will, as has been our custom in former years have for your inspection a complete line of operating instruments apparatus, etc for every branch of Surgery

You will find here instruments of special pattern made according to the exacting requirements of their authors

One of the items of special interest which will be shown is our

Universal, Noiseless Bone Surgery Equipment

with instantaneous stop hand piece. This engine can be used for bone transplants cranial antrum sphenoid frontal sinus and mastoid operations

New Books

Cullen on the Umbilicus

In Dr Cullen's new work you get chapters on embryology, anatomy, infection, the newborn hemorrhage, granulation tissue at the umbilicus, umbilical polyp, gastric mucosa, the umbilicus, Meckel's diverticulum, testicular cysts, patent urachus, mesenteric diverticulum, prolapse of the bowel, concretions, cancer, Paget's disease, diphtheria, pythias, tubercles, atrophy, fecal fistula, hypertrophy, angioma, lymphocele, connective tissue growths, dermoid sweat-glands, abdomen, myoma, papilloma, adenomyoma, cancer, congenital hernia, exstrophy of the bladder, urachus and its diseases, acquired urinary fistula, etc., etc.

Octavo of 775 pages, with 269 illustrations. By THOMAS S. CULLEN, M.B., Associate Professor of Gynecology, Johns Hopkins University. Cloth, \$7 5 (35s) ; Half Morocco \$9 00 net.

New Mayo Clinic Volume

This new Mayo Clinic Volume is bigger and better than ever before. It contains 9 important clinical talks and research reports—such as mouth sections, relation of amebiasis to pyorrhea, tonsillectomy, roentgenologic determination of gastric motility, roentgen diagnosis of gastric cancer, gastric jejunal ulcers, differential diagnosis of gastric and duodenal ulcers, a diaphragmatic hernia, best treatment of cancer of cervix, oddities of blood pressure, diabetes, spleen, pancreas, treatment of bunions, bone work, herpes, etc., etc.

Octavo of 978 pages, with 300 illustrations. By WILLIAM J. MAYO, M.D., Chief of Mayo Clinic, and their ASSOCIATES at The Mayo Clinic, Rochester, Minn. Cloth, \$6 00 (35s) net.

Albee's Bone-Graft Surgery

Dr Albee's bone-graft methods, particularly his bony bone-grafts, are revolutionizing bone surgery. In this new book you get for the first time all Dr Albee's successful technique in practical application. You get a full and clear description of his electric method of operating, outfitting the technique of its use—illustrated. The section on fracture repair contains 100 pages and contains 100 illustrations, taking grafting in a very kind of fracture.

Octavo of 4 7 pages, 332 illustrations, 3 in color. By FRED H. ALBEE, M.D., Professor of Orthopaedic Surgery, New York Post-Graduate Medical School. Cloth, \$6 00 (35s) net; Half Morocco \$7 5 net.

Graves' Gynecology

This new work, both textbook for medical student and reference work for the practitioner and gynecologist. A central section is devoted to *physiology* of the pelvis, ovaries, and to *relativistic gynecology*. A special section is devoted to enteropneustic intestinal bands, and movable kidney. The first two parts are devoted to *gynecology*—drug and mechanical treatments. This third part is a treatise on *gynecology*. It includes profusely illustrated description of those gynecologic pests that the author seems most fearful. Microscopic pathology is presented almost entirely by drawings with full legends made from sections of the most collected pathological specimens.

Octavo of 77 pages, with 45 original illustrations. By WILLIAM P. GRAVES, M.D., Professor of Gynecology at Harvard Medical School. Cloth, \$7 00 (35s) net; Half Morocco \$8 50 net.

S S WHITE

Nitrous-Oxid-Oxygen Surgical Apparatus

*For the Induction and Control
of Non Asphyxial Anesthesia*

Safe, compact, efficient—with the mixing and administration of gases under the operator's instant control.

The gas flow at all times is unerringly shown by indicators in the glass-covered mixing chamber. The electrically warmed inhaler tubing delivers any mixture at approximately body temperature.

The transparent Surgical Inhaler No. 7 meets every requirement in minor or major surgery. Its simple valve control makes promptly available a choice of methods for inducing partial or profound anesthesia—straight inhalations of nitrous-oxid and oxygen, nitrous-oxid or oxygen alone, nitrous-oxid-oxygen-ether sequence and re-breathing.

The stand supports four cylinders, two each nitrous-oxid and oxygen, permitting a reserve supply of gases for instant use. For hospital or clinical work where quantities of gas are consumed, the larger cylinders, which can be quickly connected, will prove more economical and convenient.

Illustrated catalog describing various types of S S White Nitrous-Oxid Oxygen Surgical Apparatus mailed free upon request.

New Device for Treatment of Oblique Fractures

(By F. W. P. Chase, M. D. and E. Donaghy Martin, M. D.)

A new simple and valuable method of treating oblique fractures. No more screws, no chance of loss of apposition as with Lane plates.

The force of the lever fits the band snugly around the bones. Slightly relaxing screw as instrument is turned over slit fixes band in position.

No Screws Required

No screwing up means time saved. This device corrects oblique band six inches by 3/16 inches, with slit in one end and small hole in other. This band is passed easily around the bones, the free end is inserted through slot and made fast to pin on screw lever.

Price with two bands \$7.50

Strain Eliminated

The strain involved in holding fragments in place while fastening plates is eliminated. The band is cut, any desired length by using pair of scissors or bone cutters. The cut end is then pressed down and the band remains in place. Replaced fragments held in position.

Extra bands, each \$0.25

"AMBUMATIC"

WASHABLE ABDOMINAL SUPPORTERS

Made buckled or laced. Adjustable to support low, middle or upper part of abdomen or as an pillow, carrying the abdomen as in a sling.

AMBUMATIC Supporters relieve pain out of position from sudden strain leaving the incision unprotected.

AMBUMATIC Supporters are light and comfortable to the wearer, yet durably made and absolutely efficient. They enable the patient to resume work or business with perfect safety earlier than would otherwise be possible.

The "AMBUMATIC" Supporter is the best all-around assurance that anyone can have following laparotomies.

Illustrative descriptive literature, order blanks and samples of materials gladly mailed to any surgeon on request.

NEW EDITIONS

of Standard Works Among the
Appleton Publications Which
Have Been Completely Revised
and Brought Up to Date

The New Things in the New Editions

Osler's Principles and Practice of Medicine

A revision has been made of the 8th edition with extensive corrections and insertions incorporating the recent advances of medical knowledge in the infectious diseases typhoid and para typhoid fevers, pneumonic and pneumococcal infections, cerebrospinal fever and anterior poliomyelitis in pellagra, in diabetes mellitus and in syphilis. Changes have also been made in the sections on whooping-cough, tetanus, amebic dysentery, gout, cancer of the stomach, pernicious anemia, tabes dorsalis and arthritis deformans.

Holt's Diseases of Infancy and Childhood

For this 7th edition of Holt the old book has been completely revised with the addition of sixteen new chapters, the most important of which are those on acidosis, neuropathy and exudative diathesis, cardiac arrhythmia, acute lymphatic leukemia, Banti's disease, osteogenesis imperfecta, Still's disease, syphilis of the nervous system, pellagra, epidermic catarrh, duodenal ulcer and idiocyneuresis to foodstuff. More than twenty chapters have been entirely rewritten with the addition of new illustrations.

Hiss and Zinsser's Text-Book of Bacteriology

The practical development of bacteriology has gone ahead with such strides within the last few years that a new edition of this book became indispensable for the use of students and laboratory workers. The sections on culture media, immunity, the summary of facts and problems, micro-organisms, especially the pneumococcus and gonococcus, treponema pallidum, M. tuberculosis, and typhus, have been thoroughly revised to include the latest data on these subjects.

Rosenau's Preventive Medicine

The rapid increase in our knowledge of hygiene and sanitation has necessitated a complete resetting of this popular work. The chapters on leprosy, mushroom poisoning, beriberi, pellagra, carbon monoxide, chlorinated lime, vital statistics, disinfection, quinin prophylaxis for malaria and the mental diseases have been rewritten and the following subjects added: prevalence of venereal diseases, chancroid, the Schick reaction, the Bang method of suppressing bovine tuberculosis, emetin, military hygiene, and about twenty other subjects of importance in preventive medicine.

NAME _____ ADDRESS _____

Dr Howard A Kelly's Stereo-Clinic

The Most Important Surgical Publication of the Age

40 Sections

Now Ready

80 Operations by Eminent Surgeons

A realistic and vivid reproduction of an *Actual Clinic* showing classical operations, not as idealized but as actually performed in the operating room

What the Medical Journals Say

Journal of the American Medical Association:

By means of these stereograms, Dr. Kelly has brought to the library of every surgeon the Clinic room and the actual operation so that the various steps of the operation may be studied leisurely.

Surgery, Gynecology and Obstetrics:

We are ready to greet with pleasure and enthusiasm this present realistic series of surgical operations by our best surgeons, shown in relief with all the circumstantial reality of the Clinic which they were taken, and we confess that in looking them over we find that pleasant surprise has waited us.

New York Medical Journal:

The idea is new one and is well carried out. The physician sits in his office and has before him lectures on an operation, surgical or gynecological, which he wishes to study. While reading the lecture, he sees also in consecutive steps, the whole operation instead of following an operation quickly performed in a crowded amphitheatre.

Canadian Journal of Medicine and Surgery:

We do not hesitate to say that this is one of the most important works of this kind that has ever appeared in print.

The STEREO-CLINIC is itself complete work on surgery and we know of no better instrument that can be made.

American Journal of Surgery:

The study of few pictures in this STEREO-CLINIC showing for example, operations within the pelvic and abdominal cavities, demonstrates at once that Dr. Kelly has overcome the obstacles that stood in the way of producing what others have conceived of and failed to effect—satisfactory successive stereograms of operations in actual progress.

Northwest Medicine:

The STEREO-CLINIC really transports the Operative Clinic from the hospital to the physician's library where he can study at his leisure, and review its technique as often as he desires. The work will commend itself to every careful student of clinical surgery.

IMPORTANT ANNOUNCEMENT

New Work

Just Ready

THE TREATMENT OF

DIABETES MELLITUS

WITH OBSERVATIONS UPON THE DISEASE BASED UPON
ONE THOUSAND CASES

By ELLIOTT P JOSLIN, M.D

Assistant Professor of Medicine, Harvard Medical School Consulting Physician, Boston City Hospital
Collaborator to the Nutrition Laboratory of the Carnegie Institution of Washington, Boston

Octavo, 440 pages, illustrated Cloth, \$4.50 net

THE NEW TREATMENT OF DIABETES—the Allen treatment—by means of fasting and the importance of physical exercise for diabetic patients are fully discussed in this work. Complications are described along with their treatment. This saves repetition and shows the doctor how to handle the complication when it develops.

The hopeful tone which the author's experience with his own patients has enabled him to assume regarding such complications as tuberculosis arterio-sclerosis and gangrene will be most helpful to practitioners who read this book. The *section on Surgery* will enable the surgeon to operate on diabetic patients *without sending them into coma*.

Under *Aids to the Practical Management of Diabetes* the author gives a list of the things every patient should know complete and precise directions for nurses history chart and dietary and urinary records now successfully in use in many institutions also the actual diets employed in typical groups of cases.

The section on *Foods and Their Composition* is so arranged as to make it unnecessary for a physician owning this book to possess any other book on food values either for the treatment of diabetic or other patients. Standard recipes and diets for severe cases of diabetes are given notably an appropriate diet for severe diabetic patients who are poor.

No physician who has diabetic patients can afford to be without this book.

John B. Murphy

John Benjamin Murphy

BORN DECEMBER 21 1857 APPLETON WISCONSIN

GRADUATED RUSH MEDICAL COLLEGE 1879

CHIEF SURGEON MERCY HOSPITAL

PROFESSOR OF SURGERY AND CLINICAL SURGERY
NORTHWESTERN UNIVERSITY MEDICAL SCHOOL

CHIEF OF EDITORIAL STAFF
SURGERY GYNECOLOGY AND OBSTETRICS

PRESIDENT AMERICAN MEDICAL ASSOCIATION 1911

PRESIDENT CLINICAL CONGRESS OF SURGEONS
OF NORTH AMERICA 1914

FOUNDER AND REGENT
AMERICAN COLLEGE OF SURGEONS

HONORARY FELLOW
ROYAL COLLEGE OF SURGEONS OF ENGLAND

DIED AUGUST 11 1916

An Appreciation

DR. JOHN B. MURPHY possessed those intellectual, physical, and personal qualities which make a surgeon. After graduating from Rush Medical College in 1879 and serving an internship in Cook County Hospital Dr. Murphy went to Vienna and came under the direction of that master surgeon Billroth, then at the height of his great career. Billroth was a man of charming personality and most original mind, and his students today fill the chairs of surgery in many Teutonic universities. During these formative years of Dr. Murphy's European sojourn Albert was also one of his favorite teachers. Few men ever equaled Albert's ability to logically present clinical surgery. Fired with zeal Dr. Murphy returned home and came under the influence of the father of modern surgery in the West — Christian Fenger — who was unequaled as a teacher of surgical pathology. Dr. Murphy combined the qualities of Billroth, Albert, and Fenger.

The reputation of a surgeon, in the final analysis, must rest upon (1) originality (2) teaching by word of mouth (3) teaching by the printed word, and (4) surgical judgment and operative skill.

Dr. Murphy had a marvelously fertile and original mind. Possessing a brilliant surgical imagination, he early deviated from the beaten paths and invaded new territory and yet with such acumen that nothing which he originated has failed to live. Like those of the great *musicians*, his productions are still masterpieces; they mark epochs in surgical progress. He made the experimental laboratory a hand maiden to surgery and carefully investigated every detail of his constructive work by animal experimentation before applying it to man.

As a teacher of surgery by word of mouth he had, in my opinion, no equal. Clear and logical, he started with facts about which there could be no dispute, progressed from these facts toward new ground, yet along pathways more or less familiar to all, and finally taking us by the hand, so to speak, he led the way to new truths by the light of his surgical genius.

As a writer he was prolific. His early work was in the field of abdominal surgery. The Murphy button taught us to solve many problems connected with gastro-intestinal surgery. His monograph on "Ileus" still stands a monument to his scientific ability. The history of surgery of the appendix, pelvis, and upper abdomen, as well as of the kidney shows evidences of his genius. Dr. Murphy next developed surgery of the lungs and, in the oration on surgery delivered at Denver in 1898, he laid the foundation for modern surgery of the lungs, so far ahead of his time was this that we have only of late awakened to an appreciation of its value. Dr. Murphy's work on surgery of the nervous system helped to lay the foundation for the present practice, and again his latest work on bones and joints, in which he was engaged during the closing years of his life, are perhaps the greatest contributions to these subjects of our generation.

Dr. Murphy was skillful as an operator of fine judgment, humane, sane, sound, and free from fads. What surgeon has not felt, on seeing him operate, a just pride in the science and art of surgery and expressed the hope that in the event he or a member of his family must have an operation, so good a surgeon as Dr. Murphy might perform it?

The American surgical profession has lost its leading spirit. In Dr. Murphy's death at the age of fifty-eight, well may we regret the unfilled twelve years which go to make up the allotted span of man. And yet, when we review what he has done, we freely acknowledge that even in the time the light lasted he accomplished more than any other surgeon of his time.

William J. Mayo

Our Chief of Staff

JOHN B. MURPHY was the underlying support of SURGERY GYNECOLOGY AND OBSTETRICS and the INTERNATIONAL ABSTRACT OF SURGERY from the time of their inception to the day of his death. He was the inspiration for every move of merit that SURGERY GYNECOLOGY AND OBSTETRICS has stood for and fathered. He was the adviser, personal friend and aid to the editor and his associates, and when difficult problems arose, his strength of character, his personality and his power of vision all were contributed unsparingly toward right solutions. Dr. Murphy was one of the few who maintained at the first conception of the Journal that it would succeed if it were comprehensive and served the needs of the surgeon. And to this ideal he inseparably attached his program of personal energy and financial support.

When the Clinical Congress was developed through an informal invitation of the Journal, both the surprising response to this call and the far-reaching benefits it offered to surgeons fired his imagination and he declared for a permanent organization. Through his force the organization became swiftly the great clinical society that he predicted for it; it served the practical needs of the surgeon.

When at the third session of the Clinical Congress some discussion arose as to whether America should have a great society for the advancement of surgery, it was Dr. Murphy who was recognized by the President of the Congress to second the proposals of the officials. On that occasion he made such a compelling appeal that every man in the audience grasped not only the great vision but also how the vision could become fact. On his motion then the committee of nine was authorized and the American College of Surgeons ceased to be a dream and became a certainty.

These three organizations, which have become powerful agencies throughout the medical world, were but important incidents in the constructive mind of Dr. Murphy. But each of these organizations owes its existence to his enthusiastic support to his uncompromising determination that each represent fundamentals of progress in surgery which are worth while.

The personal loss to the staff of the Journal is too great, and at this time the heart is too full to dwell here on more than the mountain peaks of his service. The details of a wonderful association and friendship are sacred, and the writer mourns the loss of the greatest friend he ever knew.

John Benjamin Murphy

*He went away as he had lived nobly careless of himself
and thinking only of the things he had undertaken to do*

By thought, by action and by self-discipline, he trained a body and mind given by a pure inheritance into a strong physique, an acute brain and a dominating personality

With unsatisfied industry he acquired the knowledge of his art and made his mind a possessor of the recorded deeds of his confrères of the world

He learned surgery serving with indefatigable energy the needs of helpless humanity and taking counsel of his fellow workers in every field old and new in which his profession was practiced

He had a creative mind, trained to investigate facts, and suspicious of traditions with a courage to bring forth the new a judicial mind that judged so correctly the value of the new his genius brought forth that the things he wrought were recognized by science as enduring principles of surgery

He imparted to others his knowledge from a great storehouse by an irresistible enthusiasm, begotten by his appreciation of truth in a way that appealed to the mind, the conscience and the responsibility of his hearer and that made him the impelling teacher of his time.

His experiments were made in the laboratory in the dead house and in the animal operating room He thus proved theories by facts but never at the expense of those he served.

The impelling text of his life—in experiments in writing in the practice of his art, and in his burning utterances as a teacher—was Have uppermost in your mind the welfare of the individual who entrusts his life to your care

He worked and pleaded for higher standards. He was democratic in his methods. He condemned complacent entrenched interests as a bar to progress His life was a protest against ignorance and pretense He believed that most things worth while came from those not bound by tradition He encouraged the beginner and listened to the obscure.

He labored with more and more concentration of effort, as the wonders and possibilities of his task were revealed, trusting his strong body injured by abstinence and continued work to perform the almost superhuman task imposed upon it, and then the body broke and his life in the fullness of its power was sacrificed. Greater love hath no man than this, that a man lay down his life for his friends."

He loved God and expressed this love in his work for men and little children He was the devoted father the beloved husband the staunch friend, and the inspirer of all who came within his influence.

He was the human man developing through many years of self-discipline indefatigable work, untold sacrifice and desire of highest service into the super man—the high priest of the most exacting profession.

THE EXTENDED OPERATION FOR CARCINOMA OF THE UTERUS¹

BY RUBIN PETERSON M.D. F.A.C.S. ANN ARBOR MICHIGAN
Professor of Obstetrics and Gynecology University of Michigan

FOUR years ago at the Baltimore meeting of this Society it was my privilege to take part in the symposium on uterine cancer. In that paper I said that while I believed in the radical abdominal operation greater experience had not made me any more confident that its primary or ultimate results would be favorable to the next patient operated upon. I have had no reason to change this opinion during the past four years. Unfortunately added experience has strengthened my belief that the extended operation for cancer of the uterus is an exceedingly dangerous operation all ways attended by a high primary mortality and that it is no operation for inexperienced hands. However it must be continually kept in mind that in spite of these defects today it is the only method unless it be the extended vaginal method which holds out to the patient with carcinoma of the uterus a reasonable hope of complete cure. I make this statement in advance of what will be revealed by the other essayists as to the results of radium or other methods of treatment. No one will be more glad to discard the radical abdominal method than will I if I can be shown that more patients can be ultimately cured by less dangerous methods.

To arrive at any just conclusions regarding the radical operation it is absolutely necessary that the primary and ultimate results be considered together. Every one who has performed the operation realizes how easy

it is to dodge the issue and perform what Clark has well called makeshift operations. What is easier than to avoid going beyond a mass in one or the other broad ligament in which the ureter is embedded and tying the uterine artery close to the uterus as in the ordinary panhysterectomy? Thus choosing the easiest way may save the operator a primary death but it just as surely dooms the patient to a continuance of the disease and ultimate death as did the old vaginal hysterectomy. Such an operation is not an extended operation for cancer of the uterus and should not be classified as such. If it be not excluded it will show in the final summing up for if the patients be kept track of they will be found to have died of so-called recurrences which in reality were no recurrences at all since the disease was not removed.

I would not be understood as asserting that an operator has not a perfect right to dodge the issue and save his patient primarily when he feels that a prolongation of the operation means but one thing—death. However I do insist that such operations should not be classed among the extended operations for carcinoma of the uterus for if so included they give a false conception of the primary mortality in fact it is not enough to state that such and such operations were radical. If they be radical it will be demonstrated in the ultimate results—the number of patients surviving five years or more. If these results be favorable then and only then will we

¹Read at the meeting of the American Gynecological Society, Washington, May 6, 1916.

be convinced that the operations were indeed radical.

Looked at in another way the burden of proof is upon the radical abdominal operator to show if his ultimate results are poor why he chose the abdominal in preference to the safer vaginal route as a palliative procedure, because it is a palliative method if it cannot be shown that quite a percentage of patients are alive and well after five years. We may or may not know at the completion of a certain radical operation whether it has accomplished its purpose. If macroscopic cancerous areas have been left behind it should be stated in any classification of radical operations for cancer of the uterus that in so many cases the operations were performed while in other cases, although the radical operation was attempted, it had to be abandoned on account of an extension of the disease not realized when the operation was begun.

It is different with microscopic areas of cancer. Here it is perfectly justifiable for the operator to conclude that he has performed the radical operation, if the principles of the technique such as ligation of the uterine arteries external to the ureters and removal of a long cuff of vaginal tissue below the cervical cancer be carried out. In reality excluding implantation metastases, an avoidable error of technique, every recurrence after a radical abdominal operation for cancer of the uterus, is evidence that the operator did not accomplish his purpose although he may have been justified in thinking at the time of the operation that he had.

PRIMARY RESULTS

As in the former paper I shall still include cases of cancer of the fundus with those of the cervix for both classes of cases have been subjected to the radical abdominal operation. However in order that the operative results may be compared with others, the primary and end results of carcinoma of the fundus and of the cervix have been considered separately. Since the 1912 meeting I have not employed the extended operation upon a single case of carcinoma of the fundus but have depended upon the ordinary panhysterectomy. Since 1912 there have been 14

cases of ordinary hysterectomy for carcinoma of the fundus with two primary deaths or a primary mortality of 14 per cent. There have been two recurrences.

This is a worse showing than in the former report where there were 11 radical operations for carcinoma of the fundus with one operative death or a primary mortality of 9 per cent, and only one recurrence in the remaining 10 cases. It confirms the position of Weibel who bases his conclusions upon 67 cases of carcinoma of the fundus from Wertheim's clinic. These cases were operated upon by different methods radical abdominal simple abdominal panhysterectomies, supravaginal amputations and vaginal hysterectomies. While the radical abdominal method was attended by the highest primary mortality, it also showed the highest percentage of ultimate recoveries, notwithstanding the fact that this method was employed in only the most advanced cases. In 31 cases the regional lymph glands were found to be involved five times or in 16 per cent.

The only recurrence in 10 cases of cancer of the fundus surviving the radical operation reported in my last series occurred in a patient where regional lymph-glands showed carcinoma. Just because our results are better in carcinoma of the fundus after ordinary panhysterectomy should not blind us to the fact that only by the very radical operation can the individual patient be given the best chance of a non-recurrence. There has been but a single recurrence in 10 patients surviving the radical abdominal operation for cancer of the fundus, although these patients are all beyond the five year limit. Hereafter I shall perform the radical operation upon all operable cancers of the fundus.

I had reason to think that greater experience with the operation under discussion carrying with it necessarily a reduction in the time required to complete the operative procedure would lower the primary mortality in my hands. This expectation was further justified by my results, since there were only 4 deaths in the last 37 cases in the last series or a mortality of 10.8 per cent. But my hopes were doomed to disappointment since the mortality has been increased from

22.5 per cent to 25.4 per cent there being 15 deaths in a total of 59 cases.

It is rather a thankless task to attempt to explain these latest deaths three of which resulted from shock and two from peritonitis. The same technique was employed as with the previous cases but with far worse results. I had thought it possible to judge with a fair degree of precision whether the cancerous process had advanced beyond the point where it was fairly safe to attempt the radical removal of the uterus especially if the final decision was reserved until after the abdomen was opened. But I judged incorrectly in these cases since the patients died of shock, the result of prolongation of the operation for a time sufficient to overcome the difficulties met with. The two patients dying from peritonitis should have been saved but were not in spite of all precautions to avoid sepsis.

It must be constantly borne in mind that every case of cancer of the uterus must be studied as an individual problem, so far as surgical treatment is concerned. First of all is the disease so far advanced as to preclude any hope that the patient can be cured by radical operation? Long ago it was determined that while much could be learned of the extent of the disease through careful vaginal and rectal palpation the final decision had to be made after the abdomen was opened. Only in this way is it possible to determine definitely the nature of induration to the sides of the uterus whether due to cancer or to pelvic inflammation.

If the parametria be involved by cancer well outside of the uterus it must be decided from the extent of the involvement and the other factors in the case whether to attempt the removal of the carcinoma radically or employ some palliative procedure. The other factors in the case are the age of the patient not in years always but the actual age as revealed by the condition of the kidneys, the heart and the blood vessels. Cancer patients do not stand prolonged operations well especially is this true when the uterus is the seat of the cancer. This is easily demonstrated when such patients are compared with women of the same age who have had to undergo prolonged operations for other con-

ditions in other words a patient with cancer of the uterus is a poor risk at best. Where the kidneys and vascular system are impaired it may be folly to subject her to such a serious operation because of the slight chance of her primary recovery. It may be far better for the patient to prolong her life as much as possible by palliative measures.

Using our best judgment we may and do make mistakes and attempt the impossible with the result that the patient does not recover primarily. But it is the height of folly in my opinion to speak continually as if the entire question of primary mortality after the radical operation for carcinoma of the uterus depended solely upon the extent of the disease. As a matter of fact that is only one of the factors in the problem the others being nearly if not just as important.

The responsibility of what the patient will decide rests after all with the surgeon. The victim of cancer of the uterus above every thing else wants to be cured, not only primarily but so that there will be no return of the disease. She may be willing to take a great risk if there be a fair chance of being cured but not one woman in fifty but will choose palliative measures and the prolongation of life rather than an almost hopeless operation so far as primary results are concerned. It is hardly fair for the surgeon to justify his course of taking large chances with the life of an individual cancer-of-the-uterus patient by saying that inasmuch as without an operation she is doomed to a horrible death consequently any operative procedure is justifiable. By so reasoning

he is not respecting the rights of the patient whose wishes not the surgeon's, should be paramount.

OPERABILITY

I am in no position to speak regarding operability of the cancer cases seen by me since May 1912 since I have been trying out the various methods of cauterization and have not used the radical operation for cancer of the fundus when it could have been employed. During the past four years I have seen in my university and private clinics 124 cases of cancer of the uterus, 107 cases of cancer of the cervix, and 17 cases of cancer of the fundus (Table III).

Unquestionably some of the cancer of the cervix cases could have been subjected to the radical operation, just how many I am unable to say but I was anxious to give the cautery treatment a fair trial not only in the so-called inoperable cases, far advanced cases, but those in the doubtful class as regards choice of operation. Again, 31 patients were so far advanced that nothing could be done or else they refused operation.

I was not fortunate in my selection of cases for the radical operation as shown by my results, and the discouragement that followed undoubtedly influenced me in the choice of cautery methods. However my experience with the cautery has not convinced me that it is in the slightest degree curative. On the contrary I believe that the method must be reserved for those cases of cancer of the uterus where palliative measures only are indicated or where it may be serviceable in preparing a cancerous cervix for radical removal.

I have already spoken of my experience with panhysterectomy for fundus carcinoma

TABLE IV.—End-Results of the Radical Abdominal Operation—5 Cases of Cancer of the Cervix and Fundus operated upon at least five years ago

Number of cases	5
Primary deaths	0
Number surviving	41
Number of recurrences	1
Died of intercurrent disease	
Patients alive and well five years or more after operation	7
Percentage of permanent cures of all cases operated upon (Wertheim's formula)	56 2%
Percentage of permanent cures of those surviving the operation (Wertheim's formula)	69 2%

and my determination to employ the radical operation in the future for this class of cases.

With the exception of these comparatively few cases where the radical operation might have been or was employed, the very large proportion of the cases of uterine cancer were inoperable from the standpoint of a possible cure. They were far advanced cases even more if I am any judge than the previous 125 cases which came under my observation. This is not very encouraging so far as the results of our campaign against cancer are concerned, but it furnishes convincing proof of the need of such a propaganda.

END-RESULTS

I am able at this time to report the end results of 41 cases of cancer of the cervix and fundus since the patients have all been operated upon five years. I am aware that percentages based upon such a small number of cases have only a relative value when compared with percentages of other operators based upon a large number of cases. As a matter of fact however we must employ the percentage method, if we are to compare results both large and small. Still it is best to keep in mind that percentages favorable or unfavorable, in a small series of cases do not tell the whole story.

In Table IV have been recorded the end results in 51 cases of cancer of the cervix and fundus combined, since the radical operation was performed for both classes of cancer. Naturally the end results will be better than when cancer of the cervix is considered alone, since there is less tendency for carcinoma situated in the fundus to recur. I might again emphasize the point that this is true if the radical operation has been employed, the

TABLE V—End-Results of the Radical Abdominal Operation for Cancer of the Cervix—40 Cases operated upon at least five years ago

Number of cases of cancer of the cervix	40
Primary deaths	9
Percentage of primary mortality	5
Number of patients with recurrences	11
Percentage of recurrences	36.4
Number dying of intercurrent disease	2
Number of patients alive and well at least five years after operation	18
Permanent cure of all patients operated upon by radical method (Wertheim's formula)	47.5%
Permanent cure of patients surviving the operation (Wertheim's formula)	62.0%

reverse being the case if ordinary panhysterectomy has been done

In the 41 patients surviving the radical operation there were 12 recurrences two died of intercurrent diseases one tuberculosis and the other heart disease There were 27 patients alive and well five years or more after the radical abdominal operation.

In order that there be no misunderstanding regarding the method of arriving at end results in this and the other tables it may be well to state that every patient was located and her condition ascertained for this report. In other words just because a patient with cancer of the uterus operated upon radically had passed the five year limit at the last report four years ago it was not assumed she was well today Her condition was ascertained by a letter from the patient herself or from her physician. Fortunately I am in a position to keep track of these cancer cases and have been able to secure the post-operative history of each patient.

Wertheim's rules for working out the statistics of the end results for cancer patients subjected to the radical operation have been followed in the tables because they are the simplest. All patients who die from intercurrent disease or who are lost track of must be subtracted from the total number of operations to ascertain the percentage of permanent cures in all cases operated upon To obtain the percentage of permanent cures of those surviving the operation the number of patients living five years or more after the operation must be divided by those surviving the primary operations after deducting those dying of intercurrent diseases and the number lost track of

TABLE VI—End-Results of the Radical Abdominal Operation for Cancer of the Fundus 11 Cases operated upon at least five years ago

Number of cases of cancer of the fundus	11
Primary deaths	1
Percentage of primary mortality	1
Number of patients with recurrences	1
Percentage of recurrences	9.0
Number of patients alive and well at least five years after operation	9

The end results as shown in Table IV are surprisingly good and very encouraging Five years or more after the operations 56.2 per cent of patients operated upon for cancer of the cervix and fundus are permanently cured while 60.2 per cent of those surviving the operations are well with no recurrence

In order to forestall objections that the results were due to the inclusion of fundus with cancer of the cervix cases the latter to the number of 40 the total number operated upon five years or more ago have been arranged in Table V The greatest interest centers around the number of patients alive and well after five years (18) Thus 47.3 per cent of the total number of patients with cancer of the cervix subjected to the radical abdominal method remain cured after five or more years while 62.0 per cent of those surviving the operation remain cured

But better than percentages better than anything else is the knowledge that 18 women out of 40 subjected to the radical operation for cancer of the cervix may be pronounced cured since they have passed the five year period without a recurrence This compensates in part for a high primary mortality since very few if any of these women would be alive today had other methods of cure been attempted

There have been no further recurrences in the 11 patients with cancer of the fundus mentioned in the last report, Table VI Of these one died from the operation and one from a recurrence one year after the operation The remaining 9 patients are alive and well from five to twelve years after the operations It has been considered inadvisable to figure the percentage of cures in such a small series of cases

The time elapsed since the radical operations has been recorded in Table VII Six patients have gone five years five patients six

 Number of cases less than five years after operation

years seven patients seven years, three patients eight years, two nine years, two twelve years, and one patient eleven and thirteen years respectively. While it is impossible to state positively there will be no further recurrences in this series of patients who have passed the five year limit, we have every reason to believe that such will be the case in most instances. However it is interesting to note that one of the recurrences and deaths occurred in a patient who had been apparently free from the disease for five and a half years after the radical operation for cancer of the cervix.

It may be stated that the patient mentioned in the last report as having had a recurrence in the vaginal cicatrix five months after the operation with no recurrence for two years subsequently died of the disease.

SUMMARY AND CONCLUSIONS

1. Further experience with the radical abdominal operation for cancer of the uterus confirms the belief that it is an exceedingly dangerous procedure and will always be attended by a high primary mortality.

2. Even if the percentage of operability of cases of cancer of the uterus markedly increases in this country and elsewhere there will always be border line cases attended by a high primary mortality.

3. This is true because it is not always possible even with the greatest care in examination of the patient prior to operation to estimate the extent of the disease.

4. Errors in judgment mean death from shock if the disease be too far advanced or failure to complete the radical removal of the cancerous uterus.

5. However in spite of a high primary mortality it is the only procedure with the possible exception of the extended vaginal operation which holds out any reasonable promise of a permanent cure.

6. Primary and end results of the radical operation for cancer of the uterus must be considered together in order to judge of the good accomplished in a given series of cases.

7. Unless the operations be radical the end results will be poor and if they be radical the primary mortality must be high.

8. If the end-results be poor the burden of proof is upon the radical abdominal operator to show why he did not choose a much safer palliative procedure.

9. Since 1912 experience with 14 ordinary panhysterectomies for cancer of the fundus shows worse primary and end results than in 11 cases previously reported where radical removal was performed.

10. This showing and the results following removal of carcinoma of the fundus by various methods in the Wertheim clinic as reported by Weibel lead to the conclusion that, because carcinoma of the fundus is more easily cured than when the cervix is involved, we are not justified in thinking it can be treated any less radically than carcinoma of the cervix.

11. The primary mortality in 59 cases of cancer of the cervix and fundus treated by the radical abdominal operation was 25.4 per cent.

12. The extent of the involvement in cancer of the uterus can only be determined definitely after the abdomen has been opened. If the parametria are not too much involved and the condition of the patient's kidneys, heart, and blood-vessels warrant a prolonged and depressing operation it is justifiable to attempt the radical operation.

13. During the past four years 124 cases of cancer of the uterus have been seen in the university and private clinics. The disease was so far advanced in 36 cases that operation was refused or nothing was done. The cautery

method was tried in 58 cases and proved valueless except as a palliative procedure.

14 In spite of attempts to educate the public regarding cancer the cases of cancer of the uterus seen during the past four years were more advanced than has formerly been the case.

15 The end results in 51 patients operated upon five or more years ago were most gratifying combining fundus and cervix cases 27 of the 51 patients were alive and well after five years or 52.2 per cent of all cases operated upon while 69.2 per cent of all those surviving the operations were alive after five years.

16 Of 40 cases of cancer of the cervix operated upon five years or more ago 18 of those surviving the operation are alive and well today. Thus 47.3 per cent of the total

number remain cured after five years while 62 per cent of those surviving the operation remain cured.

17 These percentages were obtained by Wertheim's formula where patient dying of intercurrent disease or those lost track of are subtracted from the total number of operative cases or from the number surviving.

18 The length of time elapsed since the operations upon the 18 patients who are alive and well vary from five up to thirteen years. There is every reason to think these patients are permanently cured although one patient did have a recurrence and died between five and six years after the radical operation.

19 In spite of the high primary mortality the end results in those surviving the operation encourage us to continue with the procedure in suitable cases.

X-RAY TREATMENT OF UTERINE HÆMORRHAGE¹

By ROBERT T. FRANK, A.M., M.D., NEW YORK

Associate Gynecologist, Mt. Sinai Hospital

INTRODUCTORY

THE X ray has been employed in gynecology for a sufficient length of time to allow the profession to form an accurate idea of the merits and demerits of this method of treatment. Nevertheless the conclusions arrived at vary greatly. Some authors particularly those of the Freiburg school and many roentgen therapists laud the X ray highly others especially certain gynecologists view the entire question of X ray therapy with suspicion and are inclined to class the method with the numerous transitory fads so common in contemporary medicine.

The present paper aims to defend X ray therapy from its friends. Properly employed in properly selected cases the treatment is invaluable and indispensable in gynecology. Used promiscuously by the uninitiated roentgenization is as dangerous as the surgeon's scalpel in the hands of the ignorant and the meddlesome.

The writer has used the X ray for a number of years. He has never given the exposures himself but has always referred the patients to the same roentgenologist. The selection of cases, the general directions (i.e. the effect to be attained such as the toning down of bleeding amenorrhœa etc.) the control of physical findings have remained in the writer's hands while technical questions have been left entirely to the judgment of the X ray specialist. No attempt to discuss the minutæ of technique will be made in this paper. Such information is readily accessible (1). Burns or other serious disturbances are practically unknown today if treatment is entrusted to competent hands.

MODUS OPERANDI OF THE RAYS

The X rays affect uterine hæmorrhage directly by their influence upon the ovaries (2) there is also a certain amount of evidence that uterine fibromyomata are influenced directly (3).

Ripe and partly ripening follicles are very susceptible to the rays. Primordial follicles on the other hand are extremely resistant even to massive and prolonged exposure, the ovaries of young women proving more resistant than those of older females. Whether this increased resistance is due purely to the greater number of primordial follicles in the young is not known.

As the menstrual function is dependent upon ovulation and the subsequent development of the corpus luteum (4) such uterine hemorrhages as result from normal or abnormal ovarian influences are necessarily affected by the inhibition of follicle ripening and ovulation. If all ova are destroyed, permanent amenorrhoea results if all ripe and ripening follicles are killed menstruation ceases, until some primordial follicles have had time to ripen and to rupture. Moreover considerable clinical evidence obtains that certain qualitative changes arise from roentgenization and persist after cessation of treatment, such as permanent diminution of menstrual bleeding. The physiological changes at the basis of this phenomenon are unknown.

Certain observation showing increase of connective tissue in fibromyomata which were subjected to raying have been interpreted as direct X ray effects (*loc cit*). Quite possibly however the fibrosis is an involution effect due to the withdrawal of ovarian stimuli from the tumors, comparable, though not identical, with the shrinkage of fibroids usually noted at the physiological menopause.

TECHNICAL

Fractional treatment implies exposure to the rays for 4 to 6 minutes of one or more large fields in the lower abdomen two to three times weekly over long periods of time. Such graduated dosage, though slow of effect, usually permits of accurate control of the degree of influence exerted upon the ovaries. It is therefore, especially recommended for cases where reduction of bleeding and not amenorrhoea is desired.

Intensive treatment according to the improved Freiburg technique permits of the use of enormous doses at each sitting (small

multiple fields filtration cross fire and lately also the Coolidge tube). By this means amenorrhoea may be achieved within a short period of treatment (9 to 18 weeks). This form of treatment is applicable to cases in which profuse bleeding must be controlled within a short period of time. Graduated effects are less readily obtained.

It is at times indicated to give one or two intensive treatments, to obtain control of the bleeding and then to continue with fractional doses in order not to produce amenorrhoea. An experienced technician can thus produce the desired effects almost at will.

APPLICABILITY

X ray therapy is applicable in

- 1 Functional menorrhagia and metrorrhagia of adolescents.
- 2 Functional menorrhagia and metrorrhagia during sexual maturity.
- 3 Functional menorrhagia and metrorrhagia preceding the climacterium.
- 4 Menorrhagia and metrorrhagia due to fibromyomata.

1 Adolescent hemorrhages. Prolonged and irregular hemorrhages between the ages of 13 and 18 years are not uncommon. The majority of cases respond to general tonic treatment, uterine styptica (ergot, styptol) and hygienic measures. A small number require one or more curettages. A still smaller number in whom the preceding measures fail to cure are relieved by serum injections calcium chloride by mouth or rectum, or transfusion. The few remaining cases, usually quite desperate because of their extreme anemia and debility after all measures have been tried in vain, are saved from hysterectomy or oophorectomy by X ray treatment. One or two intensive treatments are followed by fractional exposures until complete amenorrhoea is obtained. This effect is usually not attained for several months during which the bleeding occurs less and less frequently and in diminishing quantities. If vasomotor symptoms (flushes) develop the exposures should at once be diminished, as the dosage has been sufficient to produce amenorrhoea within a short time.

The amenorrhoea may persist for 8 to 12

months then scant and irregular (every 3 to 6 months) period appear finally normal menstruation is re-established. Permanent amenorrhœa is almost impossible to obtain in very young women.

Functional menorrhagia and metrorrhagia during sexual maturity. Occasionally cases are encountered in which purely functional hæmorrhages necessitate interference. The patients usually are in the early thirties and have had one or more children. The bleeding may take the form of either menorrhagia or metrorrhagia or both. Inflammation can be excluded both by the history (absence of venereal infection, normal puerperiums etc.) and by the physical findings. Usually the sole change noted is a moderate symmetrical increase in size of the entire uterus. Repeated curettages either produce only temporary palliation or are of no avail. The curettings regularly show endometrial hyperplasia or cystic endometrial changes. Formerly such cases after palliative measures had failed were treated by atmocauter or hysterectomy. Some of these patients desire more offspring.

When the condition is clear — i.e. absence of inflammatory lesions, curetting showing absence of carcinoma — X-ray treatment is applicable. If no more children are wanted amenorrhœa may be induced otherwise the bleeding should be toned down by fractional dosage; the more advanced the age of the patient the less exposures are needed. When the periods occur only at 4 to 6 months intervals and are scanty it is well to temporarily stop treatment in order not to run the risk of producing the menopause. Such patients may later conceive and bear healthy children.

3. *Functional preclimacteric menorrhagia and metrorrhagia.* In these cases carcinoma must always be excluded by one or more curettages (microscopical control). The curettings ordinarily resemble those obtained in Class 2. Unless the adnexal regions are free X-ray is also contra-indicated. Many of the cases clinically fall into the group of so-called fibroids, uterine myopathies, metritis, etc.

Other thing being equal the patient should

be given the choice between operation and X-ray. In cases in which vaginal hysterectomy promises to prove technically a safe operation should be preferred on the other hand in obese, emphysematous patient or those appearing to be poor operative risk, roentgen treatment is to be recommended as less dangerous than operation.

A few intensive treatments regularly produce permanent amenorrhœa. If this outcome is not obtained a mistake in diagnosis has been made (carcinoma, pedunculated submucous fibroid).

4. *Menorrhagia and metrorrhagia due to fibromyomata.* This class of cases has given rise to the largest amount of discussion. Kroenig and Gauss (6) claimed 100 per cent cures where the method was used and an applicability of 85 per cent. The writer on the other hand finds an applicability of only 5 per cent in his material (7). Between these widely divergent views all manner of opinions are noted.

To form a correct opinion a number of factors must be taken into consideration. The discovery of a symptomless fibroid *per se* does not indicate any interference. In the writer's experience only 45 per cent of fibroids require treatment especially if the patient is not informed of the presence of a tumor. Some member of the family may be made aware of the condition in order to safeguard the physician. Unless fibroids produce menorrhagia and metrorrhagia, pressure symptoms or enlargement of the abdomen, their presence is rarely noted and operation not considered.

Bleeding is the symptom most often complained of and most readily relieved by raying. Before X-ray treatment can be considered carcinoma must be excluded by exploratory curettage. The absence of cancer can be demonstrated only if the entire endometrial cavity is accessible to the curette. Uteri which contain tortuous cavities (submucous fibroids) ought therefore not be rayed.

Where pressure symptoms are severe or where large tumors are noted the writer excludes the use of the rays because several months of treatment must elapse before con-

siderable reduction in size of the mass and consequent relief can be looked for

Kroenig and Gauss consider the following conditions as contra indicating X ray treatment

1. Pedunculated submucous fibroid partly extruded from the cervix.
2. Gangrenous or suppurating fibroids.
3. Combination of fibroid and endometrial carcinoma.
4. Fibroids in which rapid growth, profuse metrorrhagia, and unsuccessful roentgen treatment makes the fear of sarcomatous degeneration likely
5. Fibroids causing acute incarceration of the bladder

Besides this they rarely recommend radiotherapy for patients below the age of 35 years as permanent amenorrhoea is difficult to obtain.

These contra indications are not sufficiently rigid. Abdominal diagnosis, including gynecological diagnosis, is notoriously uncertain. Surprises are constantly encountered. Even the experienced clinician will occasionally "slip up" on an apparently simple diagnosis, mistaking, for instance a cyst for a fibroid. In order to protect the patient, it is necessary to exclude all doubtful and complicated cases. What constitutes a doubtful or a complicated case remains a matter for the judgment and experience of the gynecologist to decide. The writer in a series of 419 unselected cases, which were admitted for operation to Dr Brettaner's service at Mt. Sinai Hospital, found 140 complicated cases (33 per cent) as the Table I will show

Of the 140 cases at least 74 (53 per cent) presented conditions absolutely contra indicating raying. Many of these conditions were not and could never be diagnosticated before operation.

Absolute contra indication to X ray treatments in the writer's opinion is present, if carcinoma or sarcoma are found or suspected if ovarian cysts or tumors are felt, if the uterine tumor is rapidly growing if the tumor is large (size of a 5 to 6 months pregnancy) if the palpatory findings are doubtful (suspicions of adnexal trouble, of rectal or sigmoid tumor or adhesions, etc)

Cervical cancer		5.00 per cent
		8.50 per cent

Pedunculated or degenerating tumors, when recognizable are also contra indications. Urgent symptoms will necessarily preclude the use of the rays.

In clear cases of uncomplicated fibromyomata not excessive in size but causing symptoms, the question of raying versus operation may be considered. The decision rests with the patient, who should be enlightened in regard to the risk of operation (mortality 0.5 to 2 per cent) on the one hand, contrasted with the duration and expense of X ray treatment on the other

SOCIAL CONSIDERATIONS

X ray treatment can be given to the impecunious only in well equipped and well endowed institutions. In addition to the initial expense of the installation the operator's time the electricity consumed, and the replacement of tubes etc produce a formidable expense account. Fractional exposures (4 to 6 minutes) cost approximately \$3.00 each to cover expenses and may have to be continued 2 to 3 times a week for many months. Intensive exposure, sufficient to produce amenorrhoea and shrinkage of a fibroid in a

In six operations, 7 patients died. In 4 of them the cysts could not have been used (malignant of uterus and papilloma of ovary, fibroid and pregnancy with placental necrosis, fibroid) extending from cervix, septum, fixed increasing bladder, vesical reaction.

woman over 35 years of age will cost from one hundred to three hundred dollars at a minimum

INDICATIONS

Taking into consideration the absolute contra indications the danger of operation the expense and time involved the writer believes that about 5 per cent of fibroids (i.e. 10 per cent of those requiring interference) should be treated with the X ray. These indications are met in uncomplicated cases in which (1) operation is declined in which (2) operation is contra indicated because of extreme nervousness or psychical unrest, in which (3) operation is inadvisable because of serious heart disease renal or pulmonary lesions

SUMMARY

1 The roentgen ray produces amenorrhœa by destroying the ovarian follicular apparatus or oligorrhœa by partial destruction of follicles. The resulting menopause symptoms correspond in character and degree to those of the post-operative menopause

2 The choice lies between two methods of application (a) the fractional weak requiring prolonged use but readily controllable (b) the intensive massive more rapidly producing amenorrhœa.

3 Obstinate cases of hæmorrhage in adolescents can be cured. Only such cases as have resisted all other forms of therapy should be selected

4. Functional hæmorrhages during sexual maturity if conditions are unmistakable and curettage shows absence of carcinoma, may be relieved by producing oligorrhœa (with the possibility of subsequent pregnancy) or definitely cured by inducing the artificial menopause.

5 Preclimacteric functional hæmorrhages are readily cured by the production of the menopause. At this age malignancy must be even more carefully guarded against

6 Uterine fibroids may be slowly reduced by X ray treatment. All complicated cases should be excluded as otherwise serious or fatal mistakes may occur. In properly selected cases (5 to 10 per cent) the choice between operation and roentgen therapy may be left to the patient. In patients with serious heart lesions nephritis or pulmonary trouble or in the hyperneurotic preference should be given to the X rays

CONCLUSIONS

X ray in gynecology has proved an invaluable addition to our armamentarium. It enables the gynecologist to exert graded effects upon the ovary and thus control the menstrual cycle in degrees varying from slight inhibition to permanent destruction of function. It also causes fibroid tumors to diminish in size or to disappear

The main danger to be apprehended in X ray treatment is their application by error to malignant tumors. Such danger is minimized by excluding cases which present doubtful or complicated findings. Hence the treatment must always be controlled by the trained gynecologist because diagnostic accuracy is far more essential than if operative measures are contemplated

PRECANCEROUS CHANGES IN THE UTERUS

By WILLIAM S. STONE, M.D. New York

THE failure of scientific medicine to discover either a cause or a cure for cancer does not deny an assurance of a promising field in a more definite investigation of the local physiological and pathological changes which relate to the inception of the disease in individual organs.

Numerous conditions are recognized clinically as preceding or associated with cancer of the uterus in a variable percentage of cases. Trauma of the cervix during parturition resulting in a variable amount of ectropion is generally regarded as an important factor in the etiology of cancer of the uterine neck, but its histogenetic significance—whether related to the presence of scar tissue, to regenerative hypertrophy or in furnishing a larger field for atypical strife between two kinds of epithelium—is far from established. Chronic inflammatory diseases are becoming more definitely recognized as antecedents of neoplastic growth in the uterus, as well as in the breast and other organs.

Polese (1) for example, states that an endocervicitis preceded cancer of the cervix in 34 of his 48 cases and we find in the records of numerous observers how often such changes are related to the history of gonorrhea less often to that of tuberculosis. Syphilis is more definitely related to the inception of a cancerous disease in some regions of the body than any other common disease. In the uterus its relation is less well defined, but with our present resources in diagnosis a promising field for pathological research appears to be furnished in a closer study of those lesions designated as leucoplakia. Ewing (2) states that the cervical erosion is the most definitely established lesion known to precede cervical cancer and for corpus carcinoma, he says, the chief definite etiological factor is the association with myoma. Evidence of this frequent association of myoma with cancer of the uterus is furnished by numerous writers. Taussig (3) states that in a personal communication from the Mayo Clinic he learned that

myomata were present in 10 out of 40 cases of cancer of the corpus uteri in that clinic.

The observation of such causal relations however important they may be in the study of the occurrence of uterine cancer does not include its formal histogenesis the study of which becomes necessary in order to define the term precancerous.

Clinicians are generally agreed that there are no pathognomonic symptoms of uterine cancer until the tumor growth has become well established and usually not until its destructive capacity is grossly manifested. Atypical bleeding or discharge combined with other symptoms and a careful physical examination can only create a weak or strong suspicion of its early existence without the aid of a competent histological examination from which it is universally expected that a positive confirmation or denial of the clinical suspicions will be made. Failure to receive a positive diagnosis often creates in the mind of the clinician a suspicion of the incompetency of the pathologist or in the mind of the pathologist that he has not been furnished with the proper material. Each of these conditions may maintain but an analysis of the histological criteria upon which a positive diagnosis of a fully established cancerous growth is made shows that the pathologist, like the clinician is ordinarily not prepared to make such a diagnosis until some amount of destructive capacity is histologically manifested. In other words, cancer is an evolutionary process requiring time to show its actively destructive purpose. Ewing (2) says, It is not true that a pathological condition must be either cancer or not cancer. It may be neither the one nor the other. It may be in the process of becoming cancer. Using this author's analysis of the histological criteria in the diagnosis of cancer we have:

(1) Cellular overgrowth passing beyond that observed in other processes affecting the same tissue (2) atypical qualities of the cells metaplasia, anaplasia (3) loss of

polarity (4) heterotopia (5) desmoplastic properties (6) local invasive properties (7) metastases. Before there is an appreciable amount of heterotopia or invasive features however innumerable combinations of criteria may be seen each varying in quantity and quality. In some cases the amount of proliferation will make a striking feature in others the atypical quality of the cells—their size irregular shape peculiar staining qualities especially the larger size and hyperchromatism of their nuclei or their loss of polarity—will present such pictures that one feels reasonably certain that a malignant growth is in a developing stage. To many of such areas the term precancerous seems to be appropriately applied.

In the literature of uterine cancer we find much to support the idea that the evolution of a malignant growth can be observed from its beginning in definitely benign lesions to a stage in which it becomes a fully developed neoplasm. Schottlaender and Karmann (4) in their extensive monograph express the evolutionary character of cancer in the use of the terms immature moderately mature and fully mature according to the number and kind of morphological features that they present without regard to their histological type size or age. Contrary to the opinion of the majority of pathologists they believe that although there is no specific criterion by which the earliest beginnings of cancer-cells can be recognized it is possible to recognize an immature stage of cancer before its destructive growth is shown especially in the squamous cell form most of which appear in this stage. To those cases in which the morphology appears doubtful they use the term precancerous. While other writers are not so frank in the use of this term there is much evidence in their discussion of atypical changes of benign lesions in the uterus and their relation to the development of malignant growths to justify its application to a definite variety of intermediary changes.

Metaplasia. The transformation of cylindrical epithelium into the stratified variety has been produced experimentally in the stomach of lower animals by Fuetterer (5)

and Possner (6) and metaplasia of epithelium in the gall bladder stomach urethra and other organs has become established as a definite factor in the development of squamous-cell carcinoma in these organs. The uterus offers an especially fertile field for the study of the significance of this change in the evolution of malignant neoplasms. A certain amount of epithelial change and proliferation is shown by Klein (7) Mueller (8) and others to occur as a result of the physiological functions of menstruation and pregnancy and the factor of atrophic changes of the surface epithelium after the climacteric in the production of epidermization is discussed by Moencke (9) R. Meyer (10) in finding islands of stratified epithelium in the surface epithelium of the uterine body of a newborn infant and in subsequent observations has contributed much to the factor of developmental error. Friedlaender (11) observed small islands of stratified epithelium both on the surface and dipping in a few places into the glands of the lower segment of the uterine body of a child of five which he ascribed to hæmorrhagic effusions and exfoliation of particles of mucosa during a severe scarlatinal nephritis. The potential frequency of metaplastic change in the uterine mucosa is discussed by Werth (12) in the regenerative changes following curettage. Its frequency as presented by Zeller (13) in every form of chronic endometritis is questioned by subsequent writers but its occurrence in long existing chronic inflammation due to gonorrhœa tuberculosis and perhaps to syphilis is amply attested by numerous observers—Gebhard (14) von Franke (15) Ruge (16) Hengge (17) Oeri (18) Kaufmann (19) Sitzenfey (20) Schauenstein (21) Hitschmann (22) for an explanation of this process in the uterus offers the view that under pathological conditions the uterine epithelium may acquire the old embryonic capacity of that of the müllerian duct to form indifferently either cylindrical or stratified squamous epithelium in any part of its course and believes that, exclusive of polypi and other benign tumors its presence in the form of a true epidermization does not occur except as a malignant process. As a

histological criterion in the diagnosis of neoplastic changes its importance is related to its diversity of form and extent in those lesions under discussion.

Cervical erosion. The strongest argument against the histogenesis of carcinoma from this lesion has been the apparent infrequency which cancer has been observed clinically to follow such a common lesion. The best clinical record of such a sequence is that of Beckmann (23) who in a case, 37 years of age, that he had treated for an erosion over a period of five years finally saw a squamous cells carcinoma develop. In another 43 years of age, after two years duration of a lesion diagnosed as ectropion, an excision was made one and one-half years after which a carcinoma appeared. Several factors suggest themselves as contributing to the infrequency of such observations (1) The failure of the patient to consult a competent clinician before the tumor is well established (2) the length of time that such benign lesions probably exist before atypical changes begin preclude the continuous observation by a single clinician (3) the frequent cure of such lesions by minor surgical procedures (4) the orthodox conception of the pathologist that no intermediary stages can be recognized morphologically between benign and neoplastic change. The evidence, however in pathological literature has become sufficient to direct our attention to a closer study of the atypical changes which frequently occur in the course of healing of cervical erosions. Ruge and Velt (16) long ago expressed the opinion that erosions are not always a simple and unimportant process, and that an isolated erosion gland cannot always be differentiated from an isolated carcinoma gland without the surrounding tissues. Amann (24) refers to a number of cases in which the newly formed epithelium in a healing erosion spreads like a portio epithelioma. Winter (25) states that a true portio epithelioma not rarely forms from a healing erosion. Koblanck (26) can only express the differential character of a healing erosion and a portio carcinoma in the greater or less amount and regularity of epithelial metaplasia and the more or less atypical

qualities of the cells. Alfieri (27) has traced a carcinoma of the vaginal vault to a follicular erosion gland in a case of endocervicitis. Von Franke (15) in a case 43 years of age, found typical carcinomatous epithelium in the glands of a follicular erosion which he regarded as suspicious. Rubin (28) has recorded three cases of undoubted incipient cancer arising in a definite proliferation of atypical epithelium on the surface and in the glands of healing erosions, in which the diagnosis was made (1) from indistinct definition of cell outline, especially in the deeper layers (2) from the irregular large, hyperchromatic nuclei occasionally lumped together (3) no definite stratification of the layers and lack of alignment of the basal cells (4) marked nuclear granulation, as seen frequently in carcinoma in which hornification has not appeared. Mitoses and hornification, he regards as variable qualities. Schanenstein (21) gives a comprehensive description of the evolutionary features of cancer of the cervix in a report of four cases. His first case presenting an atypical proliferation of epithelium cells in a circumscribed area of the portio and along the lower part of the cervical canal, differed quantitatively from a healing erosion in the amount of cell proliferation along the surface and the extent to which the glands were filled with stratified epithelium and, qualitatively in the atypical character of the cells, in their loss of polarity in the deeper layers and the presence of numerous atypical mitoses. The other three cases, which appear to be definitely established carcinomata, differed from the first case in the amount of their atypical qualities and in the distinct heterotopia and slight stroma invasion. No macroscopic growth was found in any of the cases but in the three fully established growths it extended superficially along the entire cervical canal in one to the lower part of the corpus mucosa in another and to the corpus and vaginal wall in the third the vaginal epithelium being preserved over the growth. The morphology of the cells in the first case differed slightly more from those seen in atypical healing erosions than it did from the other three cases the latter differing from

each other chiefly in the amount of definition of cell outline. Under a high power the differentiation between the cells of the first and other cases he says could not be made. Schottlaender and Kermauner (4) made a similar observation regarding the differential morphology of such cases. In other words Schauenstein made the diagnosis of a definitely established cancer in three of his cases by a destructive action manifested by a distinct heterotopia and invasion of the glands not only by a direct proliferation through their mouths but also by bursting through their walls with which they came in contact. He believes that the first case was becoming a similar growth and only needed time to show its destructive action. K. Ulesko-Stroganowa (29) in a report of three cases describes the histological features of developing carcinomata on the base of healing erosions but her drawings do not confirm the descriptions and the rapid regression of the processes that she was able to demonstrate by an examination of the uteri which were removed four weeks later in two cases and of the cervix which was amputated two weeks later in the other makes it seem probable that in these cases there was only an exaggerated amount of cellular proliferation in the process of a healing erosion in two of the cases and a gonorrhoeal infection in the other. They show however the evolutionary character of the process. Cullen (30) to whom we are much indebted for his analysis of the histological criteria in the diagnosis of uterine cancer shows pictures of sections in the neighborhood of fully established tumors which he regards if taken by themselves as suspicious.¹ If no other evidence of growth existed how shall such changes be interpreted except as representing the developing stage of cancer?

Leucoplacia. The potential elements in these lesions of the tongue to develop cancer has long been recognized. Weir (31) 1875 was the first to describe leucoplacia of the female genitalia in the report of two cases occurring upon the vulva both of which developed cancer. Since then a few writers have described their occurrence on the vagina, portio, cervical and uterine canal which in

most instances after a long time have developed into cancer. Von Franque (15) made the first clinical observation of leucoplacia of the portio developing into a carcinoma observing the case as beginning in an erosion. His second case observed over a period of six years finally became a carcinoma. Berkeley and Bonny (3) consider leucoplacia of the vulva as the first stage of cancer. Sweeney (33) reports a case 3 years of age giving a history of syphilis and a positive Wassermann. It was also associated with a gonorrhoeal proctitis. No improvement followed the use of salvarsan and six months later a hysterectomy was done. Nothing of importance has been written regarding the etiology of these lesions in this region or their relation to syphilis except that in a few instances there has been a history of syphilis. So few cases of uterine leucoplacia have been recorded that it must be considered clinically a rare disease. It has appeared in the cases so far reported on the portio in association with similar and usually more extensive areas upon the vaginal walls or extending along the cervical and uterine canal to the fundus. The lesion appears as yellowish white slightly elevated patches of different sizes discrete or joined to each other by narrow bridges. The patches are adherent to the underlying tissue which bleeds if they are wiped away (von Franque, Sweeney). It has been described in a more extensive and diffuse form under the name of psoriasis or ichthyosis by von Rosthorn (34), von Franque (15), Zeller (13) and others. Its pathology as given by d'Hotman de Villiers and Thérèse (35), Jayle and Bender (36), von Rosthorn (34) and von Franque (15) consists of a marked metaplasia and thickening of the horny layer with increase in the keratohyaline granules of the stratum granulosum (Sweeney 33) resulting in complete epidermization and often showing considerable epithelial down growth. The more extensive growths which have existed a long time may present the picture of an adult acanthoma as for example the case of von Rosthorn (34) which is so regarded by Hitschmann (22) and others. This epidermization of the uterine mucosa relates specifically to the histogenesis of a

number of recorded cases of carcinoma, in which an extensive but superficial spread of the growth has occurred, covering a greater part of the mucosa of both the corpus and cervix—von Piering (37) Ruge and Veit (16) Benckiser (38) Hofmeier (39) Gebhard (14) Cellhorn (40) Kaufmann (19) Schauenstein (21). Some of these cases have shown acanthoma in the corpus and adenocanthoma in the cervix, or focal areas of acanthoma in an adenocarcinomatous structure for which an explanation may be reasonably found in the pre-existence of leucoplakia. Pfannenstiel (41) says every case of epidermization is not suspicious, but it is a precancerous stage in the same way that glandular hypertrophy and hyperplasia is to adenoma and adenocarcinoma.

Uterine polyps Numerous writers have directed attention to the frequency of sufficiently atypical epithelial metaplasia and overgrowth in uterine polyps—Klob (42) Billroth (43) Amann (24) Keldler (44) Winter (25) Kroemer (45) Bullus (46) Kuestner (47) Gessner (48)—to furnish evidence of their malignant tendency. Oertel's (18) description and drawings of the changes in both the surface and gland epithelium justify his conclusion that, although a diagnosis of a fully established neoplasm can not be made, they contain the potential elements of a developing cancer. He also reviews the literature of similar cases. J. Williams (49) describes a mucous polyp in which the down growth of epithelium into the glands is atypical enough to create the impression of a developing malignant growth. Opitz (50) directs attention to the frequency of epithelial metaplasia over that part of the polyp projecting into the vagina in which he sees a base for the development of a malignant change.

Submucous fibromyomata The importance of these tumors in the development of carcinoma, especially if they become pedunculated, relates primarily to the circulatory and nutritional changes they produce in the neighboring mucosa. We are indebted to Sitzenfrey (51) for a comprehensive description of the changes which occurred in two cases. In the first instance, the histology

of the curettings in a case of necrotic submucous fibroid showed an immature epidermization and a slight papillary proliferation of the surface epithelium and mouths of the gland ducts. In one area the cells became more atypical and heterotopic suggesting at two points a beginning invasion of the underlying stroma from which he regarded the case as strongly suspicious of a malignant formation. The case remained well however during 4½ years of observation. In the other case 50 years of age a submucous fibroid had been removed six years previously. A curettage for bleeding and discharge revealed an extensive metaplastic growth of surface epithelium and deep invasion of the gland ducts. Because of her age the presence of a necrotic polyp and other submucous myomata, a hysterectomy was performed. The uterine mucosa had a rigid white opaque appearance except near the insertion of a fibrous polyp where it appeared to be softer. Microscopically the mucosa was generally epidermized from the upper part of the cervix to the fundus as a result of a long-existing pyometra. Two layers could be distinguished in most of the areas a markedly hornified and a proliferating germinative qualitatively sufficiently atypical in a few areas both on the surface and in the glands to arouse suspicion of a malignant change but for some time it was regarded as a benign epidermization. Subsequently however von Franque discovered in a section of the anterior wall an area in which the atypical character of the cells the heterotopia and stroma invasion appeared to justify the diagnosis of carcinoma. In this area a figure is shown of atypical cell growth bursting through the membrana propria at the fundus of a gland, while the epithelium nearer the mouth of the gland appeared normal. In this connection Sitzenfrey's observation of another case 28 years of age is important. After a manual extraction of the placenta and a puerperal infection atypical bleeding occurred over a period of two years during which three curettings were performed. The first curettings showed a very marked overgrowth of both surface and gland epithelium in association with the changes of a diffuse chronic endometritis, but there

Fig. 1. Erosion. Chronic endometritis. Slight epithelial proliferation.

Fig. 2. Cervical dysplasia. Mucoid degeneration. Marked papillary growth.

were none of the features of a neoplasm. The subsequent curettages showed a marked regression of the process; in the last only a few places presenting a slight stratification of both surface and gland epithelium. Similar changes of benign epidermization were observed by Hengge (17) in two cases 44 and 49 years of age.

Glandular hypertrophy and hyperplasia. The glandular type of uterine cancer presents greater difficulties in the diagnosis of its incipient stage than the other forms because the preservation of the normal gland type persists in so many instances until the amount of neoplastic structure has reached bulky proportions. The frequency also of advanced grades of gland hypertrophy and hyperplasia in menstruation, pregnancy, and chronic inflammatory conditions adds to the difficulty making it at times quite insuperable. The claim of (Chard (14) that a malignant adenoma arises by a gradual transition from the ordinary form of hypertrophy and hyperplasia is not supported by the majority of pathologists. Baecker (15) however reports a case in which during a period of ten years the uterus was curetted 6 times. The

first 18 examinations showed ordinary hyperplasia, the nineteenth a benign adenoma, and the last a definite malignant neoplasm. Schottlaender and Kermauner (4) in an analysis of the histological criteria of their cases do not minimize the difficulties which the diagnosis of this type of growth presents in its inception, but in cases in which the change is limited even to the upper layers of the mucosa in which the only destructive sign is that of the lessened amount of interglandular stroma in which the eversion and inversions of the gland epithelium are atypically excessive and in which the staining quality of the cells, especially of the nuclei is altered, they offer a description which makes the diagnosis of a beginning neoplastic growth something more than a subjective feeling. Whenever minimal amounts of such morphological change occur in definitely focal areas of otherwise normal structure, especially if physiological and other pathological causes may be excluded, and when they occur at the age when malignant growth is most common, are we not justified in applying the term precancerous? Cullen has described the differential features of glandular carcinoma of the corpus uteri, and in a few of his case-illustrations and interpretations are given

Fig. 3 Epidermal metaplasia in cervical erosion. Pregnancy.

Fig. 4 Small mucous polypoid masses, epidermal metaplasia.

which seem pertinent to our subject. Atypical proliferation of both surface and gland epithelium are seen which he defines to be suspicious, or probable areas of beginning carcinoma; the definite diagnosis, however, depending upon the presence of a macroscopic tumor or the existence in other parts of a fully established growth. His case number 4508, page 527, appears to the writer to be very suggestive of a precancerous change. Two illustrations are given showing an atypical proliferation of epithelium, one on the surface and the other in a gland which created enough suspicion of malignancy in the author's mind to request the patient to travel 300 miles for a second curetting. Nothing was found at the subsequent operation performed three months after the first, and the patient's condition was reported to be well three years afterward. Cullen's conclusion from the sequence of events that the patient did not have a fully established

growth is undoubtedly correct but to the writer it seems reasonable to make an interpretation other than that such a proliferation was simply part of an acute endometritis. The argument that solid masses of cellular proliferation such as are shown in one of the illustrations are not characteristic of early adenocarcinoma of the uterus is true but from the literature which the writer has given it seems not at all unlikely that both the surface and intraglandular proliferation may express the presence of focal areas of metaplasia perhaps in the process of becoming leucoplakia as a result of a gonorrhea of which the patient's history was said to be suspicious. If so the case may be reasonably considered precancerous.

As an additional contribution to the literature of the subject of precancerous change the writer offers the following cases which he has collected from the uterine material in the Pathological Laboratory of the Cornell University Medical College.

Fig. 2. Cervical polypoid papillary degenerative proliferation.

Fig. 3. Papillary neovasculation. Mature glandular proliferation.

CASE 1. Papillary rosion. Chronic cervicitis. Slight epithelial proliferation (Fig. 1).

It was submitted to the laboratory for diagnosis. The specimen has an increased chronic interstitial inflammation. There are numerous foci of epithelial protrusion into the area of the mucosa, which then enter into papillary tufts covered in the surface by a thin layer of epithelium but largely by the epithelium on the tips. One or two places have even given place to epithelial proliferation in the surface layer. There are numerous sections of epithelium within the tufts, but they are not numerous enough to make the diagnosis of beginning neoplasia.

CASE 2. Cervical polyp. Marked papillary overgrowth (Fig. 2). Shallow ulcers with laboratorial diagnosis. The uterine cavity is filled with epithelial proliferation in the area shown in Fig. 2. The epithelium is scanty and there is no appearance of any glandular structures. Mucoid degeneration with ill-defined tufts. The typical polypoid appearance appears to be in case 1 but it is not the case in this situation, a tumor (Fig. 3).

CASE 3. Epithelial metaplasia in a cervical lesion (Fig. 4).

Age 35. Pregnant in third month. At 11 weeks gestation the uterine cavity is empty. A

section of the polypoid mass is removed for diagnosis. The uterine cavity is covered by a thin layer of stratified epithelium which is not more than three or four cell layers thick. The most superficial of which appear to be cylindrical. In the proximal part of the mass, the glandular and immediately beneath the uterine epithelium is a cluster of glands filled with epithelial cells that are not atypical enough to be designated cancerous, but more so than is usually seen in a simple erosion. The upper portion of the amount of metaplasia in these glands is compared with that on the surface is also an atypical change. It has been designated as a precancerous change and the clinician has been requested to make an early diagnostic excision in a month.

CASE 4. Small mucous polyp. Cervical rosion. Excess of epidermoid metaplasia (Fig. 4).

Clinical history. Age 40. Mother of 6 children last 3 years ago. Menstruation scanty. Discharge for some time lately tinged with blood. Cervix was lightly ectropic and just within the external os there was a very small polyp which was excised for diagnosis.

The histological examination shows normal cylindrical epithelium hanging abruptly into a slightly thickened stratum basale which presents

small atypical papillary growth with thick glands in this area. Normal glands are seen in Fig.

Fig. 7. Patches of cervical leucoplakia.

4 there are numerous papillary outgrowths mostly covered with normal cylindrical epithelium beneath which are numerous and irregular metaplastic glands, mingling properly with similar metaplastic outgrowths from an underlying hypertrophic gland. There is no trace of hornification, but there is proliferation of the deeper layers and grossly irregular outline of the glands. The quality of the cells, however, is mostly benign and the process appears to be a very atypical metaplastic change to which we would apply the term precancerous. The patient refused amputation of the cervix, but there is every reason to believe that she is well, one year after the examination was made.

CASE 5. Cervical polyp. Extensive papillary and epidermoid proliferation (Fig. 5).

Clinical history not available. The papillary structure is excessive, showing numerous areas with little if anystroma between contiguous papillae with apparently normal cells. In the field shown in Fig. 5 there is so much metaplasia and overgrowth that it is difficult to say that carcinoma has not already become established. There are traces of heterotopia and stroma invasion.

CASE 6. Papillary endocervicitis. Miniature islands of epidermization (Fig. 6).

Slide submitted to the laboratory for diagnosis. Clinical history and gross material not available. The section shows the sign of chronic inflammation

Fig. 8. Downgrowth from completely epidermized surface.

and slight papillary formation. The remaining of cylindrical cells is generally well preserved. In one or two areas there are very small islands of epidermization which possess the miniature form of leucoplakia. In another section there is a larger island showing the same change. The interval between these sections relates to the changes seen in Cases 7 and 8.

CASE 7. Leucoplakia of the cervix. Papillary proliferation. History of syphilis (Figs. 7 and 8).

Clinical history. Age 50, married 7 years, 6 children, 5 miscarriages. Typhoid fever at 4 years of age, scarlet fever at 4, measles at 40. At 4 years of age, lesions which appeared on both legs persisted until he was 6. When 30 was in hospital for 6 weeks with double otitis media and a disease of the throat which resulted in perforation of the palate. From an investigation made at that time it was learned that both her father and mother had syphilis before she was born. A brother also had the disease. She was treated for syphilis periodically for some time thereafter. At 33 she married and two children died. Menstruation as girl was painful and she had leucorrhoea. It has always been profuse and during the past five years irregular. The last period began seven weeks before admission to the hospital and continued for six weeks. She has recently had attacks of vertigo and pains in the legs.

Fig. 7. Histological section of the cervix showing a large, retroverted uterus with a thickened endometrium and a small intramural fibroid. The cervix is dilated and contains some areas of atrophic endometrium. A hysterectomy was performed.

Fig. 8. Metaplasia and proliferation in deep solid cervical glands resembling initial inflammation.

especially in the length of the foot so that it has been difficult.

First examination. There is a scar at the site of the perforation of the placenta and there are scars of old lesions in the neck posteriorly in the internal os. The site of the previous ulcer of the leg. There is a paralysis in the right leg. There are no symptoms. The Wassermann test is positive. The uterus is large and retroverted. There is no thickening of the appendages. The cervix is dilated and contains some areas of atrophic endometrium. A hysterectomy was performed. Cross section. The uterus is much enlarged but with the exception of a small intramural fibroid about the cervix there is no apparent tumor growth. The normal rugae of the cervical mucosa have entirely disappeared and the surface is covered with whitish yellow, lightly elevated patches which are millimetric in the region of the internal os. The mucosa of the cervix appears to be thin and on gill.

Histology. Section of the cervical canal shows a marked thickening of the stratified epithelium with little tendency to elongate with overlying a few dilated glands and broken by the openings of a few lightly hyperplastic glands. The chief features are shown in Fig. 7 in which numerous islands of epithelial cells are seen lying on and within

the papillary meshwork. The small papillae joining each other in such a way as to make apparent a number of newly formed glands. At intervals normal glands open upon the meshwork between which are small areas of epithelialized glands appearing like epithelial nests. In another area shown in Fig. 8 there is a slow growth from a more completely epithelialized surface representing the metaplastic transformation of a gland which because of the direction of the section resembles carcinoma nests. The mucosa of the cervix shows only the changes of an atrophic endometritis. Some sections of the troma show marked evidence of a chronic myositis. There is a focal overgrowth of small muscle cells with hyperchromatic nuclei distended lymph channels and numerous new blood vessels with thickened walls. We have then in a case giving a history of syphilis and other severe infections and presenting clinically strong suspicions of a cancer of the cervix typical patches of leucoplakia extending along the entire course of the cervical canal and grouped within areas of a papillary proliferation of epithelium. In other words there are the prototypes of two forms of malignant change — epidermoid carcinoma and papillary adenocarcinoma of the cervix.

Case 8. Epithelialization of the cervical mucosa. Leucoplakia. Cervical polyp. Tubo-ovarian abscess. (Fig. 9)

Fig. 1. Precancerous gland hyperplasia of corpus.

Clinical history. Age 33 single, no children. Had complained of profuse menstruation, discharge and pelvic pain. No history of leukoplakia. Examination showed large hard cervix which was markedly eroded. A clinical diagnosis of chronic endocervicitis with erosion was made and the cervix was cauterized. Diseased appendages were subsequently discovered and an operation revealed tubo-ovarian abscess on one side and pyosalpinx on the other. The gross material is not available.

Histology. A section of the cervix shows the cervical mucus transformed into a thickened layer of stratified squamous epithelium with marked tendency in areas to keratinization and well marked papillary downgrowth. In the field shown in Fig. 9 the metaplasia has extended to gland around the lower end of which is a thin layer of round-cell infiltration. The stroma shows marked hyperplastic change with numerous blood-vessels and perivascular areas of fibrosis. The cells of the epithelial layers are well differentiated but the basal cells show slight proliferation in some places. If similar process covered the entire mucus of the corpus, it would present a picture not unlike that in our Rosthorn (34) case of ichthyosis, which Hirschmann (35) and others have said is a metastasizing carcinoma.

Case 9. Isolated cervical gland showing metaplasia and proliferation. One gland in interstitial inflammation (Fig. 10).

No information is available regarding the clinical history or gross material. The gland appears to be isolated from the deep structure of the cervix and partly transformed into stratified epithelium which gives some evidence of proliferation. The quality of the cells is slightly typical. In other sections there is normal stratified surface epithelium overlying

Fig. 2. Advanced precancerous hyperplasia of corpus.

(Fig. 11) three superficial normal glands and total 14. A variation in the proportion of the glands in this gland is impossible to make but there is undoubtedly relation between the glandular changes and the peripheral interstitial inflammation. As prototype of tumor growth, think of those cases in which malignant growth begins directly as basal nodule within stroma of the cervix.

(Fig. 12) Precancerous gland hyperplasia of corpus (Clinical history suggestive of cancer) (Fig. 13).

Clinical history. Age 55. Menopause entered seven years previously. There had been continuous bleeding for eight weeks. Has been cured three times the last one week ago after which the bleeding ceased and has not yet recurred. The enlarged size of the uterus, bowels, has not yet diminished. The material removed by the first curettage is said by competent pathologists to present the same picture as that from the last operation which was sent to the laboratory for diagnosis.

Histology. There is advanced glandular hyperplasia and hyperplasia throughout all of the areas. The stroma, however, is abundant except in few places where the glands have become dilated into small cystic spaces lined by one layer of low cuboidal epithelium. In the area shown in Fig. 14

although there is no appreciable difference in the amount of interstitial stroma the glands in stroma

Fig. 3 Atypical proliferation in the endometrium

Fig. 4 Benign endometrial tumor

ture is essentially altered. The epithelial outgrowths and ingrowths are more prominent feature. The all show a tendency to be as much an irregular proliferation of the cells as the normal layer and the nuclei are hyperchromatic. Now with the retraction of breaking through the membranous propria. This case illustrates the immediate practical side of the problem. With such a histological picture the decision relative to therapy should be made by a competent clinician provided he has a proper appreciation of the histologist's interpretation of the expression precancerous. In this case a delay in radical surgical measures is planned.

CASE 1. Advanced precancerous hyperplasia of the endometrium. (Fig. 12)

Age 3. Atypical bleeding. The uterus is much larger than normal presumably because of the presence of an intramural fibroid.

Histology. The uterine material is decidedly different from that of Case 10 but it is doubtful if the hyperplasia is growth other than the fibroid will be found. The glandular hyperplasia is considerably more advanced but numerous of the stroma is uncharacteristically abundant to exclude a tumor process. In the area shown in Fig. 13 the glandular tissue together with the cell material in the lumen is thicker than that of Case 10. Their histological qualities are chiefly of the type of the hyperplasia.

Qualities of the cell protoplasm. Ingrowth and ingrowths are numerous and there appear to be a tendency to form more than one layer. Hyperplasia is faintly expressed. Because of the presence of the fibroid the decision in regard to the correct therapeutic procedure is easier to make. Unfortunately we have not yet received the gross specimen because the patient has thus far refused a radical operation.

CASE 2. Atypical epithelial proliferation. Acute endometritis (Fig. 13)

Clinical history. Age 28. One child six years previously. Several attempts have been made during the past year to hasten delayed menstrual periods. Atypical bleeding for several weeks. Curettage was performed.

Histology. The changes are mostly those of an acute endometritis. In a few areas however there are traces of epithelial overgrowth in which the normal quality of the cells is altered showing a few large irregular and hyperchromatic nuclei clumped not unlike that seen in giant cell formation (Fig. 14). From the benign character of the clinical history and the presence of an acute endometritis we are unable to attach much serious importance to these focal changes.

CASE 3. Benign endometrial tumor (Fig. 14)

The clinical history. A gross microscopical

available. The section is that of a cervix with normal surface epithelium and a few superficial erosion follicles. In Fig. 4 there is bow gland hypertrophy and hyperplasia of sufficient amount to closely approach that found in a tumor growth. It is situated deeply within the stroma without signs of inflammatory change. The lining cells everywhere preserve the normal type of mucous cell. It seems not improbable that such process is a prototype of that infrequent form of adenoma of the cervix, in which the mucous cells preserve their normal type after the glandular growth has reached bulky proportions and become clinically malignant.

SUMMARY

It seems to the writer that the evidence in the literature and the material which he has presented justifies the following comments.

1. As the positive identification of a malignant neoplasm can not be made histologically until definite destructive capacity is recognized it seems reasonable to relate more definitely the other histological criteria of cancer to the developmental stage of its growth, the closeness of the relation in a specific case depending upon the quality and quantity of such criteria as may be present.

2. If so we find in the study of uterine pathology numerous morphological alterations of epithelial growth which differ but little from the regenerative activity of benign lesions but which after a longer or shorter time show features that are differentiated with difficulty from the alterations we know typify malignant neoplasm.

3. The strongest support of this assumption is derived from the reproduction of types which are seen in the different stages of their progress. We find the atypical features of a healing erosion for example determined by the original type of the primary erosion—simple papillary follicular and we find the atypical types again reproduced in the different types of fully established uterine cancer. In the writer's cases there are atypical healing erosions which are prototypes of either an epidermoid cancer or a papillary adenocarcinoma. There are leucoplasias which are prototypes of adult acanthomata. There are glandular hyperplasias which lead to adenoma or adenocarcinoma. Finally there are focal areas of leucoplasia combined

with adenomatous hyperplasia which may well furnish an origin for tumors designated as adeno-acanthomata. In short, for each type of fully developed carcinoma there is a corresponding type of benign and intermediary change.

4. Clinical observation increasingly confirms the sequence of definite benign lesions in the uterus and cancer but its evidence is thus far too scanty either to confirm or deny their histogenetic relations. In order to work out this problem a closer co-operation is required between the clinician and the pathologist with the idea constantly in mind that the morphological features of intermediary stages may exist. It is no argument against such an assumption because no tumor process presents or follows in a given case. The evidence is already sufficient to show that a fully established cancer may exist for a certain time without giving gross evidence of its presence and numerous cases are recorded in which the curette has completely removed the disease.

5. There is no reason to assume that precancerous changes without treatment always develop into malignant growths. We know different types of fully established tumors have a different capacity to grow and destroy rapidly or slowly and it does not seem reasonable to assume that a developing cancer has the same momentum that a fully established tumor possesses.

6. In the study of beginning cancer of the uterus Sitzsney (20) Schauenstein (21) Schottlaender Kernhauser (4) and Pronai (53) direct attention to the important observation that a certain type of early cancer spreads superficially over wide areas before showing marked invasive feature. It has occurred to the writer that such a mode of growth may account in some measure for the widespread extent of the process before it receives the attention of the clinician.

7. From a practical standpoint the decision regarding the proper therapeutic procedure in these cases should be assumed by a competent clinician.

The writer desires to express an appreciation of his indebtedness to Professor James Ewing for numerous criticisms and suggestions and

also to thank Drs L. Esperance Caturani and Mallett for much of the clinical and pathological material

A DETAILED STUDY OF THE PATHOLOGICAL CAUSES OF STERILITY WITH THE END-RESULTS¹

BY JOHN OSBORN POLAK MSc MD FACS BROOKLYN

Professor of Obstetrics and Gynecology Long Island College Hospital

PROBABLY no question is of such sociological significance to the gynecologist as that of sterility. Homes are wrecked lives are sacrificed and fortunes lost, all because of the inability of a woman to conceive or to successfully bring forth the fruits of her conception. Certainly no subject taxes the resourcefulness and ingenuity of the gynecologist more. Do what we will many women from one cause or another are destined to remain fruitless.

It would seem from an extensive study of

our case records that the number of sterile women is increasing at least an increasing number is applying for relief. Yet a large majority of those who apply present such gross lesions that little or nothing can be done to help them.

We may define sterility as the inability on the part of the woman to produce a living child. This inclusive definition is propounded so that we may include in this discussion the part which syphilis plays in the etiology. Sterility may further be divided into the so-

called primary sterility where the woman has never been pregnant, and the secondary type where she has borne a child or has had a miscarriage and remains sterile thereafter. In this study which is a personal review of 798 case histories of patients from the writer's private practice we will attempt *first* to analyze the many etiological factors which have entered into the causation of this symptom *second* to discuss the treatment of the individual case based upon an etiological diagnosis, and *finally* to summarize our end results, in the hope that this contribution may add something to this already overwritten but unsolved subject.

It must be primarily admitted that conception depends *first* upon the perfect consummation of the sexual act *second* on the proper fecundation of the ovum, and *third* on the proper nourishment of the impregnated ovum during its growth and development after its final location in the decidual bed. It is thus apparent that certain conditions are essential for conception. Findley has tersely summarized these as follows:

- 1 The deposit of semen containing active living spermatozoa in the upper portion of the vagina.

- 2 The passage of the healthy spermatozoa to the ovule through the cervix into the cavity of the uterus and into the tube.

- 3 A healthy ovum which has unhindered transit from the ovary and after impregnation, through the tube into the uterine cavity.

- 4 A decidual bed for the impregnated ovum to find a permanent resting place in the endometrium until the period of viability.

These conditions entail a healthy male producing a healthy active, well-developed long ciliated spermatozoid capable of rapid movement through the semen. Furthermore, the seminal discharge should be free from infective bacteria. For these reasons, the husband of each woman in this series has been subjected to a most exacting examination by a competent urologist. This examination has not only included an investigation as to the potency but as to the presence of past or present infective disease. The passage of the spermatozoon through

the cervix is dependent upon the activity of the particular spermatozoon and the amount character and reaction of the glandular secretion from the cervix. Acids in very weak dilutions are destructive to the spermatozoa and thick muco-pus acts as an almost insurmountable barrier to the progress of the male element.

Proper ovulation depends on the efficiency of the individual ovary. This implies a healthy egg bearing area and the free delivery of the ovule through the ovarian tunic. Consequently conditions which have resulted in a thickening of the tunic militate against conception. Chronic inflammatory changes, prolonged acute infection, fatty degeneration, tumors, adhesions and senile atrophy all impair the egg-producing quality of the ovary as well as tend to thicken the tunic to such an extent that ovular rupture may be prevented.

The proper transit of the ovum from the ovary to the uterus requires a healthy patent fallopian tube. Fecundation is supposed to take place at the outer end of the fallopian tube, from whence the impregnated ovum is propelled along the course of the tube into the uterus where the endometrium has been prepared by the development of a decidua for its reception and permanent nutrition. Hence conditions which interfere with this free transit may be accepted as causes of sterility. While a tube may not be patent to an impregnated ovum, its lumen may still be sufficient to allow the passage of the spermatozoon and impregnation of the ovule in its distal portion. This is shown by the great frequency of tubal pregnancies, occurring after long periods of sterility which are due to the results of chronic inflammatory disease.

The conditions of the tube which may impair the transmission of the impregnated ovum are either congenital or acquired. Of the former we may mention tortions, constrictions, angulations, and diverticula, while acquired lesions are commonly the result of inflammatory processes, which either occlude the lumen or destroy the epithelial lining of the tube or produce peritubal adhesions which distort the tube and thus prevent the passage of the ovum.

On arriving in the uterus the impregnated ovum locates in the decidual bed prepared for its nourishment which usually is situated just below the uterine ostium of the tube on the anterior or posterior wall of the uterus and unless the endometrium has been the seat of disease the ovum develops at the site of its primary implantation. Syphilis of the endometrium may prevent implantation of the ovum or cause its early discharge from the uterus. Circulatory derangements which produce hyperplastic and fungoid changes in the endometrium contribute largely to the unrest of the ovum. These circulatory changes may be produced by displacements, fibroid tumors, sexual excesses, lacerations and subinvolutions and result in an endometrial hyperplasia. Such conditions change the character of the uterine secretion producing toxic discharges from the involved surfaces of both the body and cervix which may cause the death of the sperm cell and thus produce another factor which is antagonistic to the occurrence of pregnancy.

The foregoing may therefore be considered the essential factors in the fecundation and the development of the impregnated ovum. Hence it may be deduced that where any of these elements are defective sterility may result. McDonald claims that there is primarily a congenital anomaly (hypoplasia of the genitalia) in the etiology of all cases of primary sterility. This however has not been the experience of the writer who has found that a preceding salpingitis has been responsible for more cases of sterility than all other causes combined.

It is commonly admitted that the general health of the woman has much to do with the occurrence of pregnancy. It is also known that men become less potent from the strain of overwork and that nervous excitability decreases the individual's potency. Women who have become rapidly obese are not infrequently sterile. Hence it will be seen that each individual case must be analyzed as to its etiology before any form of treatment can be considered and this analysis must include an investigation of both contracting parties for in our opinion the operative treatment of a woman for sterility alone

without the actual inspection of her husband's spermatozoa is not only unjustifiable but frequently does actual harm to that woman and brings discredit to gynecology. Reynolds in a recent paper presented before the obstetric section of the American Medical Association offers the following working hypothesis for determining the cause of sterility in the individual case:

1. He states that when the spermatozoa are abundant in number, normal in form and appearance, furnished with long cilia and capable of rapid movement through the semen, the male may be considered as *satis factorily potent*. While this is essentially true, our experience has taught us that the presence of infective bacteria in the semen or prostatic discharge, even if the spermatozoa are well formed, will often vitiate their potency because of the effect produced by these bacteria on the generative organs of the receiving female.

When the normal spermatozoa are killed or lose their vitality overrapidly in the secretions of the individual woman, the chemico-physiologic character of her secretions furnishes an effective cause for the sterility.

These alterations in the secretions of the woman which are fatal to the spermatozoa may be located in the vagina, in the cervix, in the body of the uterus or in one or both tubes. Any of these secretions may exist with normal secretions above it but alterations in the secreting surface in any of these localities usually vitiates all the secretions below it owing to the admixture which takes place for acids in very weak dilution are rapidly fatal to the spermatozoa. Finally when the spermatozoa are observed to penetrate without apparent loss of vitality to the fundus of the uterus and to survive there for a normal length of time, *deficient quality of the ova* may be considered as the probable cause of the sterility. Lade estimates that there are 2,500,000 spermatozooids in a single ejaculation and it is stated that the spermatozoa will not live longer than twelve hours in the acid secretion of the vagina, yet in the normal secretion of the uterus and the tubes they will commonly retain their activity and vitality for 12 or eight days. In

Leopold's case the woman had not had sexual intercourse for thirty seven days prior to the abdominal section which he performed when active living spermatozoa were found in large numbers in the fimbriated end of the tube. We have frequently noted during microscopic examination of the withdrawn semen the effect of the mucopurulent secretion from an infected cervix on the activity and life history of the spermatozoa. They may be seen struggling around trying to free themselves from the sticky mucus and finally exhausted from their struggle to push on die. Hence we feel that the tight fitting plug of mucus in endocervicitis is a real obstacle to the advance of the spermatozoid. Lescapasse claims that the secretions in different women dissolve the spermatozoa of different men and thus produce a sort of immunity action. This is probably the explanation of why certain healthy women fail to conceive by apparently healthy males and then upon re marriage promptly conceive.

Huehner has checked up the progress of the spermatozoid by microscopic examination of the spermatozoa *in situ* in the genitals of the woman by taking the woman's secretions at different locations at definite periods after the intercourse and in this way has determined the action of the secretions and the comparative vitality of the spermatozoa at different locations in the genital tract. This has in his experiments given a direct index of the chemicophysiologic action of the individual secretions and affords valuable evidence as to the possibility of impregnation in a particular case.

While acute ante flexion of the cervix, in fraccervical hypertrophy and pronounced retroversion of the uterus act as causes of sterility by mechanically removing the cervix from its position in the seminal lake they will not prevent conception unless there is some change in the chemicophysiologic action of the cervicovaginal discharge.

Aside from these factors already referred to certain clinical observations are worthy of mention as they contribute materially in determining the value of treatment. The average interval between marriage and the birth of the first child is seventeen months and

the probability of impregnation decreases thereafter. Only 25 per cent of women bear their first child after four years. Therefore a union may be regarded as presumptively sterile when after three years of married life no child has been born. Hypoplasia of the genitalia is a common cause of sterility. In infantilism may be found in the uterus alone or in the uterus, vagina, and external genitalia, or associated with other evidence of congenital hypoplasia as loose right kidney, just minor or funnel pelvis, long back, cannonball abdomen, intestinal ptosis, small head, weak ligaments, high roofed mouth under weight and unstable nervous system. When the uterus is *infantile* it retains the shape and appearance of the uterus of the girl before puberty. It may take one of two types it may be long and slender with a small fundus, a long isthmus and a long conical cervix, or it may be shorter with a long isthmus, small fundus and a small cervix, with most of the cervix placed above the insertion of the vagina and but little projecting into it. The first type has usually a marked ante flexion while the second is frequently associated with marked narrowing of the vagina in its upper part. The infantile uterus usually has a long isthmus with the plicae palmatae of the mucosa of the isthmus well marked and longitudinal instead of being thin and horizontal or twisted. The vagina is commonly involved with infantilism of the uterus. This takes the form of a narrowing particularly of the upper part of the vagina, thus obliterating the seminal lake consequently instead of being balloon or pear shaped with the largest end upward, the vagina is tubular or sausage-shaped. As a result of this the semen is not retained where it should be after coitus but is expelled from the vagina. Fruitful normal women retain the semen, while sterile women usually lose it. The vulva may also show signs of infantilism e.g. lack of development of the labia majora or labia minora.

In managing our cases of sterility we have begun with a thorough investigation of the life and functions of both contracting parties. In no case included in this report was the examination of the male omitted. These examinations were conducted by J. S. Read

and include investigation as to the past performances of the man as well as for his present potency for men who have infective bacteria in their prostatic secretion can produce such inflammatory changes in the female genitalia as to prevent all hope of future pregnancy

Unless the man was potent, no attempt was made to improve the condition of the woman as regards her sterility though many women were operated on for the cure of complicating lesions. If the man was found potent the woman was put through a thorough and painstaking routine beginning with her previous history including the history of her development, illnesses, nutrition, habits of occupation, rest, and general health. Inquiry was always made into the habits of her sexual life. This was followed by a general examination of the heart, lungs, nervous system, stature, nutrition, whether emaciated or obese and followed by a pelvic examination to determine the presence of anomalies at the vulva, of the vagina in the cervix or uterus or the presence of the results of infection as shown in Skene's glands in Bartholin's glands in the cervix in the uterus, tubes, ovaries, and adjacent peritoneum.

The reaction of the vaginal and cervical secretions was thoroughly investigated and the presence of gross pathology in the fornices noted. A Wassermann test was made in all of those who presented themselves with histories of abortions or premature labors with death of the fetus. To make this study 798 case records have been reviewed. Two hundred and thirty one were found to be inaccurate or incomplete, the patients failing to return for subsequent examination or the husband's record having been omitted or for some such reason these histories were excluded from our consideration making a total of 567 from which we can draw our conclusions. From this number however there must be some further deductions such as those cases where the man was impotent, having aspermia or deformed and sluggish spermatozoa or where the original infection remained uncured. These cases total up to 64. Furthermore we have excluded those women who were found to have such gross lesions of the uterus and adnexa as to har-

them from even the possibility of pregnancy and those constitutional conditions as cardiac decompensation and diabetes which should forbid conception. Of the former there were 70 of the latter 6. Subtracting these cases we begin with 427 women in whom pregnancy is a possibility. Many of these however presented such pathology that we could not say that conception was even probable. For this reason I propose to consider the etiology and the end results of the several forms of treatment instituted in two general classes. In the one we will include infantile and congenital anomalies: 73 normal pelvis free from circulatory or inflammatory complications, 146 uncomplicated retroversions, 20 and infracervical hypertrophy, 5 making 244 in all. While in the second class we will place the remaining 183 cases all of whom presented some evidence of the results of an infective process at one or more locations along the genital tract. It is intensely interesting to note the frequency with which infection has invaded these several susceptible points. Our records show that the glands at the introitus were infected 43 times while 104 presented an endocervicitis with a mucopurulent discharge. These were complicated with a posterior parametritis in 78 instances. Fibroid tumors of varying size and of the subperitoneal type producing no symptoms and only discovered in the course of the examination were recorded in 54 cases. Ovarian cysts varying in size from that of an orange to that of a seven months pregnancy was the apparent cause of sterility in ten instances. The results of infective processes in the tubes were found in 90 cases. These were almost always associated with inflammatory or cystic changes in the ovary. In 11 cases the tubal infection had extended to the pelvic peritoneum and the patient though presenting no gross lesion which was palpable at the examination was the subject of recurrent attacks of pelvic peritonitis. In each of these cases a double hydrosalpinx was the resulting lesion. Retrodisplacement of the uterus complicated by tubal or ovarian disease was noted in 61 women. Prolapsed ovaries palpable and tender often producing

severe dyspareunia, were relatively frequent, as we find that they were noted as a complicating lesion in 92 histories. Only three patients with acute vaginal inflammation presented themselves. In 2 of these the *Neisserian* bacillus was isolated. The other showed numberless diplococci that would not stain gram negative.

In the first class which includes all the cases of infantilism, mention should be made of the frequent association of bony pelvic anomaly. Funnel pelvis, male pelvis and justo-minor contraction were noted with such frequency that we feel that the subject should have more consideration than has been given it by the gynecologist in the past, for it seems questionable when a woman has a definite bony pelvic deformity whether we are right in employing operative measures for the cure of her sterility when we know she will have a difficult operative labor. Certainly the patient or her husband has a right to the knowledge of these facts. In the 73 cases recorded as having an infantile uterus, bony pelvic anomaly was recorded 41 times. This was shown in the short external measurements, the depth of the symphysis pubes a narrow subpubic arch, the short bischial diameter or faulty inclination of the pelvic brim.

TREATMENT

The treatment, as may be supposed from a glance at the foregoing statements, was in all cases directed toward the correction of the existing causative lesion. In the first class, this included the employment of alkaline douches, of the graduated dilators, the Baldwin or Davenport stem, dissection of the cervix, after the methods of Dudley or Ponsi amputation of the cervix, and correction of uterine displacements.

In the second class both local and operative measures were employed. In those cases of uncomplicated cervicitis and endocervicitis where the tenacious mucous plug presented the obstructing lesion the mucous was removed with peroxide of hydrogen on a rotary applicator or with a Bier suction apparatus and the mucosa sterilized and an iodized phenol solution applied and the patient directed to follow this application with

douches in the recumbent position before retiring using a solution of bicarbonate of soda, a tablespoonful of the soda to a quart of water. Vaccines and destruction of the cysts with the electric cauterizing knife have also been employed, but our best results have been obtained from simple antiseptic measures. Women who have repeatedly aborted in whom the Wassermann test was reported negative were curetted and the cavity of the uterus thoroughly iodized by packing the uterus with strip gauze soaked in iodine. *This was left in place for twenty minutes* and was then removed. These patients were then advised not to cohabit for a period of three months. In the meantime special attention was given to improving the condition of their general health, by exercise, tonics and fresh air. Those presenting large fibroids not involving the uterine cavity had the tumor removed by myomectomy. Small tumors received no surgical consideration. In the 10 cases of large ovarian cyst unilateral oophorectomy resulted in 8 of the women becoming pregnant. From this observation it would seem that a large cyst of one ovary militated against the proper functioning of the other ovary until that cyst was removed. Infective processes in the tubes were dealt with by unilateral ablation, bilateral ablation with resection of the uterine ends or of the fundal segment of the uterus, or by salpingostomy. Frequently it was found that the inflammatory process had passed through the tube and time had allowed considerable resorption, and that it was the resulting adhesions which had closed the abdominal ostium and embarrassed the ovarian function. Freeing these and suspending the ovary has frequently resulted in pregnancy. In the series of retroversions complicated by tubal and ovarian disease all the women were subjected to abdominal exploration and investigation. In these the tubes were freed from adhesions, ablated or resected the ovaries suspended after the method suggested by my associate William P. Pool, and the round ligaments shortened by following one of the techniques suggested by Webster Gilliam Montgomery Coffey or Neel.

Of the cases of prolapsed ovary we have

found that an ovary out of place has its tunic thickened from circulatory stasis. So we have been in the habit of suspending such ovaries after puncture of the superficial cysts to reduce their weight and have thus established a better ovarian circulation. No resections have been done except in six cases of large white ovary in obese women with amenorrhœa where the tunic was extensively thickened. In these cases a large wedge-shaped piece of the cortex was removed and the area of excision closed with fine catgut sutures. This has re-established menstruation in all six cases and resulted in a pregnancy in three.

In the 13 cases of congenital anomalies which include extreme anteversion of the cervix with deep posterior invagination, anteversion of the body and cervix and infantile uterus the following corrective operations were done. In the anteversions of the cervix in which the invagination of the posterior lip was 4 to 5 centimeters or more in length a posterior dissection after Dudley's technique was always elected in order that the cervical os so constructed could be placed in the seminal lake. In the anteversions of the body alone we have elected Reynolds' procedure combined with the use of the intra uterine stem (Baldwin). In anteversions of the body and cervix our procedure has always been dependent upon the amount of cervical invagination. If this was considerable a posterior dissection in conjunction with the Reynolds anterior colpotomy will straighten the canal. On the other hand when the portio was short gradual dilatation, an anterior colpoplasty and the introduction of a glass stem often produced relief.

In the true infantile uterus it is questionable whether much should be done. Our only pregnant result in this type have been two ectopics and five miscarriages, for not only is the anomaly in the uterus but in tubes, ovine and vagina and the dysmenorrhœa which is prominent is only temporarily relieved by operation. In this class we doubt if any plastic procedure is of much avail as we have found that the presence of scars in a small vagina embarrasses sexual relations. Slow dilatation with Hegar's sound up to 16 to

20 millimeters and the introduction of a Davidson stem has afforded some relief but no infantile uterus in this series has developed a pregnancy and gone to term. Seven have conceived, the two ectopics referred to above and in 5 the impregnated ovum has reached the uterus and developed there only to end in an abortion at the second or third period.

Included also in our first general classification are 146 normal pelvis free from circulatory or inflammatory changes of any sort. These women had been married for periods of three years or more and had never been pregnant before applying to us for relief. The husbands were potent. The reaction of the secretion of the vaginal vault was determined in each case. One hundred and nine showed varying degrees of acidity. Examination of the semen *in situ* in these cases showed many immobile spermatozoa. In all who gave an acid reaction alkaline douches of soda bicarbonate and soda phosphate one ounce to the quart were advised to be taken on a douche pan after retiring. Pregnancies resulted in 75 or about 70 per cent making this our most successful series. Thirty-seven showed no change in secretion yet only 4 have become pregnant is the result of local treatment. No operative procedure of any sort was done in this apparently normal pelvis class. This rather goes to confirm the theory that certain women are immune to impregnation by certain men.

Of the 20 uncomplicated retroversions 11 were repositionable and could be maintained in position with a pessary. Six of these women became pregnant while 9 because of a deep posterior invagination of the cervix could not be held in place with a support. These were operated on by the Webster-Baldwin-Gilliam technique and a Dudley dissection. Of these 5 have become pregnant. This shows conclusively to my mind that the position of a cervix in its relation to the seminal lake has much to do with conception provided the secretions are not destructive to the life of the spermatozoa.

Intravaginal hypertrophy of the portio has given us not only the best surgical cures but amputation of the hypertrophied portion of the cervix has been followed by pregnancy.

going to term in each of our cases (5 in all)

In the second class made up of 183 women presenting some evidence of the results of an infective process, postpartal postabortal or gonococcic in origin pregnancy has been relatively infrequent. Of the 104 women subjects of endocervicitis with a mucopurulent discharge only 21 became pregnant. Eight conceived as a result of one local treatment in which the mucous plug was removed with a bicarbonate paste and the canal swabbed with iodized phenol. Three became pregnant promptly after the glands were destroyed with the cautery and 10 following the persistent use of the carbonate of soda douche.

Of the 90 cases which were found to have the results of infective processes in the tubes uterosacral ligaments and cervical canal the intra uterine and tubal pregnancies are equally divided, there being three of each. The abdomen was opened in all of these patients because of the history not because of the gross pelvic findings. There was invariably present a history of infection, with sterility dyspareunia and local discharge. Tubal ablations were done 35 times resections 31 times, and freeing of adhesions in 30. Two ectopics occurred in resected tubes, against 3 intra

uterine pregnancies. One ectopic occurred in a freed tube but no uterine pregnancy. Of the 54 fibroids, myomectomy was done in 20 and hysterectomy in 34. Six pregnancies occurred following myomectomy 4 going to term. Following the 10 unilateral oophorectomies for large ovarian cysts, 8 women became pregnant.

One hundred and thirty two uterine and 3 ectopics are the sum total of pregnancies occurring in 358 women in whom conception was a probability or 37 per cent.

This study has shown us that—

1. A very large number of the sterility cases applying for relief have no chance whatever of becoming pregnant, as the pathology is such as to make conception impossible.

2. The male is largely responsible for our poor results in treatment.

3. There is a definite chemicophysiologic factor in conception at present unexplainable, which is a cause of preventing conception.

4. Operative procedures on the uterus, except amputation of the hypertrophied portion have but a slight influence on the end results in the treatment of sterility and finally that each case must be individualized and both contracting parties carefully studied before any treatment is inaugurated.

SYPHILIS OF THE BODY OF THE UTERUS¹

By CHARLES C. NORRIS M.D. F.A.C.S. PHILADELPHIA

FREQUENCY

THE antiquity and frequency of syphilis is well known. It has been estimated that from 10 to 15 per cent of the urban population of certain European cities is syphilitic. In some of the hospitals in this country the percentage has been found considerably higher than this. The disease is from two to four times more frequent in men than in women probably from 1 to 4 per cent in women would be a conservative estimate.

It is only since the discovery of the spirochæta pallida in 1905 and the development of

the Wassermann test two years later that the true frequency of this form of infection has become recognized.

In spite of the prevalence of syphilis it is remarkable how seldom the disease has been observed in the body of the uterus. In a review of the literature one cannot but be impressed by the paucity of reference and our incomplete knowledge of this subject. A review of the *Index of the Surgeon General's Library* to 1914 showed but thirty-six references by thirty-one authors, and reference to the *Index Medicus* from 1909 to date disclosed only eight contributions to the sub-

¹Read before the American Gynecological Society, Washington, May 18, 1916.

ject The majority of the modern gynecologic textbooks have either no reference to syphilis of the body of the uterus or at most the subject is dismissed in a few sentences. A pleasing exception is noted in the recent work of Krankl¹ in which a chapter is devoted to syphilis of the uterus. This contains an excellent review of the literature. Our reviews showed rather frequent reference to syphilitic manifestations localized in the cervix such as chancre mucous patch gumma and a condition which the obstetricians term rigid cervix which is prone to produce dystocia. Lesions of the cervix however do not fall within the scope of this paper so that we shall omit them and consider only syphilis of the uterine body.

PATHOLOGY

Various classifications for the syphilitic lesions of the body of the uterus have been suggested. The amount of material from which to draw conclusions is as yet rather small. Many cases have been reported as syphilis of the uterus which are at least of doubtful authenticity. This is especially so of the period prior to 1905. In many cases uterine hemorrhages have been attributed to syphilis which are open to doubt.

It is theoretically possible that the endometrium may be the seat of a primary sore. This is however unproved. The fact that the spirochæta pallida may become attached to or even possibly enter spermatozoa is well recognized. In recent years the frequency with which cases of syphilitic infection in women without evidence of a primary sore being demonstrable have been recorded make this possibility worthy of consideration. On the other hand it is well proved that the spirochæta pallida exhibits a strong predilection for squamous epithelium in the primary infection. This however may be the result of misplaced reasoning as the areas naturally most exposed to chancre are covered with this type of tissue. Two other explanations offer themselves for those cases in which no primary sore has been demonstrated the one that the disease has been hereditary and

the other that the chancre has been present in the vagina or cervix and has been overlooked. The fact that chancres produce mild symptoms and are consequently not looked for offers a probable explanation in many cases. It must be remembered that in women a chancre does not leave behind it such definite evidence of its previous existence as it does in men and that the period of its existence is more transitory than in the male. The possibility of the primary sore occurring within the body of the uterus should however be considered.

In 1911 Hofman² presented before the Society of Obstetricians and Gynecologists in Berlin an interesting specimen of gummatous endometritis. The patient from whom this specimen was obtained died of chronic sepsis a few weeks after delivery. At post mortem gummata and other evidences of syphilis were demonstrated in organs other than the genital tract. The endometrium in this case contained numerous small gummatous-like tumors the tissue lying between these was infiltrated with small round cells and presented other evidences of a subacute or chronic inflammatory reaction. For the most part the normal constituents of the endometrium were unrecognizable being replaced by the gummatous tissue. This in some areas was two or more centimeters in thickness. The entire endometrial cavity was more or less involved. The uterine body was enlarged and softened.

A more common form of syphilitic endometritis manifests itself by changes in the glands and stroma the latter being chiefly involved. It is characterized by changes in the blood vessel walls and condensation of the stroma. Exactly how frequently this condition exists is not known. Chase³ recent conclusions regarding the frequency of syphilitic endometritis in general require further confirmation. Recasen⁴ has described a form of syphilitic endometritis in which the mucosa is thickened and hyperplastic. Ulceration of the endometrium is not infrequent and resulting scars may also be

⁴Recasen, 8, Ann. d. Acad. d. obst. (etc.) Madrid 9, IV, 95.

observed. This is particularly likely to result during the tertiary stage. Such lesions have been described by Franceschini. The histologic picture in specimens of syphilitic endometritis probably varies not only with the stage of the disease but with the period of the menstrual cycle in which the tissue is examined. The underlying musculature is usually more or less involved. Whether or not mucous patches or other secondary manifestations occur in the corporal endometrium is unknown. Many authors¹ (Franceschini, Chiarleoni, Rille Fasola, Spinelli, Morisani and La Torre) believe that such lesions are not uncommon and that in some instances they produce leucorrhœa, dysmenorrhœa, and uterine pain.

Lesions of the myometrium may be divided into (1) a more or less diffuse metritis which is usually accompanied by an inflammation of the endometrium, and (2) gummata. In the former condition the uterus retains its normal shape, it may or may not be enlarged and is usually harder and firmer than normal. In at least one reported case the uterus was atrophic. The walls of the uterus are lacking in their normal elasticity and in some instances have been almost cartilaginous in consistency. An œdema of the uterus and per uterine tissues has also been observed. In syphilitic metritis the blood vessels as a rule present the chief changes. The lesions are not peculiar to the uterus but are those common to syphilis of the more frequently attacked areas of the body. Morisani² as a result of histologic studies of syphilitic uteri considers angiosclerosis of frequent occurrence. Findley³ in his excellent textbook considers this subject in detail and apparently concurs in this opinion. A fibrosis of the uterine musculature accompanies the blood vessel changes.

Gummata of the uterus may be single or multiple and vary considerably in size but are usually moderate in dimension, and

differ in no respect from similar lesions arising elsewhere in the body. A student of the literature pertaining to the pathology of syphilis of the uterus cannot fail to be impressed with the paucity of well authenticated cases and with the fact that as yet our knowledge of this subject is far from complete. From a clinical standpoint the question of so-called syphilitic uterine hemorrhages is of perhaps the greatest interest. The common practice of attributing symptoms which clear up under antisymphilitic treatment in patients exhibiting a positive Wassermann test to a syphilitic origin is at least open to scientific doubt. Probably the bleeding in many of these cases is properly attributed to syphilis, but on the other hand with a disease as frequent as syphilis and taking into consideration the numerous and often obscure non syphilitic conditions which cause hemorrhage it is but reasonable to assume that combination of these may occur and the hemorrhage be in some instances due to a condition totally apart from specific origin. The writer believes that this is a fertile field for further investigation. With the increasing facilities with which the *spirochæta pallida* may be demonstrated and the fact that curettage is a frequent and in many cases a justifiable method of treatment of uterine hemorrhages of obscure origin it would seem not a difficult procedure to work up a series of cases from which a definite basis of histologic study could be made. If for example a series of specimens in which the *spirochæta pallida* was demonstrated was obtained and these were then studied from a histologic basis the results of the latter would go far to establish upon a firm basis the pathology of syphilis of these structures and we would then be in a position to state positively whether or not certain histologic changes were sufficiently characteristic to warrant a diagnosis of syphilis or whether we should have to depend upon the demonstration of specific organism. With the possible exception of gummata it is doubtful whether a histologic verification is sufficient.

The German views pertaining to this subject are well expressed by Meyer.⁴ He states

that very little is known about the syphilitic inflammation of the uterus but that Doederlein¹ Weber and others are of the opinion that there is no characteristic change in the uterine mucosa which can with certainty be described as syphilitic

SYMPTOMS

These naturally vary with the character of the lesion. With the present unsatisfactory status of the pathologic changes produced the symptomatology is necessarily uncertain. Undoubtedly hæmorrhage is the symptom which has attracted the most attention. We have already mentioned the fact that hæmorrhage is frequently attributed to a syphilitic origin without convincing proof. Hæmorrhage is by no means a constant symptom in endometritis or metritis in general although variation and menstruation are of frequent occurrence. In such conditions the ovaries are usually more or less involved in the inflammatory process and whether or not the menstrual irregularity occurring in these cases is the result of the uterine or the ovarian involvement is open to doubt. This naturally opens the entire and much debated cause of such hæmorrhages. Time will not permit a discussion of this subject; it suffices to say that the author is of the opinion that inflammation in either the ovary or the uterus may under certain circumstances result in menstrual irregularity but that in the majority of cases the ovary is the governing factor.

The most frequent form of hæmorrhage described is menorrhagia. In 1906 Dreyer² collected from the literature fourteen cases of hæmorrhages attributed to uterine syphilis. A year later Muratow³ called attention to the fact that syphilitic hæmorrhage from the uterus is not so rare as we might think and as evidence of this he mentions the cases of hæmorrhage which do not respond to the ordinary styptics and curettage but do well under specific treatment. He points out that in such cases the uterus may be neither enlarged nor painful but is firm in

consistency and the cervix often hypertemic. Hæmorrhages in young girls Muratow⁴ believes are frequently due to a latent form of hereditary syphilis. In 1909 Falk⁵ demonstrated before the Berlin Obstetrical Society a case of luetic ulcer of the portio associated with syphilitic metrorrhagia which disappeared under specific treatment. Recasens⁶ reported six cases of syphilitic metritis five of which were cured by treatment but in the sixth case carcinoma of the fundus was suspected and a hysterectomy was performed but upon microscopic examination no cancer was found. Merowsky and Frankenstein⁷ have described three cases of tertiary syphilis in which amenorrhœa persisted for 6 years in two cases and for 8 years in the third. In two of these the menses returned after the exhibition of specific treatment and the third menstruated vicariously through the nose after treatment was instituted. These authors attribute the amenorrhœa to either constitutional causes such as often produce amenorrhœa in subjects of pulmonary tuberculosis or to a syphilitic oophoritis.

McIlroy Watson and McIlroy⁸ applied the Wassermann test to one hundred gynecological patients in only six of whom was there a clinical history of syphilis.

The test was positive however in forty-three cases negative in forty-eight while in the remaining nine cases it was doubtful. They state that their results show that cases in which uterine hæmorrhage apart from tumor is the principal feature syphilis very frequently is present. They are also in accord with Muratow (cited above) in the belief that some of the cases of menarchial hæmorrhage are of syphilitic origin. Further work along this line has been done by Whitehouse.⁹ He studied sixteen patients with a clinical diagnosis of chronic metritis and subjected them to a Wassermann test. Only one patient furnished a history of lues. All of the others strongly denied such a

possibility and there was no reason to doubt them. In spite of this, however seven cases gave a well marked positive reaction. These patients all applied for treatment on account of pelvic pain irregular and profuse uterine hæmorrhage and watery or mucopurulent discharge.

The physical signs obtained upon bimanual examination were those usually regarded as characteristic of chronic metritis namely a slight but uniformly enlarged uterus, firm in consistence, and tender upon palpation. The specimens removed from these cases show well marked fibrosis and peri and endometritis. Whitehouse believes that a true gumma does not occur in the corpus uteri. He also calls attention to the fact that although pyometra is usually attributed to malignant disease, he has observed two cases and records two others from the practice of another physician in which pyometra occurred in patients with well marked tertiary lesions and no evidence microscopically or macroscopically of malignant disease. He has never been able to demonstrate the spirochaeta pallida either in sections of the uterus or in the menstrual blood but is impressed with the necessity of testing by the Wassermann reaction all patients who present the clinical picture of chronic metritis or fibrosis.

As in all inflammation involving the endometrium and myometrium leucorrhœa is a not infrequent symptom. Various types of leucorrhœa have been described. Neumann¹ believes that the discharge is usually thin and moderately profuse. Pain, dyspareunia and other symptoms common to non-syphilitic metritis have been noted. As a matter of fact none of the local subjective symptoms are by any means characteristic of syphilis. The following is the report of a case of probable syphilis of the uterus.

Age 36 years white married 3 children, 3 miscarriages. Family history negative. Chief symptoms menorrhagia.

Personal history. Until the past five years has been a strong healthy woman. Married at 24 years. Three children, 1 8 and 7 years, healthy and strong. Six years ago the husband contracted syphilis and upon the development of the secondaries was placed upon treatment by his family physician.

Mumma, Leiber. Syphilis. Vienna. Syd.

At about this time he undoubtedly infected his wife. She, however gives no history of a primary sore, but the development of typical secondaries and their disappearance under treatment established the diagnosis. During the past six years or since the onset of her syphilis the patient has had three miscarriages, advanced respectively 3, 3 and 5 months the last of these 3 months ago. The patient has been treated by her family physician for syphilis until nine months ago (mixed treatment) when treatment was discontinued by the patient as she believed herself cured. Until coming to the University Hospital no Wassermann tests or attempt to demonstrate spirochaeta pallida had been made.

Present Illness. A five months miscarriage occurred six months ago one month later menorrhagia developed. Instead of the periods as formerly lasting 4 to 5 days, they now last 8, 10 or 12 days. The bleeding is for the first 6 to 8 hours moderate in amount but by the second day is profuse, bright red and takes on the character of a severe hæmorrhage. This continues for a varying period of time and gradually diminishes, a moderate mild flow continuing and lasting for week or more. As a result of the last three bleedings deep to the usual treatment such as rest in bed, ice ergot, etc. so much blood was lost that the patient has been much weakened. When brought to the hospital the patient had been bleeding for 3 days. For the last three periods patient has been bedridden during and for some time following the flow. Between periods and especially during the days immediately following the cessation of the bleeding there has been a profuse thin, non-odoriferous leucorrhœa. Dizziness, weakness, headache, and other evidences of anemia have been present. All these symptoms are worse toward the end of and immediately following the flow. There has been no pain. The appetite is variable and the bowels at times constipated.

Physical examination. This reveals a moderately well-nourished woman. The heart, lungs, liver and kidneys are normal. Blood, hæmoglobin 52 red blood-corpuscles, 5,000,000 white blood corpuscles, 4,500. Wassermann strongly positive.

Abdominal examination, negative.

Pelvic examination negative. Outlet multiparous. Good support in anterior and posterior wall, cervix normal in size and shows a well healed bilateral laceration. It is softer than normal and the canal is patulous, slightly dilated, just admitting the tip of the finger. The uterus is normal in size, shape and position. It is movable and not unduly tender even on deep palpation. The adnexa are normal. A careful examination fails to reveal any evidence of the site of the primary sore.

Owing to the lack of any assignable cause for the hæmorrhage, a diagnostic curettage was advised.

Operation. On moderate traction with tenaculum during an effort to draw down the cervix the instrument is e through the cervical tissue. During the curettage with a Martin curette the fundus was

perforated. No undue force had been used. In view of the evident softness of the uterus the fact that a perforation was present in the fundus the history of severe and persistent bleeding the age of the patient and the fact that he already had three living children a hysterectomy was decided upon and performed in the usual manner. The tubes and ovaries were not removed.

Convalescence was normal. The patient was placed upon a tonic and one administration of salvarsan was given intravenously before leaving the hospital and her family doctor advised as to the condition so that antisyphilitic treatment could be continued.

Pathologic description The specimen consists of curettage and uterus.

Curettings These consist of a moderate amount of macroscopically normal endometrium.

Uterus This has been removed by supravaginal amputation. It is normal in size and shape, measuring 7.5 centimeters from the point of amputation to the top of the fundus 6 centimeters laterally and 5 centimeters anteroposteriorly (through fundus). The endometrial cavity presents no abnormalities. An incomplete curettage has been performed. It measures 5.5 centimeters in depth. The myometrium is normal in thickness and is rather paler than normal cuts with ease and in the vascular layer large numbers of blood vessels are present the cut ends of which are remarkably prominent. These and the friability of the tissue are the chief peculiarities of the specimen. The myometrium is so soft that the walls may be squeezed through with ease at any point with the thumb and forefinger. In the posterior wall of the fundus is a perforation which will admit a small lead pencil.

Histologic description Endometrium The endometrium is normal in depth or perhaps slightly thickened. The surface is fairly smooth and is covered with a single layer of high columnar cells. The superficial layers of the stroma are infiltrated with blood serum, and chronic inflammatory products. At some points subepithelial hemorrhages are present. In one of these the surface epithelium has been desquamated. The deeper portions of the stroma are condensed and fibrous. Many blood vessels are observed. The majority of these possess well-developed muscular walls in which marked sclerosis is present. Scattered here and there are areas of chronic inflammatory reaction. The line of demarcation between the mucosa and underlying muscularis is well defined. The glands are normal in number size and shape and are of the interval type. The specimen thus resembles an endometrium the seat of a chronic diffuse inflammation with marked angiosclerosis.

Myometrium Four sections taken from various portions of the uterus. All present the same general histologic character. Immediately beneath the endometrium there is an ill-defined zone of chronic inflammatory reaction which gradually fades into the deeper and uninfamed myometrium. The

blood vessels are more numerous than normal and possess unusually thick walls. This is more marked in the media. The arteries and veins are both affected but the changes are more pronounced in the former. In some instances the blood vessels are six or seven times the normal size and in some the degenerative changes involve not only the vessel walls but also the adjacent myometrium periarthritis. In one or two areas thrombi are present while in a few fields vessels are observed in which as a result of endarteritis complete obliteration of the lumen has occurred. In many areas extravasations of free blood are present. The lymphatic spaces are dilated. The fibrous and muscular tissue stain poorly in the eosin and hematoxylin preparations. Much free serum is present as a result. In some areas the muscle-fibers can be seen partially separated. In some fields these edematous areas are more marked than in others but are quite as numerous in the fundus as in the lower portion of the uterine body. The chief histologic characteristics in this specimen are the angiosclerosis affecting chiefly the inner coats of the vessels and the areas of edema above described. Section fixed in Zenker's and in 4 per cent formalin solution and stained in hematoxylin and eosin Weigert's fibrin stain and Van Gieson's stain.

Diagnosis Syphilis of the uterus.

The histologic picture present in this specimen conforms closely to that described by other authors. Whether or not syphilis produces sufficiently characteristic lesions in the uterus to warrant a positive diagnosis has already been considered. In this case the changes were typical of those produced by syphilis elsewhere in the body and I have little doubt as to the correctness of the diagnosis. The histologic picture is not that of a subinvolution nor does it at all resemble those cases which are usually classified as fibrosis of the uterus. Furthermore the results of histologic examination is confirmed by the history and clinical findings. This patient contracted syphilis six years ago anti syphilitic treatment was discontinued nine months ago. Menorrhagia and other symptoms of syphilis of the body of the uterus developed three months later. The Wassermann test was at this time strongly positive. Whereas on account of the rarity of syphilis of the uterus all cases of the metritic variety in which the spirochæta pallida are not demonstrated should be viewed with doubt there nevertheless seems little question as to the correctness of the above diagnosis.

Undoubtedly the chief clinical symptom was the menorrhagia and the chief pathologic lesion the great softening and friability of the uterus together with the more typical changes usually produced by syphilis. Marked softening of the uterus has been noted by a

number of observers, but is by no means characteristic of this variety of infection. Weber¹ Bolt and others have recorded cases in which softening was a marked feature.

SYPHILITIC FEVER

IN RELATION TO GYNECOLOGICAL AND OBSTETRICAL PRACTICES¹

By FRED J. TAUSIG M.D. F.A.C.S. S. LOUIS

TO judge by the almost complete absence of reports concerning syphilitic fever in gynecological and obstetrical literature it is manifest that this interesting and at times important, symptom has received no consideration by our confreres. The extensive work of Gellhorn and Ehrenfest has shown that syphilis of the internal genitals is not as rare as some of us had previously supposed. My own more limited review of a series of cases in private and clinical experience, together with an analysis of the existing literature, has convinced me that syphilitic fever is also not such a unique symptom. If only we would be constantly on the watch to analyze the possible factors in the cases of unexplainable fever that we so frequently observe.

The diagnosis of syphilitic fever can rarely be made with absolute certainty. There is nothing characteristic about the temperature curve. In the milder more common forms the fever does not rise over 100 to 100.5 with a relatively slow pulse and lasts only a few days. In the severer type we have a remittent prolonged fever extending for weeks or even months with an evening rise of temperature to 102 to 103 and intervals of a few days at a time when the fever almost ceases. The mass of evidence concerning syphilitic fever doubtful as it may be in the individual case leaves no question that syphilis is at times actually responsible for the rise in temperature. Nevertheless, in analyzing symptoms we should constantly

bear in mind Virchow's warning not to call everything syphilis that appears in a syphilitic person or that disappears under antisyphilitic treatment. Thus we can explain fever that disappears under antiluetic treatment, in four different ways.

1. The antiluetic treatment may have destroyed not only the spirochæte but also septic bacteria that were the cause of the fever.

2. The antiluetic treatment may have so improved the patient's bodily resistance as to enable her to overcome fever due to other organisms.

3. The antiluetic treatment may have been merely coincident with a fall of temperature due to other causes.

4. The antiluetic treatment may actually have been responsible for the cessation of a fever due to syphilis.

On the other hand, we cannot conclude that a fever is not syphilitic because it ceases without antiluetic treatment, since we know that syphilis and all its manifestations are to a certain degree limited by the natural immunity acquired by the individual. Nor can we conclude that a fever is not syphilitic because it persists in spite of antiluetic treatment, since we know that certain cases of malignant syphilis will resist all known measures.

Scientific proof of syphilitic fever in any case would require the exclusion of all other possible causes, the finding of spirochæte pallida in the blood before treatment and the

simultaneous disappearance of spirochæta and fever under the customary treatment. These conditions it will of course for technical reasons be impossible to fill in more than a very few cases. In the main we must arrive at our diagnosis possible or probable by a careful estimation of the patient's history, physical conditions, Wassermann reaction and the effect of the treatment.

Syphilitic fever may be divided into (A) secondary syphilitic fever (B) late secondary syphilitic fever (C) tertiary syphilitic fever.

A *Secondary syphilitic fever* is that which we find preceding or coincident with the outbreak of the syphilitic rash. Fournier states that it occurs in about 20 per cent of all syphilitics. The rise is not over one or two degrees and the duration three to four days so that the patient ordinarily gives it no attention. At the outbreak of secondaries women often come to the gynecologist either because of local sores or on account of a complicating gonorrhœa or pregnancy. It would be well therefore for us to bear in mind that a slight rise in temperature at this time has no special significance. Whether it is individual predisposition or a virulent infection that is responsible for the occurrence of fever in one out of every five syphilitics at the time of the rash it is impossible to say. Occasionally we find that the fever is quite high and persistent. An illustration of this sort occurring in an obstetrical patient was noted in the following case, the data of which were kindly given me by Dr Ehrenfest.

Case — 29 years old married February 1, 1915 in good health began on April 15 to have a peculiar intermittent fever diagnosed by her family physician as typhoid, that lasted for six weeks. Shortly thereafter she was seen by Dr Ehrenfest, who found a faint secondary skin rash still visible and a suspicious sore on the labium minus. Widal reaction was negative and no other explanation for her fever could be found. Both the patient and her husband had a Wassermann 4+. The patient was thin and anæmic and at this time was three months pregnant. Under salvarsan and mercury a marked improvement of her general condition and increase in weight occurred.

The following important additional data were obtained from Dr C. Foulkrod of Philadelphia under whose care the patient was confined in January, 1916.

Owing to a nephritis and the generally weakened condition of the patient no antiluetic treatment was given just previous to and after her confinement. From January 19 to February 7 the patient had a remittent fever that varied between 99 to 102.6, averaging a little over 101 every evening. There was no evidence of any form of puerperal or other infection. Breasts, perineum, lochia were all normal. Finally in view of the persistent fever it was decided to give another dose of salvarsan. On that day the temperature rose sharply from 100.4 at 3 p.m. to 104.8° at 4 p.m., falling to 101.2 at 6 p.m. and 99.4 at 9 p.m. The following day there was still a rise to 101.4 but from February 9 on the temperature did not rise over 99.

The sudden temporary rise after salvarsan has been noted by other writers (Polano, Glaser). This additional occurrence of elevated temperature is clearly to be grouped as *late secondary syphilitic fever*.

B *Late secondary syphilitic fever* offers greater diagnostic difficulties and is less frequent than that coincident with the eruption. Graves has emphasized the occasional recurrence of short periods of elevation of temperature associated with other so-called constitutional symptoms in syphilitics for some months after the onset of the disease. He interprets such symptoms as due to the occasional outbreak of organisms accumulating in a latent syphilitic person. In such as are susceptible to elevations of temperature we may have at these times a short period of fever.

Every now and then this late secondary fever will be more persistent and have a higher range of temperature. A characteristic example of this group was reported by me six years ago.¹ A brief summary may be of interest in this connection.

C W. 23 years old contracted syphilis about the middle of her pregnancy. The following month a typical papular eruption, sore throat and adenitis occurred. She was put on protiodide of mercury by her physician and the eruption began to fade. Two months later I was called to see her on account of a fever starting four days previously running up to 103 and without apparent cause. Typhoid, tuberculosis, pyelitis, sepsis and appendicitis could be excluded. The persistence of fever up to 102 to 103.5 for the next ten days induced me to decide on premature labor with the hope of clearing up the diagnosis. Delivery of a living four and one-half pound child was accomplished.

without trouble. The fever persisted for three days more without any apparent cause, rising to 104 on the second day post-partum. I finally decided on the possibility of syphilis as a factor in the fever and gave bichloride of mercury gr 1-10 hypodermically on two successive days. The fever ceased at once and did not return.

Another less pronounced case came to my service at the City Hospital March 23 1916.

She was a negro who had been normally confined ten days previously. No evidence of pelvic infection or other inflammatory disease elsewhere in her body could be determined. Her skin still showed typical papular syphilitic spots that had appeared several weeks previously. There were enlarged post-cervical and inguinal glands. The Wassermann was negative. During the first six days she ran a somewhat irregular fever with a maximum of 102. She was then given two hypodermics of mercury bismate on alternate days. The fever promptly ceased and did not return during the following two weeks, at which time she left the institution. In spite of the negative Wassermann, I think we should strongly suspect syphilis as the cause of the fever in this patient.

Leblond also reports a case that belongs under this head.

The patient had contracted syphilis during her pregnancy. Under antiseptic treatment the syphilitic manifestations disappeared. Fetal movements ceased at the sixth month of pregnancy. No treatment was given for the following five weeks. Then 7½ months dead fetus was spontaneously expelled. There were no abrasions in the genital tract. There was no fever for the first seven days post-partum. Without any local symptoms or explanation elsewhere in her body the patient began to have a high remittent fever with slow pulse, good appetite, and complete absence of pain or discomfort. Antiseptic treatment resulted in prompt and permanent cessation of fever.

C. *Tertiary syphilitic fever* is much less frequent than the secondary types, but is of greater diagnostic importance. The fever is usually continuous and attended with an elevation of temperature of 102 to 103. Evidences of the syphilitic infection are usually absent and the symptoms have been for gotten by the patient. The diagnosis is therefore established with great difficulty and usually after considerable delay. To the 62 reasonably certain cases tabulated by Stern in 1912 I was able to add 21 additional cases including one of my own making a total of 83 cases. The organs primarily affected by the tertiary process in these cases were

Liver	29
Bones and joints	9
Lungs and air passages	
Nervous system	6
Spleen	4
Circulatory system	3
Hereditary	3
Female genitalia	1
Uncertain	7

The gummatous lesions upon the skin as well as those occurring so frequently about the external genitals of women and in the rectum do not apparently give rise to this tertiary syphilitic fever. Occasional slight elevations of temperature such as we find are more probably due to secondary infection of the ulcer. It is the deep-seated gumma such as we find in the liver and the osseous system that is most apt to give rise to this symptom. Not merely the extent of the syphilitic infiltration however is to be held responsible. Glaser for example, reports a case of syphilis of the lung with complete consolidation of one lung but with a normal temperature. Extensive liver infiltrations occur without fever in fact, the absence of fever has been emphasized in differential diagnosis as pointing to syphilis. These exceptional cases of tertiary syphilitic fever must therefore be carefully kept in mind. Abdominal surgeons have at times mistaken the fever and liver enlargement in liver syphilis for a cholecystitis. Riedel reports having made this mistake five times.

In our special field tertiary syphilitic fever may be subdivided into—

1 Cases in which tertiary syphilis of the genital tract caused the fever

2 Cases in which a gynecologic or obstetrical condition was complicated by tertiary syphilis in other organs producing fever

The interesting cases of uterine syphilis reported by Gellhorn and Ehrenfest were in part attended by tertiary gummatous infiltration of the neighboring connective tissue. I had occasion to examine most of these patients personally and some were for a time in my service at the City Hospital. In going over the temperature charts of three of these cases, those in which there was the most pronounced gummatous infiltration of uterus and parametrium, I found that all

three ran a temperature on admission that could not readily be explained except on the basis of their syphilis. In observation X (B L 307-13) the admission temperature was 101 but the subsequent records are missing. In observation VI (M B 10612-16) at the time of admission in November 1915 when the cervical lesion was comparatively small the temperature went up to 99.5 to 100 for 4 days after admission. On her second admission in January 1916 the cervix and surrounding parametrium were converted into a nodular mass such as I had never seen except in carcinoma. Only the histologic picture could convince me that this mass was really a gummatous infiltration. This woman ran an irregular fever ranging from 101 to 103.8° in the evening. While there is no denying that the ulcer was secondarily infected the syphilitic process was essentially the cause of her death and in view of the malignancy of the condition and the absence of any particular symptoms from the secondary infection the probability is that the fever was due at least in part to syphilis.

I should draw a similar conclusion from the data at hand concerning the case of malignant syphilis of the uterus reported by Hoffmann. Hoffmann speaks of the case as one of chronic

sepsis following childbirth. The colon bacillus was to be sure found in the blood culture nevertheless autopsy findings revealed not the picture of a severe colon infection but that of extensive gummatous infiltrations in the uterus right tube and ovary retroperitoneal glands lung and liver. I think the question may fairly be raised whether the fever in this case was not due to spirochate sepsis.

Turning now from these merely suspicious cases of tertiary syphilitic fever we come to one concerning which there can be little doubt as to the correct interpretation. It was reported as observation XV (Callhorn and Ehrenfest).

J L (Admission No 4048-15) colored twenty-eight years old. No miscarriages. One normal confinement ten years previously. Entered hospital because of a blood tinged vaginal discharge with pains in the right lower abdomen. Examination revealed oedema of both labia majora and minora with a small typical tertiary ulcer under the right labium minus and an indurated uterine tube. Cervix encased in an infiltration extending to the pelvic wall Wassermann 4+. There was a hyperleukocytosis nor any high fever such as you would expect with a large acute pelvic exudate due to septic infection. The bedside notes attached to the history shows however that there was a rise of temperature and moreover one that reacted so distinctly to the antisyphilitic treatment that

there can be no reasonable doubt of the diagnosis of *tertiary syphilitic fever*. The exact description of the changes wrought by the treatment upon the pelvic mass are equally convincing and are mutually corroborative of the nature of the affection.

The accompanying temperature-curve is very instructive. The temperature ranged from 100 to 101.4 from June 25 the day of admission, to July 3 the day that the patient was first put on unguentum hydrargyri and increasing doses of potassium iodide. The temperature fell to normal after a few days and then began again to become elevated, though not as high as before. Immediately subsequent to the injection of 6 salvarsan the fever ceased completely and did not return.

Cases in which a gynecological or obstetrical condition is complicated by tertiary syphilis in other organs producing fever are occasionally to be found. Two such cases have been recently reported by Glaser. One patient, the wife of a contractor developed an intermittent high fever following confinement. There was a swelling of both liver and spleen but no indication of pelvic infection. Malaria, septicæmia, and typhoid could be excluded bacteriologically. The husband acknowledged syphilis. In spite of a negative Wassermann salvarsan was given with sudden and complete cessation of fever and a disappearance of the enlargement of the liver and spleen.

The other case developed a persistent fever after a hysterectomy. No cause for this was apparent. A secondary laparotomy threw no light on the subject. Pains in the lower limbs suggested a luetic periostitis. Wassermann reaction was found to be 4+. Antiluetic treatment brought immediate cessation of fever a gain of 18 pounds in weight and disappearance of the bone symptoms.

Such cases should put us on our guard in every case of obscure persistent fever complicating a pelvic condition, to have a Wassermann reaction made and to try the effect of antiluetic treatment.

CAUSE

The cause of syphilitic fever has been the subject of considerable debate. Some insist that we must explain it on the basis of a

secondary infection with other bacteria (Rosenthal, Kirckheim) but the majority feel that the evidence at hand justifies positively the conclusion that the fever is due to the spirochætae and their toxins. Sobernheim considers it possible that the rise of temperature is due merely to the absorption of products of tissue necrosis and is therefore independent of the organism itself. If this were true however we should not expect so immediate an effect upon the temperature from antisyphilitic treatment but rather a gradual cessation of fever. Schlegelmann and others believe that when syphilis attacks the liver we are more apt to have fever since interference with the metabolism of that organ causes elevations of temperature. In this connection Stern points out the frequent association of fever in the secondary stage of syphilis with a mild degree of icterus indicative of interference with liver function. Monier and Fournier believe syphilitic fever is more frequent in women than in men but this statement has not been sufficiently confirmed. The most plausible explanation why some have fever and others do not is that put forward by Stern. In syphilis without fever it is possible that only the spirochætae enter the circulation while in those having fever the spirochætae plus their toxins get into the blood and it is the latter that produce the rise in temperature.

Additional information as to the cause of syphilitic fever may come out of our study of the rise of temperature that is occasionally seen after injections of mercury or salvarsan. Iolano found in 12 out of 106 cases of secondary lues a temporary elevation of one or two degrees after mercurial injections. Gron reports a similar occurrence in 20 out of 100 cases. Glaser found that such a rise of temperature after salvarsan or mercury injections given with the utmost precautions occurred with greater frequency in latent lues. He explains the symptom as due to the death of larger numbers of spirochætae. The resultant liberation of their endotoxins causes sufficient irritation to produce a moderate degree of fever. Bauer also found a rise of temperature after the first injections in liver syphilis.

For detailed history and description of the physical examination I must refer the reader to the article by Gailborn and Zierler on "Syphilis of the Internal Genital Organs" in the *Report on Syphilis Association Gynecological Section*.

OBSERVATIONS ON THE OCCURRENCE OF SYPHILIS IN THE UNIVERSITY OF MICHIGAN OBSTETRIC AND GYNECOLOGIC CLINIC

B. REUBEN PETERSON M.D. F.A.C.S. A.B. ARBOR M. D.C.
Professor of Obstetrics and Gynecology University of Michigan

FORTUNATELY due to the thorough and exhaustive work of the referents the participants in this symposium on syphilis in its relations to obstetric and gynecologic practice can omit introductions and references to the literature and confine themselves strictly to their portions of the discussion.

It is only within the past five years since the discovery of the spirochæta and the Wassermann reaction that syphilis can be said to have been studied with any degree of scientific accuracy in the obstetric and gynecologic clinic in the University of Michigan Hospital. Active cases of syphilis with abundant skin or mucous membrane manifestations were recognized and the proper treatment instituted but we were quite ignorant as to the extent of latent lues with the result that many cases passed unrecognized and the patients suffered accordingly. While the system carried out in the University Hospital for the recognition and treatment of syphilis is not without its faults and no doubt could be greatly improved upon it has served its purpose as a beginning and is vastly superior to no system at all.

For the past year there has been a hospital rule that every in-patient should have a Wassermann taken and while the rule has not for various reasons been so strictly adhered to as would be wished, its value is gradually becoming realized so that more and more of such examinations are being made from

each clinic. At the present time the hospital serological laboratory is making something like five or six hundred Wassermanns a month and as the serological records are most carefully kept, data is accumulating from which most valuable conclusions can be drawn.

It is the unwritten rule of the Hospital that all cases of syphilis be referred, not transferred to the Department of Syphilology for examination, advice or treatment. This is a most fortunate custom for each case is thus seen by an expert on the disease in question and an authoritative diagnosis is secured. In the same way the treatment is not haphazard as may be the case when not carried out by a specialist. If the report which is to follow can be considered of any value it will largely be due to the accurate and careful work of the serological laboratory and the scientific nature of the work emanating from the Department of Syphilology of which Professor Udo J. Wille is chief and to whom I tender my grateful appreciation.

It will remain for others to point out when and how the Wassermann reaction may fail as a test for lues. Undoubtedly it does fail in a negative way since it is fully recognized that an individual may have the disease and not show the reaction. Yet the test is of undoubted value when positive and if carried out in a series of cases is a fair indication of the frequency of the disease especially if the doubtful cases be checked up by the examinations of an expert.

First as to the frequency of syphilis in a general hospital as revealed by the Wassermann examination. The results in 2000 cases have been tabulated excluding patients admitted to the Department of Dermatology and the Departments of Syphilology and Neurology, since the inclusion of the large number of syphilitics in these two services would have interfered with the purpose of the investigation which was to ascertain the frequency of syphilis in average hospital patients.

In 2000 patients there were 110 distinctly positive Wassermans in which the diagnosis in almost every instance was confirmed by the Department of Syphilology. Among the doubtful reactions there were 8 in which the patients were afterward proved to be syphilitic. This shows that practically 6 per cent of the general run of hospital patients are syphilitic. Making allowance for the possibility that some luetics may have given negative reactions and that re-examination of the doubtful cases might have given some positives it is fair to assume that from 6 to 8 per cent of the patients in this particular hospital excluding certain clinics were syphilitic.

The percentages varied in the different series as can be seen by the following:

	Per cent
Obstetrics and gynecology	4.8
Medicine	4
Ophthalmology	3.7
Otolaryngology	5.0
General surgery, orthopedics and genit. urinary	4
Pediatrics	0

The proportion of syphilitics in this hospital material is on the whole rather low. Subsequent reports may show decidedly higher figures more in agreement with those from other hospitals. Possibly the nature of the hospital material accounts in some measure for the low percentage of syphilis since the patients are mostly from the country districts. Be that as it may the figures are presented for consideration as a contribution to the subject under discussion.

SYPHILIS IN THE OBSTETRIC CLINIC

There were 18 undoubted cases of lues in the 381 obstetric patients examined or 4.7 per cent. These patients were given the Wassermann test; their histories taken with

special reference to syphilis and all positive and doubtful cases referred for diagnosis to the Department of Syphilology.

In explanation of this low percentage of syphilis among a class of patients where the ratio apparently should be high it may be said that it is probably due to the class of patients from which the material is drawn. Although 62 per cent of the material is made up of illegitimates the average age of the 381 patients being 23 years, as a class the patients have not been unduly exposed to syphilis. They are country girls, waitresses, stenographers, telephone operators, very few being prostitutes or street walkers.

The laboratory reports show the varying degrees of intensity of the Wassermann reaction, its doubtful nature or its absence. Of the 18 undoubted cases of syphilis there were 12 with 4+, one with 3+, with + and 2 with = reactions, while in one instance although a Wassermann was not obtained on the mother the fetus showed a 3+ Wassermann and the placenta was syphilitic.

HISTORY OF LUES AND CORRESPONDENCE WITH THE RESULTS OF WASSERMANN EXAMINATIONS

This is an interesting field for investigation since it shows that in the majority of instances even where particular attention is paid to the history nothing suggestive of syphilis can be found. There was a positive history of luetic infection in 8 of the 18 cases. Of these 5 gave 4+ Wassermans, 1 a 2+ while 2 were doubtful or =. On the other hand where the histories were doubtful in three cases all gave 4+ Wassermans. In 4 cases the histories were entirely negative as to syphilitic infection but of these 4 gave 4+ reactions, 2 were 1+ while in one case the Wassermann was not obtained, the evidence of maternal syphilis being gained from an examination of the fetus and placenta.

PHYSICAL SIGNS OF SYPHILIS

In only 8 cases out of the 18 syphilitics were there positive signs of lues as revealed by careful physical examination. Of these 5 gave 4+ Wassermans, 1 was 3+ while 2 were = or doubtful. On the other hand in four cases

where the results of the physical examination were doubtful all gave 4+ reactions. In 5 cases there was entire absence of signs of lues on careful physical examination although in two of these cases there were 4+ positive Wassermans in 2 reactions were+ while it was not obtained in one case.

This is additional proof of what has long been known that in women in particular there may be few or no signs of syphilis although from other information undoubtedly the disease is present.

TREATMENT DURING PREGNANCY AND ITS EFFECT

The results of treatment of the syphilitic mother and the effects of such treatment upon the child prior and subsequent to birth are of especial interest to the obstetrician.

Of the 18 luetics, 14 received treatment, 7 before and 7 after labor while 4 patients refused treatment. The treatment consisted of varying doses of salvarsan and mercury.

There were 12 full term labors and 6 premature deliveries among the 18 luetics. All but one of the 6 patients receiving treatment before labor carried their children to full term. Of the other 6 women going to full term although in all but two instances they gave 4+ Wassermans the other signs pointed to old infections except in one case where infection took place at the seventh month. Of those receiving treatment with full term labors two were conceptional infections while the others were infected two to four years previously. Five of the six women who miscarried received no treatment before or during pregnancy. In all except a single case where the infection was old infection occurred at the time of or very soon after conception.

This is a very good showing for the treatment of the syphilitic pregnant woman so far as an aid in carrying her child to full term is concerned and shows that salvarsan and mercury are well borne by the syphilitic mother. Exceptions to this statement may be found in the literature but should not deter us from instituting vigorous treatment with

both salvarsan and mercury in our pregnant syphilitic patients.

THE RESULTS OF WASSERMANN EXAMINATIONS ON NEWBORN INFANTS

It is a routine procedure in the obstetric clinic to collect blood from the umbilical cord in a test tube and send it immediately to the Serological Laboratory for examination. In no case where the maternal blood in the 381 cases examined gave a negative Wassermann reaction was the newborn infant's reaction positive. In fact only 3 of the children of the 18 luetic mothers gave positive Wassermann reactions at birth and these mothers received no treatment during pregnancy. Two babies whose mothers received no treatment during pregnancy while giving negative reactions at birth gave positive reactions later at the twelfth and fourteenth week respectively.

Thus it would seem as if treatment of the syphilitic mother during pregnancy had a favorable effect upon the child although it must not be lost sight of that the manifestations of syphilis may develop later. As it is the rule of the department that no child of a syphilitic mother with or without serological and physical manifestations of the disease shall be sent out for adoption it will be an easy matter to ascertain the subsequent histories of the children of luetics who gave no evidence of disease when they were discharged from the maternity. This investigation on latent syphilis is now being carried on and will be reported upon later.

SYPHILIS IN THE GYNECOLOGIC CLINIC

The Wassermann test was made upon 390 gynecologic patients. Nineteen of these patients gave 4+ Wassermann reactions one a 3+ while two others with less marked reactions were judged to be luetic, making a total of 22 patients among the number examined or a percentage of syphilitic patients of 5.6.

The average age of these 22 patients was 22 years 16 were married and 6 were single.

A definite history of syphilis was elicited in only 5 of the 22 cases while in one case it was suggestive. In only one case was a

definite history of lues in the husband obtainable

The above shows the great importance and value of systematic Wassermann examinations upon gynecologic patients. If such systematic examinations be not employed local lesions may be attended to surgically and by other methods of treatment but a far more important general disease will in many cases be overlooked and no attempt made to cure the patients. Wassermann examinations are particularly important in women since in many instances the diagnosis can only be made in this way as the local manifestations of the disease are far less marked in women than in men. Many cases puzzling to the gynecologist in the past because of failure to be restored to health may be explained at the present time for many of them were undoubtedly cases of latent syphilis.

The findings in the 2 luetic patients as reported by the Department of Syphilology are extremely interesting and show what a great aid is the Wassermann test in the establishment of the diagnosis.

There were 15 cases of latent syphilis all giving 4+ or 3+ Wassermann reactions but with few physical findings in most cases only a slight adenopathy. Certainly such physical signs without the aid of the Wassermann test would have been apt to escape the notice of even the gynecologist most expert in general physical examination.

Another interesting feature about this group of syphilitics with gynecologic conditions was that in no patient was the diagnosis made from an inspection or palpation of the genital organs. Again in no case from the material submitted to the pathologist was the diagnosis of syphilis made by microscopic examination. Undoubtedly this would not be true of other gynecologic clinics where the lesions of recent acute syphilis predominate but these are pueral clinics and do not represent average gynecologic material. It is also possible that future investigations of the material at our disposal in the light of what will be learned from the discussions at this meeting will enable us to recognize what heretofore has escaped our observation.

SUMMARY AND CONCLUSIONS

1 Only by routine Wassermann tests will the obstetrician and gynecologist best serve the interests of his patients.

Especially is this true in hospital practice where even careful histories fail to arouse suspicion of latent syphilis.

3 Out of 600 in-patient in the University Hospital excluding two service the proportion of syphilitics was 6 per cent.

4 The nature of the hospital material will determine the percentage of lues but in the average hospital the ratio will not be far from 8 to 10 per cent if the entire hospital population be included.

5 The same holds true for the proportion of syphilis in any special clinic the percentage varying according to the nature of the material.

6 The percentage of lues in 381 cases in the University Maternity was 4, as shown by the Wassermann reactions and expert physical examinations.

7 In 18 cases of syphilis among the number examined only 8 gave a history of lues.

8 In only the same number (8) were there positive physical signs of lues.

9 As shown by the histories of the 18 cases there is a greater chance for the syphilitic mother treated by salvarsan and mercury to give birth to a living full term child than where no treatment be given during pregnancy.

10 The newborn infants of the mothers so treated do not give positive Wassermann reactions although undoubtedly they are syphilitic and later probably will show signs of the disease.

11 A certain proportion of the newborn children of untreated syphilitic mothers will give positive Wassermanns.

12 Out of 390 gynecologic patients subjected to the Wassermann test 22 or 5.6 per cent gave positive reactions.

13 In only 5 of the 22 luetic patients was there a history of syphilis.

14 Hence the importance of such examinations or a serious general disease will be overlooked and the gynecologic patient will remain uncured.

THE SPECIFICITY OF THE WASSERMANN REACTION

By RUDOLPH BUHMANN M.D. S. Loos

SINCE the introduction of the Wassermann reaction into the realm of medicine it has taken its place in the front rank of the various laboratory tests and reactions as an aid to the clinician in clearing up many of the obscure cases with which he is confronted. It has received both praise and condemnation at the hands of these clinicians: praise if it aided them in the diagnosis of some complicated case, and condemnation if it did not coincide with the clinical findings.

The reaction is based primarily upon the Bordet-Gengou phenomenon of complement fixation: that is the presence of an immune or antibody in the blood serum in conjunction with the specific antigen will fix the complement. The fixation of the complement is determined by the addition of corpuscles and their amoebocytes. If hæmolytic takes place the complement has not been fixed; if however hæmolytic does not occur the complement has been fixed. To illustrate the serum from a typhoid fever patient in conjunction with an emulsion of typhoid organisms fixes the complement and prevents hæmolytic taking place upon the addition of corpuscles and their amoebocytes.

Upon this theory Wassermann assumed that the serum from a syphilitic patient plus its antigen would likewise fix the complement. However as the organisms were not then obtainable in pure culture he substituted for his antigen a watery extract from tissues rich in spirochætae. By this method he obtained a fixation of the complement when the serum of a syphilitic person was used whereas there was no such fixation when the serum was from a normal person. It was therefore assumed that the reaction was the result of a specific antigen and antibody combination. This may have been true as Noguchi (4) has obtained fixation of the complement with the serum from some syphilitic patients, with an antigen made from an emulsion of spirochætae in pure culture.

The specificity of the reaction, however, received a setback a short time later when it was shown by Levaditi Yamanouchi (1) Porges and Mier (2) Landsteiner Muller and Potal (3) Noguchi (4) and others that alcoholic extracts of normal as well as syphilitic organs had the properties of binding the complement in the presence of serum from a syphilitic individual.

Although the true explanation of the nature of the reaction is lacking it is known that it does not correspond in the ordinary biological sense to that between antigen and antibody as was originally believed. Subsequent work has tended to indicate that it is due to an interaction of lipoidal substances. Future work along the lines of immunochemistry may ultimately elucidate the peculiar character of the reaction. Should such be the case, however the diagnostic value of the reaction will not thereby be increased.

From the foregoing it is obvious that the reaction is not a specific one. Now the question naturally arises: "May conditions other than syphilis give a positive reaction?" If one accepts the reports in the literature then he must believe that almost all the diseases to which the human system is heir will give positive reactions.

Thus positive reactions have been reported in frambosia (Bruck 5 and Hoffman and Blumenthal 6) in which the etiological organism is the spirochæta pertenius. In recurrent fever and dourine Korschun and Liebfried (7) report 50 per cent positive reactions. The organisms of these three diseases are very closely allied to the spirochæta pallida, which may account for the positive reactions in them. Eichelberger (8) reports positive reactions in 40 per cent of a series of scarlet fever cases. Jacobovis (9) 18 out of 55 cases. Weil and Braun (10) report positives in sepsis cancer typhoid fever tuberculosis, and diabetes. Wechselman and Meier (11) Eitner (12) Jundell, Almkvist and Sandman (13) and others report positives in leprosy. Boehm

(14) Reinhard (15) and Valerio (16) report positives in malaria Halbstaedter Mueller and Reiche (17) report positives in measles varicella and pertussis Treuber (18) reports positives in lymphosarcoma Boa and Peterson (19) report 3 positives out of 60 cases of chloroform narcosis Wolfsohn (20) and Reicher (21) report positives in veronal morphine scopolamine ether narcosis Dreyer (22) in lead poisoning Richards (23) in diabetes with acidosis Lassen (24) in sarcoma Hesse (25) in 9 of 11 cases of pemphigus Sutherland and Mitra (26) in 9 of 50 cases of malaria (3 of these were leucic) 10 out of 58 of kala azar 7 out of 34 cases of leprosy Verdozzi and Urbana (27) report 8 positives out of 9 cases of cancer of the liver Craig (28) reports that the presence of certain strains of staphylococci and streptococci will convert negative reactions into positive one Caan (34) reports 3 positives out of 85 cases of carcinoma and Simon (29) Duanay (30) and Zubrycki (31) report positives in eclampsia with jaundice Serum heavily laden with bile will occasionally prevent hemolysis taking place without the addition of an antigen

The above reports however must be accepted with a great deal of reservation for the following reasons

1 The majority of these reports date back to the infancy of the reaction

2 The liability of error on account of the delicacy of the technique required in the performance of the reaction

3 As our knowledge of the technique has advanced the number of positives in diseases other than syphilis has gradually decreased

4 Statistics of results obtained by other men in which it is the exception that positives are obtained in diseases other than syphilis namely Browning and McKenzie (35) Schridemandel (36) and MacCormac and Merson (37)

The abundance of material furnished at the Barnard Free Skin and Cancer Hospital gave me the opportunity to compare the various statistical enumerations above and to contribute to the question The following cases were examined 136 cases of malignant diseases

53 cases of skin diseases and 99 cases of miscellaneous diseases The original Wassermann method was adhered to with two exceptions namely the quantity of all of the reagents was reduced one half and the watery extract antigen was replaced with alcoholic extract One half the original quantity was used because too much blood would be necessary since two or more antigen were used in each case

Hemolytic system sheep corpuscles their amboceptor and complement

Sheep blood obtained from an abattoir immediately deheminated washed not less than five times with sterile saline solution and used within twenty-four to forty-eight hours This plan is uniformly adhered to The variation in the density of the suspension is then but negligible Occasionally one will meet with cell that are unduly fragile and will therefore show some hemolysis This is easily determined by making up a 1 per cent suspension of the cell in normal saline solution placing them in the refrigerator overnight and if the supernatant fluid is tinged some hemolysis has taken place These are not to be used

Amboceptor The anti sheep rabbit amboceptor is used This remains fairly constant for a period of from four to eight months if sealed in small ampule and kept constantly in the refrigerator

Complement Fresh guinea pig serum is used As there is more or less variation in the strength of the complement in different pigs it is preferable to use the pooled blood from several healthy animals The complement and amboceptor must be titrated for their respective units before the day's work is begun

Intigens It has been my custom to use three different antigens for the past two years These are all prepared by a similar method as follows

The tissues at once are minced and placed in absolute alcohol (in the proportion of one gram of minced tissue to ten cubic centimeters of alcohol) incubated for a period of time (usually four to six weeks) with frequent agitation then filtered and kept at room temperature Antigen of guinea pig heart

antigen B liver from a case of congenital lues or liver from an infant antigen C a cholesterol fortified human heart prepared according to the method of Walker and Swift (32)

The antigens must be carefully titrated for their anticomplementary hemolytic and antigenic properties before they are used. The guinea pig heart and the foetal liver antigens are not as sensitive as the cholesterol fortified one. The latter is unquestionably the most sensitive and reliable of all of the antigens.

The material investigated may be divided into three groups.

TABLE I.—SKIN DISEASES

Disease	Number of Cases	Negative	Positive	Weakly Positive
Pityriasis rosea	8	8	None	None
Scabies	15	5	None	None
Dermatitis	5	5	None	None
Eczema	5	5	None	None
Total	33	33	None	None

In this series of skin diseases are eight cases of pityriasis rosea, which resembles very much the secondary eruption of syphilis and frequently the clinician has to rely upon the Wassermann reaction to arrive at a correct diagnosis.

TABLE II.—MALIGNANT DISEASES

Disease	Number of Cases	Negative	Positive	Weakly Positive
Sarcoma			None	None
Malignant desmoma	5	5	None	None
Glioma of brain			None	None
Carcinoma	7	9 ¹	9	
Total	36	5	9	

This table gives the very interesting result, that of 136 cases of malignant diseases only 9 were positive and two weakly positive and 125 gave negative results. The sarcoma and carcinoma represent the various types of these diseases and in each case was the diagnosis confirmed by microscopical examination. Of the 9 positive reacting cancer cases 6 became negative or remained only weakly positive under antiluetic treatment. The remaining 3 cases discontinued treatment or failed to return for later observation. Three of the positives were epitheliomata of the tongue probably developing on a hectic

base as the patients gave a history of what was no doubt leukoplakia. The two cases that reacted weakly positive were carcinomata of the cervix.

TABLE III.—MISCELLANEOUS DISEASES

Disease	Number of Cases	Negative	Positive	Weakly Positive
Typhoid	1	1	None	None
Peri-ocular anemia	4	4	None	None
Hodgkin disease	1	1	None	None
Postinfectious	1	1	None	None
Scarlet fever	5	5	None	None
Leprosy	0	1	5	None
Tuberculosis	35	13		None
Malaria			None	None
Arthritis	6		None	None
Meningitis			None	None
Streptococcal infection	4	4	None	None
Total	99	44	5	None

Table III shows that of 99 cases, including various diseases 94 reacted negatively and only 5 positively. Three of the 5 positive reacting ones were leprosy of the tuberculous type. The other two were tubercular cases both of which gave a fairly definite history of lues.

INTERPRETATION OF THE REACTION

1 weakly positive reaction. Anything over 50 per cent hemolysis should not be interpreted as a syphilitic reaction unless there is some clinical evidence of the disease or a definite history of the infection. An individual should be spared the humiliation and condemnation of being branded with this dreaded disease with no more evidence than a weakly positive reaction. On the other hand it is the duty of the physician to protect the innocent from the possibility of an infection from one who suffers from this disease. There should be co-operation between the clinician and the serologist in all such doubtful cases repeated Wassermann reactions should be made. If these do not clear up the case then the provocative treatment should be resorted to preferably a dose of salvarsan or ten days or two weeks of mixed treatment, which usually has the effect of producing a stronger reaction if syphilis be present.

A strong positive reaction except in very rare and easily differentiated cases is definite

HIGH DEGREES OF HEAT VERSUS LOW DEGREES OF HEAT IN THE TREATMENT OF CANCER OF THE UTERUS

B H J BOLDT M.D. F.A.C.S. N. Y. E.A.

YOUR secretary has requested me to add a ten minute contribution to the symposium now before your society, my part to be on high degrees of heat compared with low degrees of heat as a palliative treatment for advanced cancer of the uterus. Inasmuch as I but recently reported the result of my observations, I can add little to that which I published in the *American Journal of Obstetrics and Diseases of Women* January 1916 except to say that judging from the many letters received from colleagues who have had experience my position is amply justified and to add that Dr F W Bancroft, of New York, has verified my position by an autopsy on a patient who had been subjected to low heat, in accordance with the technique advocated by Dr Percy.

I do not wish to be understood as detracting from the usefulness of low heat application. On the contrary I commend it but not as the method to be used under all conditions. It should be reserved principally for a second application, after the rapid destruction has been accomplished by high heat, and the charred eschar so caused has been thrown off and for cases wherein the malignant process has so far advanced that the thorough application of high heat would endanger the bladder or rectum, despite great care to avoid injury. It may happen as a secondary result, that a slough may be caused and thus a vesical or a fecal fistula be established. Although such fistulae frequently close spontaneously we know from experience, that if they do not close how difficult it is to bring about a closure by operation.

Then too the danger from secondary hemorrhage is not less with low heat than with high heat. Indeed it is held by some to be greater when low heat is used though to judge from my own experience that position is untenable.

These however would be negligible fea-

tures if with low heat alone we could accomplish a better final result. So far there has been no evidence presented by any one who has had experience with both methods properly tried on a series of patients that showed the superiority of one over the other. It may be admitted that now and then heat has cured a patient although personally I have not seen such an instance.

Indeed were I to rely solely on the report of results I should relegate heat to the has been remedies and only advise radium. But we do know that with heat properly used, and applied in properly selected cases, we have a therapeutic agent that sometimes gives remarkably good palliative effects. Dr Percy who is the strong advocate of low heat makes claims for it that I have been unable to substantiate. He asserts that it has a deeper penetrating ability on the tissues and that it destroys carcinoma elements farther away from the surface to which it is applied than high degrees of heat, and hence its potency to cure some carcinoma patients of their disease. The late Dr Byrne to whom the medical profession is indebted for bringing the treatment of cancer of the uterus with heat into vogue, many years ago made similar claims for high degrees of heat but he was unable to convince me that it was more than an excellent palliative agent. So far as I know no proof of further efficacy has been demonstrated by Percy. On the other hand the clinching facts, as shown in Dr Bancroft's case and in my case, in which autopsies were procured and a microscopical examination of the tissues made are that the cancer-cells were not destroyed to any appreciable distance from the surface of application of the low heat, certainly not farther than would have been the case with the high heat application.

Dr Charles Mayo in discussing my paper on this subject at the last meeting of the Southern Surgical and Gynecological Society

cited in proof of the curative power of low heat, used as Percy directs a number of instances in the Mayo clinic at Rochester of what seemed inoperable cases of uterine cancer that subsequently became operable adding that when the uteri in these cases were examined by the pathologist he failed to find any evidence of malignant disease in them. I cannot however accept this statement a verification of the hypothesis that low heat destroys cancer element some distance from the surface of heat application. It can be accepted only as a personal belief based upon clinical manifestation of the individual patient. In such a case my view would be that the patient had in connection with the cancerous cervix a pure inflammatory condition either parametritis or a local pelveoperitonitis which caused more or less immobility of the uterus and that as the result of the heat treatment the nearby structures became dried out and mobility of the uterus ensued but the cancer itself had not penetrated beyond the depth of the cauterization. Such clinical misstatement we also see with high heat. The inflammatory infiltration may subside but the carcinomatous infiltration remains. To disprove my contention it is necessary that the operator should when the abdomen has been opened remove a part of the suspicious infiltrated area in the pelvis a reasonable distance away from the cervix and have it examined by a competent pathologist. If that shows cancer nests and the uterus becomes mobile subsequently so that a radical operation may be done and the specimen then removed by a real radical operation fails to show cancer element we are in a position to grant the alleged deep destruction of cancer element but not until such proof has been shown.

I call attention to those instances in which recovery followed a simple extirpation of the uterus despite the presence of some parametrial infiltration and in which after a period of a few months a re-examination failed to

show evidence of infiltration. I myself recall two such instances.

But let us pass from the theoretical and clinical test to the crucial scientific test the test being a deduction as the result of an examination of tissue treated by low heat in the *living* body by which we may get evidence which is beyond the possibility of deception. This test showed beyond a scintilla of doubt that cancer nests were destroyed only in the cauterized area and in the area immediately in contact with the cauterized surface. Even within only one millimeter of the charred zone apparently unaffected cancer nests were found. Surely high heat cannot exert a less destructive action on cancer-cell.

It is far from my intent to detract anything from the credit of our colleague Dr. Percy but I believe that his enthusiasm misled him as the result of his clinical experience to become imbued with unfounded hope.

Byrne although not the first man to use heat as a palliative measure was the one to bring this treatment to a fairly extensive acceptance and was equally enthusiastic as for a time were his follower. And when I say his followers (and I am one of them) I mean those who cauterized thoroughly as was directed by Byrne not superficially as I have seen done time and again and yet called cauterization by the Byrne method.

To speak for myself I can say conscientiously that I obtained and am obtaining with high heat results equally as good as those obtained by Dr. Percy with low heat particularly since I open the abdomen as insisted upon by Percy. It is my belief that if Dr. Percy will use either high or low heat according to indications he will arrive at similar conclusions especially if he subjects his work to a critical scientific analysis whenever opportunity presents itself. I believe that the advice of our late colleague Dr. Pryor to tie the internal iliacs in cases of cancer of the cervix is also of importance as a palliative measure.

NOTES ON THE PAST PRESENT AND FUTURE OF GYNECOLOGY
OBSTETRICS AND ABDOMINAL SURGERY

B. J. WESLEY BOVÉE M.D. F.A.C.S. WASH. D.C.

YOUR organization now holding its forty first annual meeting is the parent American body of the part of medicine represented by gynecology obstetrics and abdominal surgery. As a national gynecological organization it is the pioneer of the world. Composed as it is of the men most famous in America in these spheres of endeavor for the benefit of the human race its prestige is unquestioned. To be the chosen president of it should be the laudable ambition of every earnest and scientific American worker in the specialties mentioned. It is therefore with no little pleasure and pride that I sincerely acknowledge the signal honor you conferred on me last year by elevating me to this important position. It is not always brilliancy that appeals to the hearts of one's confreres, as one is bound to observe in this selection. Having been for many years at least a consistent worker in and for this society I am prompted to believe the selection was due alone to that reason. My pride surely is pardonable when we recall the names of my very illustrious predecessors. Certainly the names of J. Marion Sims, T. G. Thomas, T. A. Emmet, Barker Goodell, Peaslee, Baldy Davis, Williams, Kelly and many others who are or have been Fellows in this society will stand until the end of time as great medical geniuses. Nor can I allow this opportunity to pass to pay a tribute to the parents of this society, Chadwick, Munde, and J. Taber Johnson all of whom have been its presidents. Though death prevents our extending the hand of fellowship to the first two the last remains to us in sterling physical and mental integrity and may honor us by his presence at this meeting. Last year on the occasion of his transfer to honorary fellowship the society signalized its affection for him and appreciation for his services to it by sending him a very handsome tribute in the form of a well prepared letter signed by each Fellow in attendance.

In a study of the history of gynecology in America one is thrilled with pride by the remarkable strength of character portrayed by the early workers. McDowell, Nathan Smith, Peaslee, the Atlees, Dunlap and others passed triumphantly through the fiery furnace of scorn, hatred and slander of communities, and even of their professional colleagues in their efforts to create a legitimate position in medicine for the surgical removal of large ovarian tumors. In Reeves' memorial of Dunlap he mentions the rebuffs the latter received from surgeons and even his college professor. Dunlap states regarding his first operation: "With a great deal of labor and care I prepared a report of the case for a Cincinnati medical journal the editor of which was my old professor of *Materna Medica* in the Cincinnati Medical College, Dr. John B. Harrison. The editor returned the manuscript with a note explaining that his reason for not publishing it was that it would encourage an unjustifiable and murderous operation which had already been tried and condemned by the profession, both in this country and Europe." Another rebuff was from a noted surgeon who told him, "You ought not to be doing such things." The Atlees in Philadelphia were condemned as murderers and butchers for doing ovariectomy and not a surgeon in New York would defend this operation when Peaslee read his paper before the New York Academy of Medicine in 1864. Kimball of Lowell, Massachusetts (1855) and others were struggling similarly to secure recognition for the surgical removal of large uterine fibroids by the abdominal route.

The work and ingenuity of Sims in the treatment of vesicovaginal fistulae will ever serve as a stimulus for the disheartened struggling against formidable agencies in various and devious avenues of study of the mysteries of the living human body and the

T. Am. Gynec. Soc. 1894, 27, 290

amelioration of its ailments. The work of his faithful pupil Bozeman in this sphere cannot but arouse admiration. Even Sims was not entirely uninfluenced by besetting disappointments and surgical failures for he was known to have become so disheartened in his work in the South that he sold his property and arranged to embark elsewhere upon a business career. Had not the New York clothing merchant violated his contract at this juncture most likely medicine would have been deprived of the aid of this wonderful man and the human family of the benefit of his medical researches. His prodigious mentality and great activity were again appropriated by our profession as by a providential intercession. Just why the master mind and hand of such a man cannot be spared to benefit mankind indefinitely is one of the unexplained mysteries of Nature.

The plastic work of the eldest Emmet and the great work of Thomas Polk and Fordyce Barker will always be appreciated. The plastic perineal surgery of J. Collins Warren the round ligament operations for the rectification of posterior uterine displacements associated with the names of Dudley Mann, Wylie Simpson, G. H. Noble, Andrews and others remain familiar to us all. Not to refer to Hodge, Parvin, Meigs and Oliver, Wendell Holmes were to slight obstetrics with its other great geniuses.

We must recall with American pride the impetus to urinary surgery given by Kelly, who popularized direct cystoscopy and ureteral and renal exploration by its aid as well as the advanced work of several Americans in the scientific treatment of urinary diseases. The work of Coffe and Baer invoked a great advance in the surgical treatment of uterine fibromata. C. I. Noble by his careful and laborious study into the complications and degenerations of these neoplasms rendered an invaluable service.

I have not mentioned these great men as comprising all the talent in obstetrics and gynecology for surely later years have not stinted us in furnishing us with wonderful skill working with precise methods and securing definite and undeniable results but rather honoring myself by claiming a cer-

tain relation ship with these great men. Boasting of the accomplishment of our professional progenitor and fellow worker may be pardonable.

Of the splendid work of the past gynecology has not neglected the great subject of cancer. This disease as it affects women is almost limited to their reproductive organs. The uterus is the organ most commonly invaded by it. Probably Wisnberg and Montagna were the first to recommend total hysterectomy for its eradication. Marshall in 1780 and Langenbeck in 1811 were the first to perform this operation though in their cases the uterus protruded from each patient. In 1814 Cutbush recommended hysterectomy by a special suprapubic method. In 1821 Sauter of Constance first performed vaginal hysterectomy for cancer of the uterus *in situ*. Recanuer in 1829 recommended a special plan of vaginal hysterectomy and the following year Delpech proposed a combined abdominal and vaginal procedure. To the lover of medical history it is interesting to read the comments upon these operations made by medical writers during the next few years. Blundell whose small book "Observations on Some of the More Important Diseases of Women" appearing in 1837, is particularly interesting. Little progress was made until January 30, 1878 when Freund began performing his radical abdominal operation after cauterizing the cervix or even amputating it when large. I cannot but yield to my sense of justice in passing and mention here that Freund employed as an essential feature of his procedure in 1878 the very position so well described in 1801 by Trendelenburg and that his since borne his name. It remained for our American gynecologist Emil Ries of Chicago to plan and recommend a very radical operation for cancer of the cervix which he succeeded in having performed in 1895 by the late Wertheim. Ries has been an indefatigable investigator of this affection and deserves great credit. Nor can we leave this subject without alluding to the inestimable original work in this affection that was done by John G. Clark and N. O. Wender at about the same time that Ries and Wertheim were beginning their work in Berlin.

The galvanocautery as employed by John Byrne Skene and many others following their advocacy of it has been most efficacious.

Of obstetrics one must speak with considerable reserve. The untrained obstetrician has been the weak spot in our preparedness. The famous teachers—Parvin Barker and others did not to a desirable extent impress our profession with the importance of this specialty. This, no doubt, was in part due to its being a heritage from the midwife who has striven to claim it as a possession. In later years an earnest effort has been made by a few very efficient teachers to secure to obstetrics a proper recognition. The vigorous propaganda by Williams has probably aroused the medical schools to an appreciation of the necessity for much better facilities for real teaching of obstetrics. From a course practically didactic with manikin demonstrations and no clinical work it has been transformed into one clinical as well as didactic. In the last few years clinical obstetrics has been a strong feature in the medical school curriculum. The requirements of the examining boards of the various states reflect the appreciation of necessity of better equipment for the practice of obstetrics and has been a very strong factor in the marked improvement in obstetric training.

A complaint of inefficient teaching of gynecology in the past may be made in full justice. Dealing with the diseases of the female genitalia has had an inherent delicacy which has deterred the teacher from bringing students in as close relation to gynecological patients as to those suffering from diseases of other parts of the body. I submit clinical work as viewed from the amphitheatre has little superiority over didactics and students must be brought in close touch with disease in order to study it to greatest advantage.

Of the child, abdominal surgery we may well say it remains at home with its parents. For surely it was brought into existence by gynecology and obstetrics. When we recall the fearless abdominal surgery of Lawson Tait the cholecystotomy of J. Marion Sims, and the determined effort of the latter to establish prompt laparotomy with suture of the injured viscera as the accepted treat-

ment of gunshot injuries of the abdomen we at once see the relation of parent and child.

Even the first nephrectomies known to history (both fatal) that of Walcott, of Milwaukee June 4, 1861 and Spiegelberg in 1867 were done with the pre-operative diagnosis of ovarian or hepatic cyst. The first successful nephrectomy that of Simon in 1869 was done for a severed ureter complicating an ovariectomy. The genius Sims did the first cholecystotomy. Thomas operation of gastro-elytrotomy was a leader for more precise and better obstetrical abdominal surgery. Much has been written and timely regarding the unpleasant sequelae of laparotomies. A remarkably large proportion of patients whose abdomens had been invaded suffered from intraperitoneal adhesions, intestinal obstruction, fecal fistula, sloughing ligatures, and various other unfortunate conditions originating in the operations. This was such a sad commentary upon abdominal surgery that it acted as an obstruction to the rapidity of growth of the justifiability of this variety of surgery. So much for abdominal surgery as placed upon a sound basis by gynecology and obstetrics.

As yet the general surgeon had little to do with abdominal surgery. Nor was his attention directed practically to it until the specialists mentioned had ripened and prominently and enthusiastically praised this great field of surgery. Its early days without general anesthesia or asepsis must be reviewed by us with shuddering amazement. Many of us have seen it without the latter when it seemed disheartening. To Crawford W. Long who like Sims, had been an obscure village physician and to the creators of clean surgery we owe no small obligation. It has been markedly developed during the last thirty-five years so that now no portion of the lower half of the torso has any unknown parts. Even the suprarenal body is being resected for quite definite indications.

It would be unpardonable not to give due credit to bacteriology for its powerful aid in arriving at the intelligent treatment of infections found in the pelvis and the abdomen. One is led to wonder at the lateness of this correlation of bacteriology with gynecic and

abdominal surgery. Even as late as December 1879 in a debate in which many of the leading surgeons of London participated Mr Timothy Holmes was able to say: "No convincing proof of the germ theory as applied to living tissue and living phenomena has as far as I know yet been offered." It was not until 1881 that the observations of Ogston on the relations of micro-organisms to surgical diseases were published. And not until the publication of Rosenbach in 1884, and of Passet in 1885 were the varieties and natural history of the common organisms of suppuration fully described and their identity established. These had to be preceded by the epoch making researches of Koch on staining methods and culture media. Since then this branch of medicine has attained by wonderful strides a position of vast importance in the three great fields of medicine under consideration.

During the forty years existence of this society there have been times when it has seemed the problems of gynecology and obstetrics were practically all solved that nothing new was to be learned and that solely practical application of known facts was to be their future. This was indeed a gloomy view for the generation that marks no advance over the work of the preceding one is practically dead. In the field of investigation of the better cementing of the brotherhood of man and of the uplifting of the human family—in all these—advances must be constant. In fact the very existence of such specialties was thought to be jeopardized. The mechanical part of gynecology surgery was being largely taken up by the general surgeon who giving little heed to the real foundation of gynecology—that of the study of womankind—perhaps thought that operations constituted the whole field of this branch of medicine. The family physician entering the practice of his profession very poorly trained in the science and practice of obstetrics soon secured a rather large obstetric clientele absolutely by propinquity. He promptly learned that women served in time of such suffering were deeply appreciative and retained his services for other professional necessities. Such conditions

naturally lent themselves to the creation in many minds even in some great one of distinct fear of extinction of these two great sister specialties in our science. And yet the jeopardy was more threatening from other directions. Uninformed clouds passed in review. In many medical colleges gynecology no longer regarded as an important peculiarity was obliged to a unimportant rôle in the work of the chair of surgery. In others it was combined with bacteriology in one chair. While recognizing both peculiarities this plan robbed both of their dignity and prestige.

Another effort to terminate the extinction of at least one of these branches of science was that of the section on surgery of the American Medical Association at a meeting a few years ago to have its sphere extended to include gynecology and abdominal surgery. It failed however and at a subsequent meeting of the association abdominal surgery was added to the work of the section on obstetrics and diseases of women. I understand an amicable adjustment has been made putting abdominal surgery in both of the sections mentioned. The situation of gynecology and obstetrics may now be regarded as stable. I believe no fear need exist of loss of recognition of either. Both are very healthy adults and not to be regarded as infant industries needing fostering care. No distinct pause in their development has occurred since the organization of this society. The training of the medical student in gynecology is on a splendid plane. The graduating student is far more proficient in gynecology today than was the general physician of several years experience a short time since. The carefully prepared case histories—prepared by students under efficient supervision—the thorough laboratory investigations and opportunity for carefully supervised physical examinations bring the students to a basis for logical diagnosis—the paramount necessity for correct treatment. The clinical teacher who frequently states something is wrong in this abdomen and I will open it and then make the diagnosis endangers his reputation.

In the teaching institutions the same plan

of instruction in obstetrics obtains to a considerable degree. Both obstetrics and gynecology are gaining in this respect and while we do not expect marvelously rapid transformation in such matters owing to the marked changes in hospital construction and régime necessary thereto nevertheless a sense of pleasure has come to the teachers in these branches of medicine from the progress of the last few years.

In abdominal surgery the dread of dire results from sepsis ignorance shock hemorrhage and several other former causes of needless mortality has nearly vanished. While problems in this field of endeavor remain unsolved, diseases of the abdomen are much better understood than formerly. Various aids are now being employed to assist in the diagnosis or treatment of pelvic and abdominal diseases and I dare say they will have notable extensions. The roentgen ray has greatly assisted in the discovery and location of adhesions, neoplasms, ulcers and stases of the stomach and intestine determining the presence or absence of biliary renal, and ureteral calculi and indeed with the ureteral catheter is an extremely reliable agent for determining whether urinary calculi above the bladder exist. We are justified in believing it will prove of great value in diagnosing pregnancy and various abdominal and pelvic tumors. Laboratory findings in huetic and Neisserian tubercular and other infections though of great importance, must and will assume a still greater rôle in our agencies. I feel sure that even improvements will be made in more careful investigation of patients histories to determine the time for operation as well as in the technique to be followed. Already the surgeon is cautious in radically invading infectious areas often delaying with advantage when the less skillful would fairly plunge into a surgical operation. F. F. Simpson has recommended marked delay even months, for radical operations in infections in and about the uterine appendages. The value of this plan can scarcely be questioned and its universal acceptance may be expected in the treatment of patients who can afford the extra time this requires. It is another feature in the conservative

practice that goes with greater knowledge. In ectopic pregnancy his advocacy of delayed operation has been quite universally heeded.

The subject of displacement of the uterus from time immemorial has been a fruitful one for lively and even bitter discussion. Careful study of the forces maintaining the position of that organ are gradually lessening the differences of the past in this respect and we may reasonably hope for full accord in it. Pelvic non puerperal infections are steadily losing their terrors and we may look for them to be practically removed from the class of highly dangerous diseases. This will be largely due to the recognition of the superiority of dependent drainage and conservation in their radical treatment.

The treatment of cancer of the uterine cervix continues to receive the very earnest attention of gynecologists and special activity in the general subject of cancer during the past three years has been enthusiastically aided by this society. Thus far the cause of cancer has not been found and no doubt this must be discovered before we may reasonably expect to gain a mastery over this dreadful disease. Its behavior as influenced by radium and long-continued, slightly elevated temperature as advocated by Percy is of interest. The use of certain rays from radium seems to retard its progress and perhaps completely destroy it while other rays from it are thought to induce the disease. If the latter be a fact we may well refuse to believe, for the present that cancer is of microbic nature. Even the Percy method emphasizes this doubt for it should stimulate microbic activity yet its retarding influence on the progress of cancer of the cervix is attested by many careful and reliable observers. But neither of these two agents can be regarded as a specific for this disease for they are both notably limited in their radius of action. Whether radium has deeper penetrating power as a cancer destroyer than the Percy heating method is a matter of doubt and the cases reported by Boldt throw grave doubt on the penetrating power of Percy's method used for this purpose. This latter method is based upon the application of a low elevation of heat to the involved tissues. And yet

for this purpose is employed an instrument so hot that it has constantly to be moved to prevent overheating and the heat is gauged principally by the sense of touch through the uterine wall which varies greatly in individuals. If this method is proved a specific against the active agent of cancer is it not to be the sole agency in the treatment and cure of cancer in the breast bladder vagina vulva and rectum? If it has a positive specificity for two inches then no part of the human body will be inaccessible to its beneficent influence.

It would appear then that our hope in cancer of the uterus continues to consist of surgery as early as possible universal education on this subject the employment of radium and high or higher temperatures and unremitting search for the true etiology of it. Radium offers benefit to other forms of neoplasms particularly to the bleeding uterine fibroid according to several credible observers. Nevertheless it is yet but an empiric agent not available to more than a very small percentage of patients suffering from the many conditions in which it is extolled and not without its evil effects such as corrosion of tissue. While we may believe enthusiastic faith has had much far too much to do with the reported results of radium application we cannot fail to recognize that this agency when properly harnessed has great possibilities in the treatment of pathological conditions. I believe it is deserving of being absolutely divorced from charlatanism and commercialism. Its exploitation has been unfortunate.

In obstetrics a nearly parallel situation is found in the attitude and sympathy several prominent workers and teachers have afforded the unsational use of the various alkaloids of hyoscyamus and opium under the alluring name of twilight sleep. In the sweeping march over the continents of this dangerous method the professional and moral fibers of even the flower of the obstetric world have been challenged. It has nearly equaled the tales of the French revolution. It is believed the danger of this awful flood has passed and the conscientious and competent obstetrician may now come down from his

Mount Ararat and pursue the even tenor of his way. Probably humanity has been benefited by this visitation only to the extent that it has prompted us to take stock of our methods and even of our humaneness and has appealed perhaps not unnecessarily to still greater concern for the suffering of our patients. The outcome of this superior substitutes for opium and hyoscyamus are now employed. Probably the open mind is now predicting that at no distant date twilight sleep will rarely be recalled to memory and nitrous oxide and oxygen inhalation during labor will be given an enduring place in the obstetric régime.

It is highly probable that cesarean section will be given a wider field of application. The vulnerability of tissues of women certainly of American women will be fully recognized and they will not be subjected to unreasonable and unbearable obstetric strain and avoidable infant mortality. Much greater advance in teaching obstetrics may be expected than has been obtained. Largely to J. Whitridge Williams should we attribute such improvement.

In abdominal and pelvic surgery at its present stage of development probably no more important matter is before us than the prevention and correction of interperitoneal adhesions. A propaganda on this subject should result in untold lessening of human suffering. Very likely an active educational campaign would greatly lessen the evil of post-operative adhesions. The finding of large areas of adhesions in the abdomens of patients who have been previously subjected to laparotomy for simple or clean conditions is far too common to escape the attention of the careful abdominal surgeon. Nor is it always the tyro that unnecessarily violates the parietal and visceral peritoneum by undue handling suturing etc. Various materials have been extolled as prophylactics against post operative adhesions. I will not tax your time by enumerating them but will refer to a few of them. Vaseline highly regarded by some of America's greatest abdominal surgeons I feel I must severely criticize. One to three years after I had smeared it over denuded peritoneal area I have re-

moved from the abdomens of patients encysted masses of vaseline having diameters up to one inch and have found adhesions were very extensive. In some places these capsules of vaseline formed a dense rigid connecting structure between several loops of intestines. Acting upon the theory that

before a fibrous exudate can form in the peritoneal cavity with its resultant plastic agglutination there must be the liberation of that hypothetical ferment, thrombokinnase its activation of prothrombin in the presence of calcium and the production of thrombin Saxon Pope experimented on sixty rabbits and published his work in January 1914. These experiments were made with many different materials and he concluded from this work that a solution of 2 per cent sodium citrate in a 2 per cent solution of sodium chloride was the best remedy. His faith in his conclusions is proved by his reporting in February 1916 the results of the employment of this hypertonic solution in 400 abdominal operations in the University of California Hospital. Walker and Ferguson, doing 104 operations on 63 rabbits, found 3 per cent of the citrate in 2 per cent of sodium chloride solution was the most satisfactory giving complete success in 70.5 per cent and 88.2 per cent partial success. Certainly such results merit our attention. In the presence of sepsis or deep or wide destruction of tissue it is not claimed these hypertonic solutions can be regarded as infallible but even here they are of use. In my personal experiences with the 3 per cent solution of the citrate in quantities of 200 to 300 cubic centimeters considerable shock has been noted. Among the questions that arise in our minds are

1. If it gives absolute success in .05 per cent in mild peritoneal traumatism can its use be extended to success in such severe peritoneal injuries as separated adhesions?
2. How long must it be in contact with the area to be of highest efficiency?
3. What is the duration of its activity?
4. Can it be used efficiently in gauze covering large areas of peritoneal denuda-

tions and brought out through the abdominal wall?

If these questions are to be later answered satisfactorily to us then we will have positively mastered this much dreaded and dangerous complication — peritoneal adhesions.

Coffey has recently invited attention to his rubber pessoidam brought through the abdominal opening used in separating pelvic adhesions in a ute attacks of adnexal infections. Though he specifically claims no hernia fell was this prolonged abdominal drainage I fear that claim will not tempt many to use this method of dealing with such conditions. I believe the paraffin-stearic gauze recommended by Fisher used as a drainage material for pelvic adhesions and conducted through the vagina will be found very satisfactory. While I have not attempted to be a seer yet I have been so impressed by some of these efforts to lessen the dreadful peritoneal adhesions that I have been emboldened to risk tiring you with this rehearsal.

We are at great loss for lack of knowledge of the influence of luetic infection on the pathological conditions we as specialists must treat. In the past the degree of precision in diagnosis of this variety of infection has been so slight that we have not been able to associate with it observed lesions to the degree of certainty that the Wassermann reaction now permits. The routine blood examination reveals a startling frequency amounting almost to regularity of the positive Wassermann which quite reliably indicates the presence of lues. It is to be hoped the attention given to this subject at this meeting of our society will have the much needed stimulating influence on the profession in general necessary to a due appreciation of the momentous importance of recognition of lues in obstetrics and gynecology.

Surely there are very many grave problems to be solved in the fields of endeavor you represent but I am unboundedly confident this society will in the future maintain in that work the prestige that has come from the high character of work it has performed.

EPILOITIS FOLLOWING HERNIOTOMY

BY WILLIAM HESSERT M.D. F.A.C.S. CHICAGO

DISEASES of the omentum are relatively uncommon and literature on the subject is scant, especially in the English language. Omental diseases are either tumors or inflammations. The former include carcinoma, sarcoma, lymphangioma, cyst, and teratomata. The inflammations are divided into two groups which include first the cases that occur post-operatively and second those not preceded by operation. Herniotomy is the operation most frequently concerned in the first group and since ligation of the omentum is done in only a small minority of hernia operations it follows that epiploitis as a complication is likely to be uncommon. Some operators with large experience in hernia work have never encountered it.

The most recent publication on the subject of inflammatory tumor of the omentum is by L. Feterhanwahr.¹ This author has collected 44 cases, 36 of which had been preceded by operation, mostly herniotomies. Lucas Championnière observed two cases of epiploitis among 275 operations for hernia. Duboi² one in 300 cases and Tuffier³ one in 600 cases.

The French literature contains the first reference to this subject in 1892 by Lucien Championnière followed by Reynier in 1893, Forge in 1896 and later by Boeckel, Meniere, Morestin, Le Dentu and others. Schnitzler's article in 1900 was the first to appear in German. Cumston and Humann are among the few who have written on the subject in this country.

American writers on hernia scarcely mention the possibility of epiploitis following ligation of the omentum. While it is true that epiploitis is a rare complication in this country due to the general use of absorbable ligature material yet the matter is of more than academic interest and should be familiar to every surgeon. The fact that two cases occurred within a short period in the writer's

practice suggests the belief that more cases would be diagnosed were there a better understanding of the subject.

The case histories which follow illustrate the acute and chronic type of this disease.

CASE 1. A young man had been operated upon for a moderate sized inguinal hernia. A large piece of omentum was mobilized and used in heavy pack of iodine gauze. The patient progressed normally for about eight days but then the wound healed slowly with infection. Then the patient developed epiploitis and complained of abdominal pain on the left side. Nausea and vomiting ensued, the illness became febrile and the bowels failed to respond. The abdominal pain became general and all the symptoms were intensified. When on the nineteenth twelfth day of the disease the condition of the patient was desperate. He presented the typical picture of general peritonitis and it was impossible to determine whether any relation existed between the peritonitis and the pre-linguinal hernia.

The abdomen was immediately opened by means of a left rectus incision on a level with the umbilicus. The peritoneal cavity was full of pus under high tension, the fluid was turbid and flaky and the bowels were covered with exudate. The ligated pedicle of the omentum was found in the upper left quadrant of the abdomen. It was about the size of a lemon covered by exudate and saturated with pus. The adhesions to the abdominal wall were easily separated and it was seen that the tumor was loosely attached to the transverse colon. The catgut ligature was still intact. A hurried examination revealed no lesion of bowels, bladder or other organs. Nothing was done further than drain but the patient died twenty-four hours after.

This infection of the peritoneal cavity could have been introduced in no other way than by the retracting omental stump. The omentum became contaminated during the progress of the operation and the pedicle proved a favorable medium for bacterial growth. The catgut was not at fault, for the same material was employed in the repair of the hernia which healed *per primam*.

CASE 2. A man 40 years of age had a large right inguinal hernia which was operated on and a large piece of omentum was removed by the aid of several catgut ligatures. The wound healed without infection and the patient left the hospital at the end

of two weeks. After a free interval of about two weeks he began to suffer vague abdominal pains. Two weeks later he consulted the writer and complained of general malaise, anorexia, constipation, pains on the right side of the abdomen and swelling about the level of the navel.

Examination of the site of operation was negative—the hernia had healed perfectly. The abdomen was slightly distended, and the muscles on the right side were somewhat rigid. To the right of the umbilicus a mass could be felt which was about four inches in diameter and fairly well circumscribed. It was sensitive to pressure, and did not move with respiration. There was dullness, almost flatness, on percussion but a zone of tympany separated this area from the liver.

There was nothing about the findings to suggest involvement of the liver or kidney and the mass was rather higher up in the abdomen than the ordinary appendiceal abscess. There was an evening rise of temperature to 100 and a leucocyte count of 10,000. The urine was negative and further physical examination was negative. These findings in the history should have suggested the diagnosis.

The abdomen was opened through a right rectus incision directly over the tumor which was found adherent to the abdominal wall. The adhesions could be readily separated and the mass freed from the wall and underlying bowels. Upon delivery the mass was found to consist of inflamed omental tissue. Almost all that was left of the omentum was involved, there remaining only a small bridge of healthy tissue where it was attached to the transverse colon. This was fortunate, for it permitted easy ligation and removal of the whole tumor. The inguinal region was found on examination from the inside to be perfectly normal. The patient recovered from the operation and remained well.

The tissue removed was hard and dense, being composed of fibrous and fatty tissue, with preponderance of the former. In the center of the mass several small abscesses were discovered from which *staphylococcus aureus* was grown. No trace of the ligatures could be discovered. This case illustrates the most commonly observed type of epiploitis, namely the subacute variety. It differs only from the ordinary in that catgut was used instead of the more notorious offender—silk. While the number of the reported cases has recovered spontaneously the findings in this case preclude the possibility of recovery without operation.

A number of types or varieties of epiploitis are described by various authors, but the classification of Peterhanwahr seems to be the best.

1. Post operative variety. (a) Simple inflammatory, hyperplastic type. (b) Suppurative epiploitis.

2. Extension from neighboring organs, not following operation.

Sauget describes three varieties as follows: (a) Epiploitis plastica simplex. (b) Epiploitis plastica with adhesion. (c) Epiploitis purulenta.

The variety most commonly observed is the simple inflammatory or hyperplastic. The free interval after operation before the onset of symptoms is variously reported at five days to three years. In the majority of cases however it will average three to four weeks.

The type of inflammation which develops in the given case depends upon the virulence of the infection or the degree of mechanical irritation. In the very acute cases, of which an example is reported in this paper, the acutely inflamed omentum is but part of a general peritonitis. As the process becomes more chronic the inflammatory products become more organized and fibrous. The mass may look like a fibrolipoma and on section one or more abscesses are usually found with the ligature as a nucleus. Adhesions to the abdominal wall are most constant, and at times large abscesses have developed which were opened by the surgeon or gained a spontaneous exit. Sinuses have formed and persisted due to the presence of masses of silk.

There remains finally to be mentioned the slowly growing chronic form which so much resembles a malignant tumor that diagnostic errors are almost inevitable. The structure of the mass is so dense and fibrous that this together with the absence of pus simulates the gross appearance of malignancy closely. It is the opinion of many that the mechanical irritation alone of the silk without any accompanying infection, is capable of developing the large fibrous growths which have been encountered.

The factors primarily involved in the development of epiploitis are the following:

1. The ligature material.
2. The manner of ligation.
3. The condition of the omentum at the point of ligation.
4. Infection.

1. *The ligature material.* In about 90 per cent of the reported cases the material used was heavy silk (Reynier, Monod).

(Guinard Braun) In a small percentage of the cases other material such as catgut or kangaroo tendon was employed. Silk alone without added infection has been known to stimulate the development of enormous fibrous masses. This is explained by Hollander on the theory that while the ligature may have been drawn tightly enough on the pedicle to secure hemostasis it did not produce necrosis and this bit of living tissue in the stump was stirred into tumor like growth by the irritation of the silk. I am inclined to the belief that there is an element of infection in all of these cases. Virulent infection will result in any of the acute types of sepsis while a mild infection may eventually become sterile or result in sinus formation. Such sinuses will not close until the offending silk is eliminated. Absorbable ligatures when infected provoke the same disastrous results as silk. The absorbability of the material when sterile precludes the possibility of any late irritative effect.

2. *The manner of ligation* has much to do with the occurrence of epiploitis. The case records show with few exceptions that the omentum was ligated either *en masse* or with a figure-of-eight ligature. This bunching of the omentum into one ligature has been a fruitful source of trouble.

3. *The condition of the omentum at the point of ligation* has had much to do in contributing to a bad result. Thus if section is made through diseased tissue the result of chronic inflammation as is so frequently observed on old or incarcerated hernias the retracted pedicle becomes a source of trouble. Reynier, Roche, Boeckel and others report cases of this kind in which silk was used.

4. *Infection.* It seems probable that infection is the most important factor acting either alone or in conjunction with any of the other predisposing causes. That the irritation which results in the formation of large tumor like masses is entirely mechanical is open to question. How often do we see silk when sterile heal in the tissues without causing any reaction whatever. When large fibrous masses develop we have bacterial irritation added to the stimulus of the foreign body the silk ligature. It is conceivable

that a low grade of infection after producing its effect might become sterile and culture taken from the silk would show no growth thus lending support to the mechanical theory.

SYMPTOM

In the very acute cases the symptoms arise a few days after peritonitis and consist of the usual signs of intra-abdominal infection within the abdomen ending with general suppurative peritonitis. In rare instances the process may become localized with abscess formation.

By far the majority of the cases run a subacute or chronic course lasting for months or even years. The time interval after operation is generally of four to eight weeks duration but cases are on record in which two to three years elapsed before the onset of symptoms.

Pain is one of the first and most constant symptoms. It may at first be in any portion of the abdomen depending on the location of the inflammation. Frequently it is in the upper abdomen and is aggravated by deep breathing, coughing, or tight clothing. Associated with the pain there is usually a rise of temperature with all its attending symptoms. There may be an absence of signs pointing to any special organ and in some cases the symptoms all subside and the patient gradually makes a spontaneous recovery. More often the disease continues progressive with finally all the signs of a localized abscess in the abdomen manifest. The pus in such cases may rupture into the bowel or succeed in burrowing through the abdominal wall.

In the type of cases that develop slowly and insidiously with vague and ill-defined symptoms there is great resemblance to the clinical course of a cancer. The presence of a palpable mass is further suggestive of malignancy. In doubtful cases the abdomen has been opened and even then the operator is in doubt whether the tumor is a carcinoma, sarcoma or of inflammatory origin.

DIAGNOSIS

In every case of a herniotomy where abdominal symptoms supervene the possibility of epiploitis must be considered. It is very likely that there have been many cases which

have not been recognized or have been incorrectly interpreted because epiploitis in this connection has received but little attention. Diagnosis is suggested by the occurrence of pain associated with the development of a mass in the abdomen. The tumor is usually on the same side as the herniotomy on a level with or above the umbilicus. The tumor has been but rarely seen in the pelvis or inguinal region. The tumor varies in size but has been known to grow very large. It is tender on palpation and is usually fixed to the abdominal wall so that it does not move with respiration. There is usually dullness or flatness on percussion as the intestines are beneath the mass.

In differential diagnosis one must consider cholecystitis, subacute appendicitis, chronic perforation of the stomach, foreign body (such as a gauze sponge), diverticulitis of the sigmoid and pancreatitis.

TREATMENT

According to Braun the development of an inflammatory tumor of the omentum after herniotomy does not necessarily demand operation for a fair proportion of such cases recovers under expectant treatment. It is fair to assume, however, that the diagnosis in some of the recovered cases might be open to some question.

The most radical view relative to treatment was expressed by Reynier, one of the early writers, who advised extirpation of the tumor as though it were malignant.

The practical lesson to be learned is that we should be familiar with epiploitis, as it may complicate recovery after a herniotomy and adopt the measures necessary for prevention. These are in fact elementary and include first a faultless operative technique, both aseptic and mechanical. There should, above all, be an avoidance of rough handling of tissues. Portions of the omentum should not be removed at all during the performance of a hernia operation unless there is a valid indication. If resection must be made, then absorbable suture material of as small a size as possible should be employed. The vessels in the omentum should be tied with many fine ligatures, and the use of *en masse* or

figure-of-eight ligatures should not be considered. Section should always be made through healthy omental tissue, never allowing any diseased tissue to slip back into the abdominal cavity.

After the diagnosis of epiploitis has been made the decision for operative interference rests with the judgment of the surgeon. The acuteness of the symptoms and the progress of the disease would be determining factors. Under ordinary conditions no harm can follow an exploratory incision. It is best to remove the inflammatory mass completely if possible. If owing to adhesions and abscess formation, removal is impossible then there should be thorough drainage.

In the event of intestinal obstruction caused by an ill-tubrous inflammatory mass, it may be necessary to resect or shortcircuit the bowel.

THE TRANSPLANTATION OF THE ARTICULAR END OF BONE INCLUDING THE EPIPHYSEAL CARTILAGE LINE

By S. L. HAAS, M.D., SAN FRANCISCO

From the Pathological Laboratory and the Surgical Pathological Laboratory of Leland Stanford Junior University School of Medicine

IN a previous paper entitled "The Experimental Transplantation of the Epiphysis" the effect of transplantation on the longitudinal growth of bone has been considered by the author (1). The results of those experiments show that the longitudinal growth ceases after transplantation of the epiphyseal cartilage line whether by itself or with a neighboring piece of epiphyseal or diaphyseal bone. In the present article a description of the macroscopic and microscopic changes occurring in the various components of such a transplant will be given.

Thus it becomes necessary to consider the changes occurring in the articular cartilage, the marrow and the trabeculae of the epiphysis, the epiphyseal cartilage line, the marrow and the trabeculae of the diaphysis and the cortical bone. Normally there are certain constructive and destructive changes taking place in a growing bone but with the additional influences of transplantation the complexity of the study is considerably increased.

In order to understand clearly the changes that take place it will be advisable to describe minutely the structure of the epiphyseal end of a growing and developing bone because certain terms not given in the usual histological descriptions are employed in the text and also because it is necessary to express in definite defining terms what is understood as epiphysis, epiphyseal cartilage line and metaphysis which are so often very loosely employed.

Normal epiphysis. In the very early periods of bone development the epiphysis is entirely cartilaginous. With the appearance of the center of ossification there is a gradual disappearance of the cartilage until only a shell remains surrounding the cancellous epiphyseal bone and marrow (Fig. 7). The cartilage at one end persists to form the articular cartilage while that at the inner

boundary forms a part of the epiphyseal cartilage line. The part of the epiphyseal line toward the epiphysis will be designated as the epiphyseal ossifying cartilaginous layer (Fig. 1). It consists of hyaline cartilage with irregularly scattered nuclei and from its epiphyseal side ossifying buds of cartilage extend into the epiphysis. In the older animal the part of the shell of cartilage connecting the articular cartilage with the epiphyseal cartilage line undergoes complete ossification so that the articular cartilage is no longer found to be inserted into the epiphyseal line. The remainder of the epiphyseal cartilage line is composed of columns of cartilage-cells, the nuclei of which are flat and heavily stained near the epiphyseal ossifying cartilage layer but gradually become round and larger on nearing the metaphysis until they finally are of a vesicular structure with a surrounding light staining protoplasm. These large vesicular cells form the boundary between the epiphysis and the metaphysis and finally become a part of the latter. It is by the proliferation of the cartilage-cells of the epiphyseal cartilage line that the longitudinal growth of bone is maintained. The exact process of this procedure will not be considered at present.

Normal metaphysis. The metaphysis is made up of osteoid tissue in which there are numerous vascular loops. Extending into the diaphysis are long irregular columns of cartilaginous matrix which are in various stages of ossification, from partial at their beginning in the metaphysis to complete at their ending in the diaphysis. This will be designated as the metaphyseal ossifying cartilaginous layer (Fig. 1). There is a rich vascular marrow between these columns of ossifying cartilage.

The material for this report was obtained from seventy-five experiments on dogs, mostly in the early growing period. All of the opera-

tions were performed under general ether anesthesia during which the usual aseptic measures were employed. At the conclusion of the experiment the foot was protected by a light plaster-of-Paris dressing which was allowed to remain from fourteen to twenty-one days, the animal in the meantime having full freedom. At the conclusion of the experiment all of the metacarpal and metatarsal bones were measured in order to determine the amount of growth. From a large series of measurements in normal animals it was found that the two central bones of the metacarpal or metatarsal region of the same and of the opposite side, are all practically of equal length (Fig. 2). This affords a standard of comparison and allows an easy method of determining the amount of actual growth. As the metacarpals and metatarsals possess but one epiphysis situated at the distal end of the bone any change in growth that takes place can only be caused by proliferation from that particular epiphyseal cartilage line.

Röntgenograms were taken of the feet in many instances. Part of the specimen was preserved in Kaiserling's solution and part used for microscopical study. The tissue for microscopical examination was fixed in Orth's fluid embedded in celloidin and the cut sections stained with hematoxylin and eosin or Van Gieson's stain. Fifty-eight of the more important experiments are described in detail.

REIMPLANTATION OF EPIPHYSEAL CARTILAGE LINE

Method. The distal end of the bone is exposed until the epiphyseal cartilage line is visible. By means of a sharp scalpel a cross section of the bone in the region of the epiphyseal cartilage line including an adjoining piece of the diaphysis and the epiphysis is excised and immediately reimplanted. The width of such a section is about 0.4 cm. The piece is anchored in place by an X-shaped suture over the dorsal surface and the wound closed in layers. At the termination of the experiment the animal is killed by means of gas.

Experiment 1. Duration 4 days. Dog 24 14
age 3 months.

In this experiment the distal part of the bone is reimplanted.

Macroscopical description. The healing is normal. There is no growth of either normal or operated bones. The reimplanted segment is in contact with the host at its distal but not at its proximal end.

Microscopical description. The articular cartilage appears normal. The marrow of the epiphysis shows definite evidence of degeneration in both the reimplanted piece and in the host. The trabeculae of the epiphysis show uniform failure of staining of the bone-corpuscles and appear to be undergoing early degeneration. The epiphyseal cartilage line presents a rather normal appearance aside from increase in width. The metaphysis shows a normal arrangement of the ossifying cartilage columns but there is some lack of nuclear staining. The intervening marrow is necrotic. The marrow of the diaphyseal part of the transplanted segment is undergoing necrosis. The nuclei of the trabeculae of the diaphysis stain faintly and appear to be degenerating. The small amount of cortex of the transplant is lacking in clear staining. The elements of the host appear normal throughout.

Experiment 2. Duration 3 days. Dog 3 36
age 3 months.

Macroscopical description. The healing is normal. There is no growth of the normal or the operated bone but there is a considerable thickening in the region of the implanted cartilage.

Microscopical description. The articular cartilage became displaced following the operation so that the outer surface is turned inward allowing a normal penetration of fibrous tissue into the articular cartilage. The marrow of the epiphysis with the exception of a small area on the dorsal side near the epiphyseal cartilage line is replaced by young connective tissue in which are some fat cells. The trabeculae of the epiphysis are for the greater part made up of a homogeneous non-cellular tissue. Some of the trabeculae especially near the epiphyseal cartilage line on the dorsal surface, begin to show proliferation of new osseous tissue about their periphery. The epiphyseal cartilage line is markedly changed; only a band of cartilaginous tissue remains, which corresponds to the epiphyseal ossifying cartilage layer. The cartilage columns are entirely replaced by fibrous and vascular tissue. The metaphyseal ossifying cartilaginous zone is replaced by newly formed osteoid tissue. In the diaphyseal marrow there is a slight increase of polymorphous nuclear cells. The trabeculae and cortex has a normal appearance.

Experiment 3. Duration 3 days. Dog 23 3L,
age 4 months.

Macroscopical description. Good healing is present. The growth of the operated bone is 2 cm. while the normal is 0.4 cm. The articular cartilage appears smooth and the marrow of the epiphysis is fairly normal. The epiphyseal cartilage line is thickened. There is a whitish streak in the distal part of the line and a broad band of white tissue in the region of the metaphysis. The li ca

of union are still distinct. The remainder of the bone appears normal.

Microscopical description. The articular cartilage is normal in appearance a little from a light fibrous deposit on the outer layer of the perichondrium. The marrow of the epiphysis distal to the transplant is of normal appearance while that of the transplant is necrotic and fibrous except for a small area on the distal side near the epiphyseal cartilage line. The trabeculae of the epiphysis show a considerable amount of osteoporosis in relation about the homogeneous central part (fig. 3). The epiphyseal cartilage line is almost double the normal width. A distinct line of lag is seen in the row of columnar cartilage which divides them transversely into a proximal two-thirds and a distal one-third. This line corresponds to the white streak mentioned in the gross description. The cells of the epiphyseal cartilage have a normal structure with the exception of those near the line of cleavage. The cartilage columns are elongated and appear to be increasing in length. The metaphyseal ossifying cartilage columns are elongated. The marrow of the diaphyseal part of the transplant is necrotic and fibrous while that of the host is normal. The trabeculae of the diaphysis show new osseous tissue on their borders. The cortex of the host presents an active periosteal new bone formation near the line of union. At one place on the outer border of the cortex there is a node of osseous and cartilaginous material in which we can plainly see the proliferation of the periosteum to form new bone. This outgrowth is most likely associated with an injury to the periosteum during the operation.

Experiment 14. Duration 44 days. Dog 33 44L age 6 months.

Macroscopical description. There is good healing. The operated bone is lengthened 0.5 cm while the normal bone is increased 0.7 cm (fig. 4). The line of union cannot be distinguished. The bone is swollen in the region of the implanted cartilage line. The epiphyseal cartilage line is irregular being quite narrow at the center and proximal to it in the metaphyseal region is a white streak which appears to be degenerated tissue.

Microscopical description. Upon the surface of the articular cartilage there is a layer of fibrous tissue. Its inner layers appear quite irregular and there is a penetration of fibrous tissue into its substance. These changes in the articular cartilage are most likely due to trauma at the time of operation. The marrow of the epiphysis appears normal. The majority of the trabeculae are entirely regenerated except the central part of some which when by their poor staining at that point. The epiphyseal cartilage line is very irregular being quite narrow at the center and normal width at the sides. The peripheral part appears fairly normal although the cartilage columns are curved and bow beginning large and hanging. In the middle there is an entire absence of fibrous columns which are replaced by fibrous and osseous tissue. The meta-

physeal region is entirely replaced by osseous trabeculae. The remainder of the transplant and host appear normal.

Experiment 15. Duration 35 days. Dog 35-6R age 4 months.

Macroscopical description. The healing is normal. The operated bone is only a little smaller than the time of operation while the non-operated bone is 1.0 cm longer than before. The joint with the articular cartilage appears fairly normal with the exception that the cartilage is a little thinner. The entire epiphysis appears larger than normal. The bone is longitudinally sectioned after 1 hour and there is still a small remnant of the epiphyseal cartilage line. The roentgen ray shows the line but the bony continuity in the normal hosts makes it more likely that it is persistent cartilage at the line of union.

Microscopical description. The joint cartilage, the trabeculae and marrow of the epiphysis are of normal appearance. The epiphyseal cartilage line is entirely lacking though leaving only a small remnant of irregularly arranged cartilage and fibrous tissue in the line of union. The remainder of the transplant and host appears normal.

Conclusion on Reimplantation of the Epiphyseal Cartilage Line

In general the changes are confined to the reimplanted tissues. The earliest changes are seen in the marrow tissue where there appears to be a necrosis of the greater part even as early as the fourth day. The marrow spaces at 14 and 21 days are filled with a fibrous connective tissue but at a later period a further differentiation takes place and new marrow is formed. In these experiments on account of the close proximity of the normal tissues of the host it is impossible to determine the origin of the regenerated tissue.

The first evidence of degeneration of the epiphyseal cartilage line is seen at 23 days and appears as a cleavage line extending through the cartilage columns so as to divide it into a proximal two-thirds and a distal one-third. Later a progressive degeneration of the epiphyseal cartilage line occurs as is shown by the 44-day and 63-day experiment, there being almost a complete disappearance of the cartilage in the latter experiment.

The trabeculae undergo degenerative changes as early as 4 days and at 23 days there is regeneration from the periphery which is practically complete at 44 days.

The transplant heals in place so that at 44 days there is no evidence of the line of union.

AUTOTRANSPLANTATION OF THE EPIPHYSEAL CARTILAGE LINE

Method In this set of experiments a cross section of bone from the region of the epiphyseal cartilage line, including a piece of adjoining epiphyseal and diaphyseal bone is transferred to take the place of a similar section from a corresponding bone of the opposite foot.

Experiment 6 Duration 23 days Dog 3 3R, age 3½ months

Macroscopical description. There is good healing. The increase in length of the operated bone is 1 cm. while the normal bone is increased 0.6 cm. The bone is broader than the normal especially at the epiphyseal end. The articular cartilage is smooth. The lines of union are just visible. The epiphyseal cartilage line is rather irregular and has lost its normal gelatinous appearance. Just proximal to the epiphyseal cartilage line is a band of tissue of white color and the bone in that region is denser than normal.

Microscopical description. The articular cartilage is of normal structure except for a small defect at one place on the surface. The marrow of the non-transplanted part of the epiphysis is normal while that of the transplanted portion are poorly stained, especially toward their centers. The epiphyseal cartilage line is divided into a proximal two-thirds and distal one-third on account of the degeneration of the tissue in that region (Fig. 5). The parts on either side of the cleavage line present fairly normal appearance. The cartilage beneath the perichondrium is in a state of active development. In the metaphysis the provisional ossifying cartilage columns have a fibrous and necrotic change of the marrow. The line of union of the diaphysis is quite distinct especially near the periosteum where there is a considerable amount of callus. There is an increase of leucocytes in the diaphyseal marrow near the line of union.

Experiment 7 Duration 23 days Dog 3 3L, age 3 months

Macroscopical description. The appearance in general corresponds to that found in the previously described experiment. The normal bone has increased 0.4 cm. while the operated bone has only increased 0.1 cm. The epiphysis, however is denser. The epiphyseal cartilage line has not the same tendency to separate and the diaphyseal part of the transplant is less dense than normal.

Microscopical description. The articular carti-

lage shows some slight changes in the inner layers and there is fibrous deposit on the surface. The marrow of the epiphysis is composed of loose fibrous tissue, throughout which are scattered marrow elements both in the transplant and in the host. In the trabeculae there is marked proliferation about the periphery of the dead central portion. This applies to the trabeculae both in the transplant and to the part of the host near the line of union. The line of union in the epiphysis is fibrous in the center and articular in the sides. The epiphyseal cartilage line is broadened and shows a line of cleavage as in the previous case. There is considerable articular proliferation at the outer ends of the metaphysis in provisional ossifying cartilage columns resulting in osseous change. The intervening marrow is chiefly fibrous, only a few marrow elements being present. The elements of the host appear normal.

Experiments 6 and 7, which were performed on the same animal show some variation in the findings in spite of the fact that the duration of the experiment was the same in each case. It is possible that the discrepancy in the results was due to the fact that on the left side there was more injury to the vascular supply as an adjoining bone was operated upon at the same time and because the size of the two transplants is different, being 0.4 cm. wide on the right and 0.7 cm. on the left.

Experiment 8 Duration 55 days Dog 9-4 ad leucost

Macroscopical description. The healing is good. There is no growth in the normal or operated bone. The joint cartilage is of blue color and the epiphyseal cartilage line is absent. The marrow has a normal color.

Microscopical description. The articular cartilage appears normal. The marrow is mature being composed of fat and diffusely scattered cellular elements. The trabeculae are quite large and are made up of compact well-stained bone. The epiphyseal cartilage line has entirely disappeared so that the marrow of the diaphysis and the epiphysis merge into each other. The diaphysis is of normal appearance.

Experiment 9 Duration 89 days Dog 10-5, age 3 to 4 months

Macroscopical description. The length of the operated bone is 0.3 cm. less than normal, while the non-operated bone is 0.1 cm. longer. The marrow appears normal. The epiphyseal cartilage line cannot be distinguished.

Microscopical description. In the articular cartilage there is diffuse arrangement of cartilage cells of the inner layer but little evidence of degeneration. The marrow of the epiphysis is composed of fatty mature marrow. The trabeculae are normal. The epiphyseal cartilage line is entirely absent.

except for two small remnants of cartilage near the border. The diaphyseal marrow and trabeculae are similar to those of the epiphysis.

Exp 100 ml to Duration 1361 Day 3 - 30L ag 13 month

[illegible]

Microscopic description. The trabeculae are marked by fibrous thickening in the intertrabecular articular cartilage. In some places the articular cartilage has lost its regular structure with replacement by a considerable infiltration of fibrous tissue. The marrow of the epiphysis is rather scanty and throughout there are numerous fibrin deposits. The trabeculae of the epiphysis are generally normal. The epiphyseal cartilage line is almost entirely absent there remaining only a small amount of fibrocartilage. The articular cartilage on one side is penetrating in and along the articular line resembling somewhat the attachment of the articular cartilage to the physal articular line as is found in the very early developmental stages. The metaphysis is occupied by a considerable amount of fibrous tissue. The remainder of the bone of the diaphysis resembles that of the epiphysis.

Summary on Autotransplantation of the Epiphyseal Cartilage Line

This series of aut transplantations of the epiphyseal cartilage line is not sufficiently complete to definitely determine each step of the degenerative and regenerative processes. However there are enough sections to allow for the following deductions:

An early restoration of the marrow takes place in the transplant as is shown in the section at the twenty third day.

The trabeculae of the transplant at first degenerate and then regenerate by the formation of osseous tissue beginning at the periphery.

The epiphyseal cartilage line shows an early degeneration and at 3 day there is a definite line of cleavage separating it into a distal one third and a proximal two-thirds. The degeneration progressively increases with the length of the experiment and at 135 days only a slight remnant of the line is found.

Changes take place in the marrow of the host similar to those at the line of union in the transplant.

COMPARISON OF REIMPLANTATION AND AUTO-
TRANSPLANTATION OF THE EPIPHYSEAL
CAPITULUM LINE

In both autotransplantation and reimplantation changes in the transplants take place immediately after excision. The marrow becomes necrotic as seen in the section 4 days, then there is a further change and finally a regeneration of the marrow. The process is about the same in both the autotransplantation and reimplantation. The trabeculae likewise show early degeneration and later regeneration. The process of regeneration of the trabeculae seems to bear a relation to the relative amount of connective tissue present and perhaps slightly more rapid in the case of reimplantation.

The change in the epiphyseal cartilage line are variable unless the experiments are performed in exactly the same way. More or less injury at the time of operation or the size of the transplanted segment seems to influence the result. Thus in a reimplantation experiment at 1 day there is a more active degeneration than at 3 day but it is found that the articular cartilage is displaced in the 1 day experiment thereby affecting the result. The processes of degeneration are very similar in the reimplantation and autotransplantation but are perhaps a little more rapid in the latter.

REIMPLANTATION OF VARYING LENGTHS OF
THE LIPOTYSEAL END OF THE META-
CARPAL AND THE METATARSAL BONES

Method After exposing the metacarpal or metatarsal the bone is sectioned at the desired place. The capsule of the joint is opened and the entire transplant including the articular surface is removed care being exercised not to injure the epiphyseal cartilage line. The bone is immediately reimplanted. It is held in place by a suture passed through the cortex of the host and transplant and by sutures passing from the surrounding tissues over the articular end of the bone. Different lengths of bone are used

in the various experiments in order to determine if the size of the transplant exerts any influence on the results.

Experiment 1 Duration 1 days. Two-thirds length. Dog 30-38 growing animal.

Macroscopical description. Good healing is present but union is not firm. There is no increase in length of either operated or normal bone. The articular cartilage appears normal. The marrow of the transplant is paler than normal. The epiphyseal cartilage line is broadened and there is a pale white line extending through distal one-third.

Microscopical description. The articular cartilage appears normal. In this section the normal relation of the articular cartilage to the epiphyseal cartilage line, as is forced in the early developmental stages, is easily made out. It is continuous with the epiphyseal ossifying cartilaginous layer of the epiphyseal line (Fig. 7). The marrow of the epiphysis is almost entirely necrotic (Fig. 8). The nuclei of the trabeculae appear pale and are evidently degenerating. The epiphyseal cartilage line is swollen (Fig. 7). In the distal one-third the cartilage columns are distorted and there is more intercellular hyaline tissue than usual. The remainder of the epiphyseal line appears normal. In the metaphysis the provisional ossification zone is of normal arrangement but the nuclei of the cells are indistinct. The marrow of the diaphyseal part of the transplant is necrotic. The nuclei of the trabeculae take a pale stain and show evidence of early degeneration. The cortical bone is made up of pale staining nuclei except beneath the periosteum where there is some new osseous tissue. The bone of the host appears normal.

Experiment 2 Duration 3 days. On third length. Dog 30-38 young animal.

Macroscopical description. The appearance is similar to that described in the previous experiment.

Microscopical description. The articular cartilage appears normal. The marrow of the epiphysis is necrotic. The nuclei of the trabeculae of the epiphysis are pale but do not appear to be so extensively degenerated as in the previous experiment. The epiphyseal cartilage line is broader than normal but its cellular elements appear almost normal. In the metaphyseal part the columns of ossifying cartilage are in part degenerated those near the periphery show evidence of proliferation. The bone of the host appears normal.

In comparing the last two experiments it is evident that the degenerative processes are more rapid and extensive in the transplanted segment which is the longest.

Experiment 3 Duration 1 days. On half length. Dog 33 36L ge. months.

Macroscopical description. Good healing is present but owing to the displacement of the transplant it is ununited (Fig. 9). There is pro-

gressively a growth of the operated and the non-operated bone.

Microscopical description. The articular cartilage appears normal except for a fibrous thickening on the outer surface and small areas in which the nuclei stain poorly. The marrow of the epiphysis is substituted by asclous fibrous, and fatty tissue with here and there some necrotic marrow. The trabeculae of the epiphysis stain rather homogeneously the nuclei appearing as shadows. There is evidence of early regeneration of the periphery of the trabeculae. These cells look like young osteoblasts and appear to be closely related to the surrounding fibrous tissue. The epiphyseal cartilage line is degenerating as is shown by the fragmentation of the cartilage cells and distortion in the regular columnar arrangement. There is definite line of cleavage in the proximal one-third of the epiphyseal cartilage line (Fig. 10). In the metaphysis there is very little evidence of ossification of the cartilage, except at one border where there is a rich network of osteoid tissue. The intervening marrow is fibrous as is the marrow

of the diaphysis. The trabeculae of the diaphysis are scanty showing homogeneous central part about which there are osteoblasts forming new bone. The cortex of the transplant is made up of two parts, an inner homogeneous degenerated part and an outer cellular part composed of young woven osteoid tissue. In this experiment the cortex of the host and the transplant are in poor contact and it is interesting to note that the greatest amount of new osseous tissue is produced from the periosteum and endosteum on the side most distant from the host (Fig. 11 and 12). It is evident that this regenerated tissue is formed by the periosteum and endosteum of the transplant independently of the host. The cortex of the host is normal (Fig. 13).

Experiment 4 Duration 3 days. Two-thirds length. Dog 35-40 L age. months.

Macroscopical description. There is good healing and union of the transplant and the host. There has been no growth of operated bone while the normal has increased 5 mm. The articular cartilage appears to be in good condition but there is a thickening of the synovial membrane. On the glenoid surface of the transplant the marrow appears pale and yellow in contrast to the normal red color of the host. The epiphyseal cartilage line is broader than normal but has no definite defects.

Microscopical description. The articular cartilage appears normal except for a slight fragmentation of some of the cells of the middle layer and the pale staining of the inner layer. The marrow spaces of the epiphysis are occupied by a loose meshwork of connective tissue in which are numerous cellular elements suggesting the beginning formation of the marrow. The bone trabeculae appear degenerated but some at beginning to show regeneration as is evidenced by a proliferation of osteoblasts on the periphery to form young bone.

There is also a considerable formation of subperiosteal bone on the lateral border of the epiphysis. The epiphyseal cartilage line is wider than normal. At one border there is a large defect in the cartilage but aside from some fragmentation and irregularity in the distal one third of the cartilage columns the epiphyseal cartilage line is of normal appearance. On the epiphyseal side near the epiphyseal ossifying cartilage layer which stains poorly there is considerable amount of newly formed osteoid tissue. In the metaphysis there is a lack of the active ossification of the cartilage columns which appear elongated and are separated by fibrous tissue instead of marrow. The marrow spaces of the diaphysis are filled with loose fibrous tissue in which there are a considerable number of marrow cells. The trabeculae of the diaphysis are very numerous and the older ones show definite evidence of regeneration about their borders. The cortex of the diaphysis of the transplant is made up of old degenerated bone about which there is newly formed osseous tissue which seems to arise from the periosteum, endosteum and in the Haversian canals. The most marked regeneration is on the plantar side which is in part due to the ingrowth from the host. There is definite evidence that the bone of the transplant has some property of forming new bone independent of ingrowth from adjoining bone of the host. The elements of the host appear normal.

Experiment 1. Duration 35 days. Three fourth length. Holes bored in the transplant. Dog 3-406, age 2 months.

Macroscopical description. There is good healing and union is firm. There is no growth of the operated bone while the normal bone has increased 0.3 cm. The roentgenogram shows the shortening and absorption of the transplant (Fig. 14). The articular cartilage appears normal although it is much thinner than normal. The epiphyseal end of the transplant is darker than the diaphyseal part the latter being quite pale when compared with the normal. The epiphyseal cartilage line is quite distinct but is thinner and more irregular than normal. Proximal to the epiphyseal cartilage line in the metaphyseal region is a white band extending across the bone.

Microscopical description. The articular cartilage is much wider than normal and there is a tendency for the cells to form in groups. There is an occasional cell shadow but little evidence of degeneration except as is shown by the poor staining of some of the cells of the inner layer. The marrow of the epiphysis is practically all fibrous with a few scattered marrow elements in some parts. The trabeculae of the epiphysis are almost entirely regenerated some however still show the dead centers with new osseous tissue about the periphery (Fig. 5). In the epiphyseal artilage line there are numerous large holes both in the columns and at the junction with the metaphysis. The epiphyseal ossifying cartilage layer is well main-

tained. The metaphysis is replaced by fibrous tissue and osseous trabeculae. The marrow of the diaphysis is fibrous but becomes quite cellular at the end near the host although the latter was playing a considerable role in its replacement. Numerous osteoblasts are present. The trabeculae show advanced regeneration those farthest away from the host are in the most advanced stage again indicating the independence of the regeneration of the different elements of the transplant. The cortex of the transplant is thin and in places it is separated by bands of fibrous tissue. This appearance is due to the ingrowth of fibrous tissue into the holes that are bored into the transplant. The degenerated parts are being substituted by new periosteal and endosteal bone which does not appear to be definitely related to the host. At the line of union there is still considerable fibrous tissue and very little tendency of the cortical bone of the host to invade the transplant. The host is of normal appearance except at the line of union where there is some fibrous tissue invasion of its marrow cavity.

Experiment 16. Duration 44 days. One half length. Dog 33-44R, age 1 month.

Macroscopical description. There is good healing and firm union. There is no growth of the operated bone while the normal bone is only 0.3 cm. longer than it was at time of operation (Fig. 15). The articular cartilage appears white in comparison to the pink color of the other bones. The capsule of the joint appears normal. On longitudinal section the transplanted piece is pale the articular cartilage is broader than usual the epiphyseal line is indistinct and there is a white band across the metaphysis.

Microscopical description. The articular cartilage is broad and is divided into two different regions an outer in which the nuclei are stained deep and an inner in which they are stained light. The cells themselves do not appear to be degenerated. The marrow spaces of the epiphysis are occupied by loose fibrous tissue in which are scattered numerous new formed marrow elements especially on the dorsal surface. The trabeculae of the epiphysis are partially regenerated. There are also some new formed trabeculae. The epiphyseal cartilage line is in an advanced stage of degeneration (Fig. 16). The epiphyseal ossifying cartilage layer is best maintained but even that is being invaded by osseous and fibrous tissue. The columns of cartilage of the epiphyseal line have been entirely replaced by fibrous and osseous tissue. At the periphery of the epiphyseal cartilage line there is a considerable proliferation of cartilage beneath the perichondrium both in the region of the columns and in the ossifying cartilage of the epiphysis (Fig. 16). The ossifying cartilage columns of the metaphysis are entirely osseous and between them is fibrous tissue. The marrow of the diaphysis is partly regenerated being intermingled with vascular connective tissue. The trabeculae of the diaphysis are fully restored in fact there is a marked increase of osseous tissue

throughout this part of the transplant. The cortical bone is quite irregular and appears to be undergoing absorption about its borders. The line of union is bony and it is possible that the transplant is being regenerated by the host. The host appears normal.

Experiment Duration 5 days One-third length Dog 34-43L, age 34 months

Macroscopical description. There is good healing and firm union. The growth of the operated bone is 0.45 cm. while that of the non-operated bone is 1 cm. (Fig. 7). The joint capsule is thickened. The articular cartilage is blue and has lost its normal form. On the longitudinal section the marrow appears yellowish the epiphyseal cartilage line is absent and the cortex is thinner than normal.

Microscopical description. The articular cartilage is of normal arrangement and the cells appear quite intact. The marrow of the epiphysis is normal being composed of marrow-elements and fat. Some of the trabeculae are normal while others are made up of a cartilaginous center surrounded by normal bone. In some of the earlier stages the trabeculae are practically all osseous and it is rather difficult to explain the persistence of the cartilage at this time. The epiphyseal cartilage line is represented by a thin osseous cartilaginous band extending across the bone (Fig. 8). The metaphyseal region is occupied by fatty marrow. The marrow cavity of the diaphysis is filled with normal fatty marrow in which are few scattered trabeculae. The cortical bone of the transplant is of normal appearance except that it is not arranged in the normal, even and regular manner. There is a considerable amount of erosion on the outer surface and osteoclasts are quite numerous. The line of union persists as a thin band of bone. The bone of the host appears normal.

The operated bone shows 0.45 cm. increase in length since the time of operation. This is the only instance in the series in which there is any appreciable growth. It is possible that under some special favoring circumstance the epiphyseal cartilage line retains the property of increasing the length of the bone. In spite of this fact, the normal bone has increased three times as much as the operated bone and its epiphyseal line persists, while the epiphyseal line of the transplanted bone has disappeared (Fig. 7). Therefore, even if the transplanted epiphyseal cartilage line in this instance retains its power to proliferate, it does so only temporarily and to a very limited degree.

Experiment 18. Duration 5 days One-third length Dog 34-43R, age 3 months.

Macroscopical description. There is good healing and firm union. The growth of the operated bone is 0.15 cm. while that of the normal bone is .45 cm. (Fig. 19). The entire specimen was preserved in Kaberling.

Summary on Reimplantation of Varying Lengths of the Epiphyseal End of the Metacarpal and Metatarsal Bones

The articular cartilage shows only slight changes in the inner layers which is indicated by an irregularity in the arrangement of the cells and the loss of some of the nuclear stain.

The marrow undergoes an early necrosis. It is possible that some of the cells may persist and later share in the regeneration but this point cannot be definitely determined. The later stages show the marrow spaces filled with fibrous connective tissue after which there is a gradual restoration of the marrow.

The trabeculae even at 12 days show disappearance of their nuclei, and in the later stages there is a gradual regeneration which takes place through a peripheral substitution of the old bone. This regeneration occurs independently of the host and seems to bear some relation to the surrounding fibrous tissue.

The epiphyseal cartilage line at first shows a crumbling of the cells at the junction of the proximal two-thirds and distal one third. Then a fissure appears in this region following which there is a continuous and progressive degeneration of the entire cartilage. The more persistent part is the epiphyseal ossifying cartilage band. There is only a very limited attempt at regeneration in the parts just beneath the perichondrium.

The marrow of the diaphysis undergoes the same changes as it does in the epiphysis and there is no earlier regeneration in spite of its close proximity to the host, although it might receive additional elements from the host.

The changes in the trabeculae of the diaphysis do not differ from those in the epiphysis.

The cortical bone at first degenerates and is then regenerated by new bone which is formed from the endosteum and periosteum. In some of the sections there is a considerable amount of erosion beneath the periosteum. It is difficult to determine whether the bone is later substituted from the host, but at first it is definitely formed from the original periosteum and endosteum of the transplant.

AUTOTRANSPLANTATION OF VARYING LENGTHS OF THE EPIPHYSEAL END OF THE METACARPAL AND METATARSAL BONES

Method. These experiments consisted of removing different lengths of the distal end of the metacarpal or metatarsal bones including the epiphyseal cartilage line and exchanging it with a similar piece from one of the bones of the opposite foot. The technique is the same as that employed in the reimplantation.

Experiment 10. Duration 34 days. One half length in union. Dog 10—R age 5 months.

Macroscopical description. The healing is good and firm union exists between the transplant and the host. There is no growth of the transplanted bone but the normal growth is 0.6 cm. The

Fig. 2. Roentgenogram of the front and hind feet of a dog showing the relative length of the metacarpal and metatarsal bones. *A* Front feet. Notice that the metacarpal bones 3 and 4 are of equal length. This is a standard for comparison and method whereby the amount of growth can be estimated. *B* Hind feet. Notice that the metatarsal bones 1 and 2 are practically of equal length.

joint is in good condition although there is a thickening of the capsule. The marrow of the transplant is scanty. The epiphyseal cartilage line can still be made out as a thin line on longitudinal section.

Microscopical description. The articular cartilage is quite irregular. The persisting cartilage is of normal arrangement but the nuclei are shrunken. The marrow near the articular cartilage is quite normal while the remainder is fibrous. The trabeculae of the epiphysis are more numerous than usual but they stain poorly with the exception of the part near the periphery of some where there is newly formed bone. The epiphyseal cartilage line is in part entirely replaced by fibrous tissue while the remainder is undergoing rapid degeneration. The epiphyseal ossifying cartilaginous layer is the best maintained. The metaphysis is entirely replaced by fibrous and new osseous tissue. The marrow of the diaphysis is entirely fibrous. The trabeculae of the diaphysis are composed of new bone although in the center of some are old nuclear free remnants of bone. The original cortex is homogeneous and the nuclei appear as shadows. There is a new formed endosteal and periosteal bone about the old cortex. At the line of union there is a large amount of callus of both endosteal and periosteal type which comes from both the transplant and the host. The end of the articular

Fig. 3. Experiment 3, 33 days, Dog 333. Regeneration of the trabeculae after transplantation takes place by the formation of new osseous tissue about the periphery of the dead bone which is gradually substituted. It occurs independently of the host and is the same in autotransplantation and in retransplantation. 4 Dead bone. B New osseous tissue on the periphery. C Organization of the marrow. Microphotograph obj 14 oc 10 inches, B & L.

fragments take a very minor part in the formation of this callus. The elements of the host appear normal.

Experiment 30. Duration 34 days. Split on half length. Dog 9-5L, age 5 months.

Macroscopical description. The healing is good but the union is not firm. There is no growth in the operated bone while the normal is increased about 6 cm. The articular cartilage is rough and irregular. The epiphyseal cartilage line is markedly changed. In this experiment the transplant has been split longitudinally before insertion.

Microscopical description. The articular cartilage is rough and irregular and in places is entirely absent. The splitting of the bone is responsible for some of these changes. The marrow is replaced by fibrous tissue although on one side there are some marrow-cells which are possibly regenerated cells. The trabeculae are made up of an outer new osseous layer within which is old dead bone. The epiphyseal cartilage line is fissured at the junction of proximal two-thirds with the distal one-third but is not so extensively altered as it is in the previous experiment. The metaphysis is of fairly normal appearance although there is not the active proliferation as under normal conditions. The marrow-cavity of the diaphysis is for the greater part fibrous with some scattered areas containing few marrow elements. There are some newly formed trabeculae in the diaphysis the older ones are necrotic or are surrounded by newly formed bone. The cortex of the diaphysis is homogeneous and without vascular staining. There is a small amount of regenerated bone from endosteum, periosteum and Haversian canals. There is more evidence of regeneration at distance from the host than in the immediate vicinity. There is considerable amount of callus from the host which is mostly

Fig. 4. Experiment 4, 43 days, Dog 334L. Replantation of the epiphyseal cartilage line. Second bone from the right, 4 shows reimplanted epiphyseal line 6 cm. shortening. The metacarpals, 3 and 4 are normal of equal length.

derived from the periosteum and penetrating into the marrow-space between the host and the replant.

After splitting the bone some of the elements seem to retain their vitality longer.

Experiment 1. Duration 44 days. (One-half length) Dog 1L, age 5 months.

Macroscopical description. There is good healing and firm union of transplant and host. The transplanted bone shows no increase in length, while the normal bone is 6 cm. longer. The transplant is broader than normal. The articular cartilage appears thickened as is the capsule of the joint. The transplant is yellow instead of the normal red color. The epiphysis is wider than normal and has lost its gelatinous appearance. The metaphysis there is a white band of new tissue.

Microscopical description. There is marked fibrous thickening of the articular surface. The cartilage is rather irregular being thicker on one side than on the other. The cells, however, appear to be normal except in one area, where there is some degeneration. On the plantar and the marrow of the epiphysis is almost of normal appearance while on the dorsal surface it is fibrous. The trabeculae of the epiphysis are almost entirely regenerated. The epiphyseal cartilage line shows extensive degeneration changes throughout there being large holes crumbling of the columns, and some invasion of fibrous tissue. There is slight regeneration near the perichondrium on one side. The metaphysis is undergoing degeneration which accounts for the white band seen in the gross specimen. The marrow of the diaphysis is partly

Fig. 1. Experiment 12. Dog 33. In the degeneration in the epiphyseal cartilage line (A) it is transplanted (B) the epiphyseal cartilage line (C). Degeneration in the epiphyseal cartilage line (A) and necrosis (B) in the junction of the epiphyseal cartilage and the columnar cartilage. Microphotograph (A) in hem. B & L.

imposed of normal element and a part is substituted by fibrous tissue. The trabeculae are entirely regenerated. The outer surface of the cortex is irregular and there is some evidence of periosteal new bone. The line of union is articular with a considerable increase of osseous trabeculae on either side.

Experiment 12. Duration 43 days. Two third length. Dog 30. 4 R. Age 3 months.

Macroscopical description. The healing is good and the union is firm. The increase in length of the operated bone is 0.1 cm while the normal is 0.3 cm (Fig. 2). The joint is well formed and contains small amount of synovial fluid. The artilage appears more white than normal. The epiphysis is of normal size. The epiphyseal cartilage line is hardly distinguishable while in the metaphysis there is whitening of the tissue that appears like a line. The layer of marrow is very pale and thick although there is a marked increase of the trabeculae.

Microscopical description. The articular surface is all normal in appearance. The marrow with the trabeculae contains large number of

Fig. 2. Experiment 12. Dog 30. In the transplanted (B) the epiphyseal cartilage line (A) and bone from the right (C) in each (A) and (B) the transplanted (B) line (A) evidence of epiphyseal line increase in length of 0.1 cm normal increase in B & L is 0.3 cm normal (equal length).

normal cellular element but there is considerable increase in osseous trabeculae and the trabeculae of the epiphysis are practically entirely regenerated (Fig. 3). The epiphyseal cartilage line is distorted and degenerated (Fig. 4).

Toward the periphery there is some regeneration of artilage which appears to arise from the periosteum and the outer artilage layers especially on the plantar side. The epiphyseal cartilage layer is osseous while the remaining part of the epiphysis is substituted by fibrous tissue.

Fig. 3. The artilage cells at the junction of the metaphysis are fairly well preserved while the osseous trabeculae columns are entirely changed into osseous tissue. The marrow of the metaphysis is made up of loose fibrous tissue in which are scattered many marrow cells. There are considerable number of new trabeculae in the metaphysis and the old ones have been nearly regenerated for an occasional small piece. The marrow evidence of osteonaplasia with a new periosteal and endosteal layer and a new dead bone area appearing in the metaphysis with the new trabeculae in the metaphysis and the new trabeculae in the metaphysis.

The evidence of osteonaplasia with a new periosteal and endosteal layer and a new dead bone area appearing in the metaphysis with the new trabeculae in the metaphysis and the new trabeculae in the metaphysis.

Fig. 7. Experiment 34. Duration 30-35 days. Dog 30-35. Reimplantation of two-thirds of the epiphyseal end of the metatarsal bone. A Epiphyseal end containing necrotic marrow. B epiphyseal cartilage line wider and more irregular than normal. C articular cartilage inserted into the epiphyseal cartilage line as specimen is from a very young animal. D metaphysis. Microphotograph obj. 5 oc. inches B & L.

Experiment 33. Duration 43 days, two-thirds length. Dog 36-4 L, age 1.5 months.

Macroscopical description. The appearance corresponds to that of the previous experiment except that the epiphyseal cartilage in this case is more intact than on the opposite side and the epiphysis is of a darker red color.

Microscopical description. The findings in general are similar to those of the previous experiment except that the marrow cells are more abundant and the epiphyseal cartilage line is a better site of preservation. There is also a line of columnar cartilage cells in the diaphysis which are possibly cartilage cells remaining behind during the normal growth of the bone.

Experiment 34. Duration 43 days. One-third length. Holes bored into the transplant. Dog 40-37 L, age 3.5 months.

Macroscopical description. There is good healing. Neither the operated nor the normal bones show any evidence of growth in length since the operation. The joint-capsule is thickened and the

Fig. 8. Experiment 34. Dog 40-37. Showing the early resorption of the marrow (A) after reimplantation of segment of bone. B Normal marrow (this higher magnification of the marrow shown in Fig. 7). A normal marrow of the bone in the same experiment (transverse transplant on right, labeled in order to bring out the marrow). B normal trabeculae. Microphotograph obj. 5 oc. inches B & L.

joint cavity is filled with fibrous tissue. The surface of the transplant is covered with a whitish, cartilaginous appearance. The roentgenogram shows the condition of the transplant (Fig. 3).

The entire specimen was preserved in Haversling solution.

Experiment 35. Duration 43 days. One-third length. Dog 40-38 R, age 3 months. Homotransplantation. Holes bored into the transplant.

Macroscopical description. Good healing is present. This is the only sample of homotransplantation in the series, the inverted transplant being taken from the animal. It is described at this time in order to allow for comparison with the previous experiment. The operated bone measures 0.5 cm. in length. It did not take the time of operation while the normal bone measures 5 cm. more. There is some roughening of the articular cartilage and thickening of the capsule. A longitudinal section of the transplanted segment is of a yellow color and shows more evidence of degeneration than the transplant of the same animal. This is clearly shown in the roentgenogram (Fig. 3). The entire specimen was preserved in Haversling solution.

Experiment 36. Duration 43 days. One-half length. Dog 39-4 L, age 3 months.

Macroscopical description. There is good healing and firm union. The growth of the operated bone is 5 cm. while that of the non-operated bone is 4 cm. The joint-capsule is thickened and there is some roughening of the articular cartilage. On longitudinal section the bone is of normal color. The epiphyseal cartilage line is bent and in its place there is a small amount of soft tissue.

Microscopical description: On the outer surface of the articular surface there is a thin layer of homogeneous stained tissue. Within this layer the cells appear normal in arrangement and structure. The marrow of the dorsal half of the epiphysis is normal while that of the plantar side is largely replaced by fat. In the tibia the trabeculae of the epiphysis appear normal. The physalarticular ligament is represented by a small amount of cartilage the greater part of which is absent thereby allowing a communication between the marrow spaces of the diaphysis and epiphysis. The metaphysis is entirely replaced by marrow and osseous tissue. The marrow and trabeculae of the diaphysis appear normal. The cortex is composed of normal bone but there is a considerable amount of osseous union of the tibia and proximal end of the humerus indicating union of the two elements of the humerus normal.

l gth Dug 3 R ag 2 m nith

Macroscopic description: There is good healing in the union. The growth of the transplanted bone is minimal while the normal growth is 1 cm (Fig. 4). The joint capsule is thickened but the articular surface appears normal. (On section the epiphyseal plate and the epiphyseal plate line is absent. The epiphyseal articular line is the normal line in the joint.)

Microscopical description. The articular cartilage is of normal structure although the nuclei take a pale stain. The epiphyseal marrow is of the normal fatty type. The trabeculae of the epiphysis for the most part have a normal structure although the nuclei of some take a light stain. The epiphyseal cartilage line is absent. The marrow of the diaphysis is normal and is confluent with that of the epiphysis. The trabeculae of the diaphysis appear normal. The cortex is irregular in the region of the epiphysis where there is considerable erosion of it, while elsewhere it is normal.

E. perimutata Duration 143 lay (On fourth
length Dog 5-3 L age 2 months

Macroscopic Description There is good healing. The operated bone has increased 0.1 cm in length while the normal bone has increased 1.3 m. The epiphysis of the normal bones are fully ossified (Fig. 24). The specimen was preserved intact.

Summary on Autotransplantation of Larving Lengths of the Epiphysis

In the autotran plantation there are more evidences of destruction of the articular cartilage than in any of the other experiment. In some section there is considerable erosion and substitution with fibrous tissue. In others partial regeneration of cartilage

The marrow of the epiphysis at first becomes necrotic. At a later period the marrow spaces are occupied by fibrous tissue.

At a still later period the marriage resumes

Fig. 4. Experiment 1. Dog 331. This is higher magnification of the epiphyseal cartilage line shown in Fig. 4. Epiphyseal cartilage line 7 day after transplantation. B normal epiphyseal cartilage line for comparison. Notice the irregular rumbling and flowering of the transplanted epiphyseal cartilage line. Microphotograph obj oc. Joches, B & L.

almost a normal structure. The regeneration seems to take place independently of the host. The exact method and source of the regenerated marrow could not be determined.

The trabeculae of the epiphysis at first undergo degeneration, and then by a process of new formation beginning at the periphery are completely regenerated.

The epiphyseal cartilage line undergoes a progressive and complete degeneration. There is some regeneration beneath the perichondrium in the early stages. This new cartilage does not possess the normal property of increasing the length of the bone.

The marrow and trabeculae of the diaphysis are subjected to the same changes as are the marrow and trabeculae of the epiphysis.

The cortex at first shows extensive degeneration but later there is regeneration from the periosteum and endosteum independently of the host. However in the later stages there is considerable bone erosion on the surface and fibrous tissue penetration.

COMPARISON OF REIMPLANTATION AND AUTOTRANSPLANTATION OF VARYING LENGTHS OF THE EPIPHYSEAL END OF THE METACARPAL AND THE METATARSAL BONES

The changes in the articular cartilage are more marked in autotransplantation than

in reimplantation although even in autotransplantation they are not very extensive.

In both autotransplantation and reimplantation the marrow of the epiphysis very early becomes necrotic. The necrotic marrow is replaced by fibrous tissue which in turn is substituted by new marrow-elements. The regeneration appears to take place more rapidly in autotransplantation.

The trabeculae of the epiphysis undergo practically the same changes in both autotransplantation and reimplantation there being at first degeneration and later gradual new formation which begins on the periphery of the trabeculae. The rate and degree of degeneration and regeneration are relatively the same in each case.

The epiphyseal cartilage line undergoes a gradual and persistent degeneration in both autotransplantation and reimplantation. In some cases the regeneration seems to be more rapid in the reimplantation than in autotransplantation while in others the opposite seems to occur. In general the processes are similar in both instances.

The marrow of the diaphysis undergoes the same changes as in the epiphysis in both autotransplantation and reimplantation. The changes take place in about the same order and degree in both cases although there is perhaps an earlier regeneration in autotransplantation.

The changes in the trabeculae of the diaphysis are similar to those which take place in the epiphysis.

The cortical bone in both autotransplantation and reimplantation at first degenerates and is then restored by means of proliferation from the periosteum, endosteum and about the Haversian canals of the transplant. There is erosion about the surface of the cortex in both groups but it is more intense in the autotransplantation. Although there is independent regeneration of the cortex from the periosteum and endosteum of the transplant, it can not be denied that the host plays a part in the new formation especially as concerns the permanent bone.

Firm union of the transplant and host occurred in both types of experiment.

Fig. 2. Experiment 2. Dog 331. High magnification of the host bone. The transplant is placed in the prepared groove. The host bone is the articular end of the metacarpal. The transplant is the articular end of the metatarsal. Compare the normal articular end of the metacarpal with the transplant.

EXPERIMENTAL TRANSPLANTATION OF DIFFERENT LENGTHS OF THE EPIPHYSEAL END OF THE METACARPAL AND THE METATARSAL BONES

Method. The two central metacarpal or metatarsal bones are exposed. By means of a sharp knife the two bones are transected at the same level. The proximal part of one bone and the distal part of the other are removed. The two remaining segments are united together by means of a suture passed through the cortex of each bone (Fig. 1). The wound is then closed. After sufficient time has elapsed the clips are removed and the animal is placed in a cast in which the distal segment containing the epiphyseal articular surface is separated from the articular surface up to the line of union. Care is taken not to disturb the union or injure the epiphyseal articular surface. The wound is closed and the articular end is held in a light plaster cast for healing. In some of the experiments only the first stage of the procedure is completed.

1.04 m long rather than normal. The articular articular end appears normal. The transplant is of fairly normal appearance through out.

Microscopic description. Only the proximal part of the bone including the line of union is present in the section. There is a large amount of cortical allumina in the plantar side arising from both host and transplant with a layer of fibrous tissue between the two ends. Numerous polymorphonuclear cells are to be seen at the junction. On the dorsal surface allumina is present only on the side of the host. The marrow of the transplant appears normal except at the line of union where there is an increase of polymorphonuclears. The trabeculae appear normal. The cortex of the transplant has lost its normal staining and appears dead at the line of union. In and around the distal end of the transplant is new bone which arises from the periosteum, endosteum and about the haerian canal. The cortex of the transplant more distant from the line of union which is not separated from the normal bone appears alive and unchanged.

Experiment 10. Duration 4 days. First stage. On half length. Dog 111R. Age 1 month. Microscopic description. The half length of the bone is 0.3 m longer than the normal is 0.0 m longer than at the time of the operation. At the time of union the articular surface is normal. The articular articular end of the transplant is normal through out the entire length of the epiphyseal articular line. The articular articular end of the transplant is normal through out the entire length of the epiphyseal articular line.

Microscopic description. The articular articular end of the transplant is normal through out the entire length of the epiphyseal articular line. The articular articular end of the transplant is normal through out the entire length of the epiphyseal articular line.

Fig. 4 (left) Experiment 5 (54 days) Dog 3-41R. Reimplantation of the epiphyseal (two-thirds of the metacarpal bone after boring holes in the transplant. Second bone from the right. 4, shows the amputated segment under going absorption. N growths since operation. Normal bone grew 3 cm. Compare 3 and 4 which are normally equal.

Fig. 5 Experiment 6 (44 days) Dog 31-41R. Reimplantation of one-half of the epiphyseal end of the metacarpal bone. Second bone from the left. 4, shows reimplanted segment 7 mm shorter than. Compare 3 and 4 which normally are of equal length.

normal. The metaphysis is normal and there is an exceptionally good blood supply. The marrow of the diaphysis is normal except at the line of union where there are fibrotic and necrotic changes. The trabeculae of the diaphysis are normal. The cortex is surrounded by a large amount of periosteal and slight amount of endosteal new bone. At the line of union there is heavy cartilaginous callus chiefly of the periosteal type which appears to arise from both the host and the transplant. The various elements of the host are normal. It is interesting to note that the only changes are near the line of union, which one would expect to be the case as in the first stage of the experiment it is the only portion of the bone which is disturbed.

Experiment 3. Duration 89 days. First stage one-half length. Dog 6 goes on this. All microscopic description. There is growth of the normal the operated bone. The articular cartilage appears normal. There is slight amount of marrow in the epiphyseal end otherwise the marrow cavity is small and its elements are scanty. A pseudoarthrosis is present.

Microscopic description. The articular cartilage appears thin but the cells are normal. The marrow is fatty and the cellular elements are scanty. The trabeculae of the epiphysis are normal. The epiphyseal cartilage line is bent so that the diaphyseal and epiphyseal marrow spaces are

continuous (ditto animal). The trabeculae and the marrow of diaphysis resembles those of the epiphysis. The cortex is thin and shows some erosion on its surface. There is periosteal and endosteal callus on the surface of both the host and the transplant but on account of an intervening fibrous layer pseudoarthrosis results. The greatest amount of callus is the side of the host.

Experiment 13. Duration 25 days. First stage 3 days. Second stage 22 days. On half length. Dog 20 goes on this.

Macroscopic description. The wound is infected and the transplant which is devoid of periosteum lies loose in the wound. The growth of the operated bone is 5 cm while the growth of the normal is 0.5 cm.

Microscopic description. The articular cartilage is of normal appearance. The marrow of the epiphysis is almost entirely necrotic. The trabeculae show signs of degeneration. The epiphyseal cartilage line shows some shrinking of the nuclei and distortion of the cartilage columns. There is evidence of degeneration in the metaphysis and an invasion of polymorphous leucocytes between the ossifying cartilage columns. The marrow of the diaphysis is likewise necrotic and contains numerous collections of polymorphous leucocytes. The trabeculae are degenerated. The cortex is poorly and on its outer surface there is considerable amount of callus. These changes cannot be considered as being entirely due to the transplantation on account of the concurrent infection. The host appears normal although there is no increase of polymorphous leucocytes in places.

Fig. 5 Experiment 6 (44 days) Dog 31-41R. Showing new formed cartilage at the periphery of the epiphyseal cartilage line 44 days after reimplantation of one-half of the epiphyseal end of the bone. The epiphyseal cartilage line is degenerated and substituted by fibrous and osseous tissue. A New formed cartilage at the border from the perichondrium. B substitution of the epiphyseal cartilage line by fibrous and osseous tissue. C metaphysis. D epiphysis. Microphotograph of 15 oc. inches, B & D.

Fig. 19 Experiment 8 9 days, Dog 34 49R. Re-implantation of the epiphyseal two-thirds of the metacarpal bone. Second bone from the left A shows the implanted segment completely united (compare with normal 2) \ absence of epiphyseal line. Notice presence of epiphyseal line in normal bone. Growth of operated bone = 4 cm. growth of normal bone = 4.5 cm.

tissue in the joint and the cartilage appears whiter than normal. On longitudinal section the epiphyseal part of the transplant is paler than the diaphyseal part the latter being of normal color. The epiphyseal cartilage line is not so regular as normal and white band is seen in the metaphyseal region. The line of union is composed of osseous tissue.

Microscopical description. The articular cartilage is normal except on one end where there is fibrous tissue mass extending into the joint cavity. At this place there is a defect in the perichondrium and fibrocartilaginous proliferation. The marrow of the epiphysis is degenerated and in its place is fat and fibrous tissue with few cellular elements. The trabeculae of the epiphysis are homogeneous with cell shadow scattered throughout. The distal bone of the epiphysis stains poorly. In the epiphyseal ossifying cartilaginous band there is loss of nuclear staining of the osseous part. The epiphyseal cartilage layer is of about normal thickness but the cartilage of minor zigzagged and the cells are beginning to show degenerative changes. Beneath the perichondrium on either bond there is some perichondrial new formed cartilage. The metaphyseal ossifying cartilaginous layer is well maintained. The osseous cartilaginous columns of the metaphysis are practically intact. The marrow of the diaphysis shows extensive regeneration. The trabeculae of the diaphysis are normal except near

Fig. 20 Experiments 10 and 14 days, Dog 30-45 R and L. Autotransplantation of the epiphyseal two-thirds of the metacarpal bone. Second bone from the right 1 on each foot shows the operated metacarpal bones. Compare 1 and 2 both normally are of equal length \ growth since operation on 1. Normal growth = 5 cm.

the metaphysis where some contain poorly stained nuclei. The nuclei of the cartilage in the region of the metaphysis poorly stained but on approaching the line of union they take deeper and more form stain. There is periosteal and endosteal new bone on the right. The line of union is not well shown but there is considerable network of new periosteal and endosteal bone in that region. The elements of the host appear normal. The marrow is of the mature fatty type. The host undoubtedly exert marked influence on the transplant. This experiment as is shown by the more marked general changes in the part nearest to it.

Experiment 15 Duration 6 days. First time 45 days second time 5 days. Length two-thirds. Dog 8 20 age 6 months.

Microscopical description. There is good healing and firm union.

In this experiment the operated bone is found to be 7 cm longer than the first operation, while at the end of the experiment it is 9.9 cm longer. Thus, there is 2.9 cm. growth since the second operation. During the life time the growth of the normal bone is 6 cm. which is practically the

Fig. 23. Experiments 24 and 5, 45 days. Dog 40-17. Autotransplantation and homotransplantation of the epiphyseal one-third of the metatarsal bone (bored holes into triangle 1). Left foot, A, second bone from right, shows the marked absorption of the homotransplant. Right foot, B, second bone from right, shows low degree of absorption in the autotransplant. Bones 1 and 3 should be of equal length.

nuclei (Fig. 7). The greater part of the epiphysis is composed of fibrous tissue in which are some scattered cellular elements. The epiphyseal trabeculae appear normal. Of the epiphyseal cartilage line there remains only a small amount of cartilage beneath the perichondrium near the surface. The remainder is ossified and is continuous with the newly formed trabeculae of the diaphysis. The marrow of the diaphysis is scanty. The elements of the host appear normal.

Experiment 137. Duration, 55 days. First stage, 5 days; second stage, 4 days. Dog 5-26. Age about months.

Macroscopic description. There is good healing but non-union occurred after both operations (Fig. 5). The operated bone measures 0.4 mm. less than at the time of the operation, but the normal bone is 0.5 mm. longer.

Summary on the Two-Stage Autotransplantation of Varying Lengths of the Epiphyseal End of the Metacarpal and the Metatarsal Bones

The articular cartilage is well maintained in every case except in Experiment 36 where

there is some evidence of degeneration of the inner layer.

The marrow of the epiphysis does not undergo any change following the first operation but immediately after the second operation degeneration occurs. It at first becomes necrotic then fibrous, and finally is regenerated. The regeneration is similar to that which occurred in reimplantation and autotransplantation although it takes place more rapidly.

The trabeculae remain unchanged during the first stage but immediately following the second operation they undergo degeneration. Regeneration then takes place in the usual manner by peripheral formation and substitution with new osseous tissue.

The epiphyseal cartilage line is well maintained during the first stage and though it functions that property is restricted to a considerable degree. After the second op-

Fig. 24. Experiments 7 (A) and 38 (B), 45 days. Dog 20-37. Autotransplantation of the epiphyseal one-third of the metacarpal bone. Second bone from right in each foot shows the union of the transplanted segments. Growth of operated bones, 5 cm.; growth of normal bone, right, 4 cm., left, 6 cm. Bones 1 and 3 are normally of equal length.

cratic even if there is good union between the transplant and the host it functions almost entirely lost and it undergoes a slow degeneration. The most marked disturbance in growth occurred when there was no union at the second operation.

The marrow of the diaphysis is more rapidly and completely regenerated than that of the epiphysis. This is due to the additional marrow cell supplied by the host.

The trabeculae of the diaphysis degenerated after the second operation but finally regenerated by the formation of new secondary tissue beginning on their periphery. The regeneration occurs before it lies in the distal part which can possibly be explained by its closer proximity to the host.

The cortex is regenerated by means of periosteal endosteal and haversian new bone which is formed independently of the host. Undoubtedly the host supplies additional

Fig. 1. Epiphysis distal. Diagram A shows the results of autotransplantation of the epiphysis of the metacarpal bone. Diagram B shows the results of autotransplantation of the epiphysis of the third metacarpal bone. In both diagrams, the epiphysis is shown in the center, with the diaphysis on either side. The epiphysis is labeled 1 and the diaphysis is labeled 2. The results of autotransplantation are shown in the center, with the epiphysis in the center and the diaphysis on either side. The epiphysis is labeled 1 and the diaphysis is labeled 2. The results of autotransplantation are shown in the center, with the epiphysis in the center and the diaphysis on either side. The epiphysis is labeled 1 and the diaphysis is labeled 2.

new bone which is of a more permanent nature than that arising in the transplant itself.

COMPARISON OF THE TWO-TAGE AUTOTRANSPLANTATION WITH THE ONE-TAGE AUTOTRANSPLANTATION

The degenerative and regenerative processes in the articular cartilage, the marrow of the epiphysis and the trabeculae of the epiphysis are very similar in both the two-tage and the one-tage experiment.

The degenerative changes in the epiphyseal cartilage line take place lower in the two-tage operation but the final result is the same, namely, complete degeneration and loss of function.

The regenerative changes in the marrow and trabeculae of the diaphysis are more rapid in the two-tage experiment because of the greater influence of the host.

The cortex likewise is more rapidly regenerated in the two-tage than in the one-tage experiment.

Fig. 2. Epiphysis distal. Diagram A shows the results of autotransplantation of the epiphysis of the metacarpal bone. Diagram B shows the results of autotransplantation of the epiphysis of the third metacarpal bone. In both diagrams, the epiphysis is shown in the center, with the diaphysis on either side. The epiphysis is labeled 1 and the diaphysis is labeled 2. The results of autotransplantation are shown in the center, with the epiphysis in the center and the diaphysis on either side. The epiphysis is labeled 1 and the diaphysis is labeled 2.

REIMPLANTATION OF AN ENTIRE METACARPAL OR METATARSAL BONE

Method. The entire metacarpal bone is raised from its normal bed and then immediately reinserted and anchored in place with suture extending from the neighboring tissues.

Experiment 38. Duration 5 days. Dog 3. Age 18 months. Metatarsal bone.

Macroscopical description. The wound is healed without infection. There is 0.2 cm. of growth of the operated bone while the normal bone is 0.7 cm. longer. The transplant is found in normal position. New joints have formed at the ends.

Microscopical description. There is considerable amount of fibrous tissue in the joint cavity and slight thickening of the outer layer of perichondrium. The articular cartilage appears normal. The marrow of the epiphysis is quite cellular and shows definite changes. The trabeculae of the epiphysis are normal although the nuclei are not so prominent as usual. The epiphyseal cartilage is entirely changed and only a thin end beneath the perichondrium is cartilaginous to be found. This cartilage appears to be an outgrowth of proliferation. The cartilage columns are lucent and in their place is

In the subsequent experiment one of the distal ends of the epiphysis of the metatarsal bone was removed and the epiphysis of the metatarsal bone was reinserted and anchored in place with suture extending from the neighboring tissues. The epiphysis was found to be described in the other experiments.

hyaline fibrous tissue which still preserves some of the parallel columnar arrangement. The metaphyseal region is occupied by a network of new bone. The marrow of the diaphysis is quite cellular. The trabeculae of the diaphysis are partly degenerated in the center. The osteons in places are poorly defined and in close contact with the surrounding fibrous tissue.

Experiment 39. Duration 4 days. Dog 3. Age 18 months. Lateral bone.

Macroscopical description. The condition is the same as in the previous experiment.

Microscopical description. The articular cartilage is partly degenerated in the inner layer. The marrow of the epiphysis appears fairly normal. The trabeculae of the epiphysis contain small shadows in their centers, surrounding which is normal bone. The epiphyseal cartilage line is represented by hyaline band in which there are shadows of fibrous tissue. At the periphery there is proliferation of cartilage which extends into the diaphysis. There is only a small amount of the diaphysis in the section. A marked periosteal and endosteal proliferation is seen on the side while on the other there is marked absorption of the osteon.

Experiment 40. Duration 4 days. Dog 3. Age 18 months.

Macroscopical description. There is good healing. No growth has occurred in the operated bone. The normal bone is 3 cm. longer (Fig. 8). The joint capsule is thickened. The bones appear slightly thicker than normal. The articular cartilage is not so thick as usual. The epiphyseal cartilage line is of pinkish color. There is evidence of degeneration as seen both in the gross specimen and in the roentgenogram. The specimen is preserved in Kammerling's solution.

Experiment 41. Duration 3 days. Dog 4. Age 18 months.

Macroscopical description. There is good healing. There is no growth of the operated bone while the non-operated bone is 3 cm. longer (Fig. 8). The joint cavity is in fairly good condition. On longitudinal section the epiphysis is of normal color. The epiphyseal cartilage line is absent but is present in the normal bones. The marrow of the diaphysis is scanty and the cavity is irregular in outline. The osteon is of varying thickness.

Macroscopical description. The articular cartilage is regular and places also defect. The synovial membrane is thickened and there is some fibrous tissue deposit on the cartilage. The articular cartilage is composed of poor quality cells in process of degeneration. There is a considerable amount of fibrous tissue penetrating the cartilage substance. The marrow of the epiphysis of the mature fatty type. The trabeculae of the epiphysis are poorly stained. The epiphyseal cartilage line is disapparing red, a few cartilage remnants being left. The marrow of the trabeculae of the diaphysis resemble those of the epiphysis. The osteon is very irregular. The osteon is

stains poorly although there is evidence of both endosteal and periosteal proliferation. The general appearance of the sections indicates that a uniform slow degeneration is occurring throughout the bone in which regenerative processes had previously occurred.

Experiment 42 Duration 113 days. Dog 3R age 3 1/2 months.

Macroscopical and microscopical descriptions. The changes are similar to those described in the previous experiment.

Experiment 43 Duration 115 days. Dog 3R age — old dog.

Macroscopical description. There is good healing. There is no increase in length of the operated nor the normal bones. The joint is re-formed; the capsule is thickened and the articular surface is rough. On longitudinal section it is noted that the marrow is very scanty having been replaced by fibrous tissue. The cortex is quite irregular and appears to be eroded on its surface.

Microscopical description. The section takes a very poor stain so that it is difficult to determine the various changes. The articular cartilage appears fairly normal. The trabeculae show little change. The marrow is fibrous and fatty. The cortex is quite irregular and there is extensive erosion in places.

Experiment 44 Duration 115 days. Dog 13L increased old dog.

Macroscopical description. There is good healing. Growth is absent in all bones. A spontaneous fracture has occurred 1.5 cm from the distal end. The general appearance corresponds to the right side although there is more evidence of degeneration.

Microscopical description. The sections stain very poorly. The articular cartilage is irregular and the nuclei take a light stain. The marrow is partly fatty and partly fibrous. The trabeculae are not arranged in a normal manner and appear degenerated in the center. The cortex shows considerable evidence of degeneration and absorption especially on its surface.

Experiment 45 Duration 208 days. Dog 3 age 4 months.

Macroscopical description. The dog removed the dressing and the wound became infected. Only a small remnant of bone is found at autopsy.

Microscopical description. The bone remnant is encapsulated by dense fibrous tissue. The bone contains well stained nuclei. At the ends and where the periosteum is absent the osseous tissue is in direct contact with the fibrous tissue. There are osteoclasts scattered between the bone and the fibrous tissue. There are some fairly normal marrow elements enclosed within the bone.

Experiment 46 Duration 98 days. Dog 6 2R age 1 1/2 months.

Macroscopical description. There is good healing. The operated bone is decreased 0.6 cm in length while the non-operated bone is the same length at the time of operation (Fig. 20). The

Fig. 8. Longitudinal sections of metatarsal bones. Side A (left) shows two implanted bones and growing absorption. Right side B shows normal growth. Wire marker indicates the original length of these bones. Growth since operation normal 0.5 cm of operated bone 0.6 cm. Note the marked absorption of the reimplanted bone.

joint-capsule shows a considerable thickening. On section the marrow cavity is found to be practically absent. The cortex is thickened and roughened.

Microscopical description. The articular cartilage is thin and in places entirely replaced by fibrous tissue. The marrow of the epiphysis and diaphysis is very scanty and of fatty type. The trabeculae of both the epiphysis and diaphysis are thick and take a poor nuclear stain. The epiphyseal cartilage line is absent. The cortex is quite irregular. In places the periosteum is absent and the surrounding fibrous tissue is closely adherent to the bone. The poor staining and appearance in general indicates a degenerative process. This can also be seen in the roentgenogram (Fig. 20).

Experiment 47 Duration 298 days. Dog 6-2R age 4 months.

Macroscopical description. The changes correspond to those found in the previous experiment. Specimen preserved in Kaiserling's solution (Fig. 20).

REIMPLANTATION OF A SPLIT METACARPAL OR METATARSAL BONE

Experiment 48 Duration 31 days. Dog 9-4 split age 1 1/2 months.

Macroscopical description. Good healing is present. There is no growth of the operated or the normal bones. The marrow is replaced by fibrous tissue and in places there is an ingrowth of osseous tissue.

Fig. 29. Experiment 40, 303 da. s. Dog 6—age 4 months. Reimplantation of entire metatarsal bones. Right, B shows the implanted bones undergoing absorption, 6 cm. shortening since operation. A, growth of normal bones. Compare A and B with A and B in 4.

Microscopical description. The section stains poorly. The articular cartilage is of normal structure. The marrow is replaced by fibrous tissue. The trabeculae of the epiphysis show loss of their clear staining. There is evidence of the epiphyseal cartilage line. In the diaphysis there is an extensive new formation of endosteal bone. The marrow of the diaphysis is fibrous. The model of the cortex stains very lightly. There is a slight amount of proliferation about the Haversian canals.

Experiment 140. Duration, 3 days. Dog 8—age 6 months.

Microscopical description. There is no growth of the operated bone while the normal has increased 5 cm. Only remnant of the bone surrounded by dense fibrous tissue is still present (Fig. 3).

Microscopical description. The remnant of bone possesses well stained nuclei. It is surrounded by dense fibrous tissue and in a few places the periosteum is present. Scattered along the surface and in the Haversian canals are numerous osteoclasts which are aiding in the destruction. There are also some marrow-elements in the Haversian canals. In the fibrous tissue away from the main bone are some particles of degenerating bone about which are many polymorphous clear cells.

Experiment 50. Duration, 37 days. Dog 4—age 4 months.

Fig. 30. Experiment 40, 1 day. Dog 4—age 6 months. Reimplantation of split metatarsal bone. Notice marked tropic of implanted bone (A). Compare with normal bone (B).

Microscopical description. There is good healing. The joint space is thickened but the articular cartilage appears to be in good condition. The bone is firm. On section the marrow appears paler than normal.

Summary on Reimplantation of an Entire Metatarsal or Metatarsal Bone

The articular cartilage undergoes slow degeneration and in some of the experiments a substitution by fibrous tissue occurs.

The marrow undergoes an early degeneration and then regeneration takes place. This regenerated marrow persisted as long as any of the other osseous parts.

The trabeculae degenerate early. Later by means of regeneration beginning at the periphery they are completely re-formed. In the more advanced stages they again show degenerative changes.

The epiphyseal cartilage line undergoes progressive and complete degeneration. There is some cartilage regeneration beneath the perichondrium at the edges but this does not persist.

HAAS TRANSPLANTATION OF ARTICULAR END OF BONE

The marrow and trabeculae of the diaphysis undergo the same changes as they do in the epiphysis.

The cortex at first degenerates and then is regenerated by new bone formed from the periosteal endosteum and about the Haversian canals. As the observation did not extend beyond 298 days it is hard to say definitely the fate of this bone but from the various pictures presented it seems as though this newly formed bone again degenerates and finally entirely disappears or only a small remnant remains.

There is always complete failure of growth after reimplantation of an entire bone.

AUTOTRANSPLANTATION OF AN ENTIRE META-CARPAL OR METATARSAL BONE

Method. The entire metacarpal or metatarsal bone is raised from its bed and interchanged with a corresponding bone of the opposite foot.

Experiment 51. Duration 36 days. Dog 1 L. split at distal end. age 9 months.

Macroscopical description. There is no growth of the operated bone while the normal increase is 0.4 cm. The joint-capsule is thickened and the cavity contains turbid fluid. The articular cartilage is rough. The distal end of the bone appears enlarged. The epiphysis is composed of a gelatinous cartilage looking material. The marrow-cavity contains soft degenerating marrow. The cortex is irregular and thickened.

Microscopical description. The joint cartilage shows a different degree of staining in the outer and inner parts. In the latter the nuclei stain poorly. There is a fibrous tissue substitution of the marrow of the epiphysis which contains collections of polymorphonuclear leucocytes. The trabeculae of the epiphysis are composed of a homogeneously stained center without nuclear stain about which is newly formed osseoid tissue. The epiphyseal cartilage line is almost entirely absent and a fissure extends through this region. The metaphyseal cartilage columns are scanty and appear to be degenerating. The marrow of the diaphysis is fibrous and the trabeculae show marked evidence of degeneration. The cortex is composed of a homogeneous non-nuclear containing tissue about which there is some newly formed bone but there is more evidence of absorption.

Experiment 52. Duration 36 days. Dog 17 R. split entire age 9 months.

Macroscopical description. The bone is 0.5 cm. shorter than at time of operation while the normal bone is 0.3 cm. longer. Joint cartilage is rough, distal end of bone necrotic and epiphysis absent.

Microscopical description. On cross section the marrow cavity is seen to be filled with fibrous tissue. The nuclei of the cortex stain poorly and the architecture is not so regular as normal. One one-third there is a considerable amount of periosteal newly formed cartilage and osteoid tissue.

Experiment 53. Duration 80 days. Dog 9. 5 L. age 3 1/2 months.

Macroscopical description. The healing is good. The operated bone is 0.6 cm. shorter than at the time of operation while the non-operated bone is 0.1 cm. longer. The marrow appears normal. The epiphyseal cartilage line is not distinguishable.

Microscopical description. The articular cartilage on one side appears fairly normal while on the other side it is practically replaced by fibrous tissue. The marrow and trabeculae of the epiphysis are normal. The epiphyseal cartilage line is almost entirely absent only a small band of ossifying cartilage is present. This band appears nearer to the articular cartilage than normal as if there is a collapsing of the epiphysis. The marrow of the diaphysis is normal. The trabeculae are normal although some contain what appears to be dead bone in their centers. The outer surface of the cortex is very irregular and eroded although the general structure of the bone is normal.

Experiment 54. Duration 80 days. Dog 10. 5 R. age 3 1/2 months inserted.

Macroscopical description. In this experiment holes are bored into the bone at various places. There is 0.5 cm. shortening of the operated bone. On section there is a large cartilaginous mass in the region of the epiphyseal cartilage line. The proximal end of the bone is smaller than normal.

Microscopical description. There is a mass of fibrous tissue extending into the joint. The perichondrium is thickened and in some places the cartilage is pierced by fibrous tissue. The cartilage that remains shows a peculiar arrangement of the nuclei and it is difficult to determine whether it is degenerating or regenerating. The marrow and trabeculae of the epiphysis and diaphysis appear normal. The epiphyseal cartilage line is represented by a thin band of ossifying cartilage at one end of which is a large amount of perichondrial fibrocartilaginous tissue which is undergoing ossification. The cortical bone is of normal structure although there is extensive erosion on its surface.

When this experiment in which holes are bored into the transplant is compared with the previous one which was left intact it is noticed that the various parts of the latter are best maintained.

Experiment 55. Duration 91 days. Dog 8. 3 L. age 6 months.

Macroscopical description. The transplanted bone is 0.3 cm. shorter than it was at the time of the operation. There is only 0.1 cm. growth in the normal bone. There is some thickening of the

joint-capsul and irregularity of th articular surface. On section the marrow-cavity is found to be occupied by cancellous bone in which are scattered marrow elements. The cortex is thickened, irregular and quit dense thus giving the bone a larger and more irregular appearance than normal.

Microscopical description. A cross section at the distal end shows an abnormally shaped marrow cavity containing fairly normal marrow. The trabeculae are more numerous than normal and in the centers of some there is degenerated bone. The cortex, the nuclei of which are well stained, sh ws a distortion of the haversian systems and about the outer surface, which is rough, are many osteoclasts. The periosteum has lost its normal appearance so that the surrounding fibrous tissue penetrates into the cortex. The proximal end is similar with the exception that the marrow is not so cellular.

Experiment 56 Duration 09 days Dog L, age 5 mo the forefoot.

Microscopical description. Only a small remnant about 1 cm long of the distal part of the transplanted bone remains. There is no growth of the normal bone.

Microscopical description. There is dense fibrous tissue surrounding the piece of bone. The bone contains mature marrow and trabeculae of normal appearance. The cortex is irregular and fibrous tissue penetrates the bone substance in some places. There are numerous osteoclasts scattered about the periphery. There is no distinct periosteum present.

Experiment 57 Duration 09 days Dog 1 IL, age 5 months, hind foot.

Microscopical description. There is no increase in length of the transplanted or the normal bones. The articular surface is rough and at its distal end the bone is fused with the adjoining bones.

Microscopical description. On cross section of the distal end there is normal piece of bone adherent to the transplant. On comparing the two, the transplant is much more irregular in outline and in arrangement of the haversian systems. The periosteum has lost its distinguishing structure and the fibrous tissue is in intimate contact with the bone. Many osteoclasts are present. The marrow and trabeculae are of normal structure but likewise irregularly arranged.

Experiment 58 Duration 155 days Dog L, old dog.

Microscopical description. The articular cartilage appears almost normal. On longitudinal section the marrow-cavity is irregular and the marrow appears paler than usual. The general appearance is one of slow degeneration.

Microscopical description. The articular cartilage is regular in outline but the nuclei take pale stain. The marrow toward the epiphysis is of this mature fatty variety, while in the diaphyseal part it is replaced by fibrous tissue. The trabeculae for the most part contain poor staining nuclei. In

the cortex the nuclei take a poor stain, excepting those immediately beneath the periosteum, where there appears to be newly formed osseous tissue.

Summary of Autotransplantation of an Entire Metacarpal or Metatarsal Bone

As far as can be ascertained from this incomplete series there appears to be more degeneration in the case of young animals than in the older animals.

In the young animals the articular cartilage shows marked degeneration and substitution by fibrous tissue. In the old animals the articular cartilage is well preserved even at 255 days.

The marrow at first degenerates and then becomes fibrous. Later it regenerates and persists for a considerable length of time.

The trabeculae degenerate at first as is seen in the 36-day experiment and then regenerate by a process of peripheral new formation.

The epiphyseal cartilage line undergoes a progressive degeneration. There is some new cartilage formed during the early stages beneath the perichondrium at either border but this eventually disappears.

The cortex at first loses its nuclear staining then regenerates and finally undergoes a slow absorption. The periosteum seems to disappear and the fibrous tissue and osteoclasts gradually absorb and replace the bone.

COMPARISON OF REIMPLANTATION AND AUTOTRANSPLANTATION OF AN ENTIRE METACARPAL OR METATARSAL BONE

The articular cartilage shows more rapid and extensive degeneration in young animals after autotransplantation of an entire bone than after reimplantation. In older animals the difference is not so evident nor is the process so rapid.

The marrow in both cases degenerates at first and then becomes fibrous and finally regenerates. The processes are about the same in reimplantation and in autotransplantation.

The degenerative processes of the epiphyseal cartilage line are the same in both reimplantation and autotransplantation a gradual complete progressive degeneration

with only a slight temporary regeneration at the periphery beneath the perichondrium.

The cortex is similarly affected in both reimplantation and autotransplantation. At first there is degeneration and then regeneration after which the periosteum loses its structure and a slow absorption occurs throughout the entire bone. Though sufficient time has not elapsed in these cases the indications are that there would be complete disappearance of the transplants if a longer period were allowed to elapse before terminating the experiment. The transplants from older animals were able to withstand the degenerative processes better than those from younger animals.

There is complete failure of growth in both reimplantation and autotransplantation of an entire metacarpal or metatarsal bone.

The splitting or incising the bone did not favor the transplantation; on the contrary it hastened the degeneration.

DISCUSSION AND REVIEW OF THE LITERATURE

Hulferich (2) in some experiments performed on rabbits in 1899 in which he reimplanted the lower epiphyseal cartilage line of the ulna came to the conclusion that the epiphyseal cartilage line under favorable conditions retained its property of producing length growth although he noted there might be a lessening of that function. Enderlin (3) who made the microscopical studies of these preparations decided that the epiphyseal cartilage line retained its vitality to a large extent. The parts near the periphery were best maintained while those at the center showed evidence of degeneration.

Zippi (4) found in autotransplantation of the epiphysis a regular healing and formation of new bone but in heteroplastic transplantation there was a complete failure.

Gakara (5) found in both autotransplantation and homotransplantations calcification of the epiphysis and complete loss of function.

Rehn and Wakabayashi (6) from a series of experiments on two-months old rabbits in which they performed homoplastic transplantation of the head of the radius concluded that the epiphyseal cartilage fully maintained

its histological structure and function after such transplantation. Their experiments are open to criticism because they do not rule out the greater growth that takes place from the distal epiphysis of the radius. In their microscopical descriptions they mention certain degenerative changes occurring in the epiphyseal cartilage line at 28, 31, 33, and 42 days after operation in which is below the normal time for ossification of the epiphyseal line in rabbits (fourth to fifth month). In the present article the results in autotransplantation are less favorable than in reimplantation. It is more than likely that the degenerative changes would be still more marked in homoplastic transplantation and that the result would be quite contradictory to those of Rehn and Wakabayashi. Obata who performed a series of experiments exactly similar to those of Rehn and Wakabayashi does not agree with their functional nor their microscopical findings.

During the same year 1912 Arhausen (7) article appeared in which he reported the results of his experiment on young rat and rabbits. He transplanted the lower fourth of the femur from a growing rat to the subcutaneous tissue of another rat. He found some degeneration of the inner layer of the articular cartilage at the sixth to twentieth day after which there was regeneration. The marrow of the epiphysis and diaphysis at first degenerated then became fibrous and at a very late period was regenerated in the epiphysis. The trabeculae at first degenerated and then regenerated. The epiphyseal cartilage line showed in the early stages a shrinking of cells and at 20 days only the peripheral parts remained alive. In the later stages aside from a slight proliferation near the periphery the entire line was substituted by fibrous tissue. The cortex showed an extensive degeneration up to 30 days but in the older stages there was considerable regeneration. In a similar set of experiments on rabbits the results corresponded quite well to those found in the rats. In another group of experiments thin sheets of articular and epiphyseal cartilage of the femur of rabbits were transplanted under the skin on the back of another animal. The marrow

was substituted by fibrous tissue except beneath the articular cartilage and near the surface. The bone trabeculae appeared to undergo degeneration with very little evidence of regeneration. The articular cartilage showed in the later stages a substitution of the dead inner layer by a proliferation from the perichondrial layer. He also transplanted the patella, either intact or split in two pieces from one rabbit to the subcutaneous tissue of another rabbit. The bone showed shrinking of nuclei at 24 days empty cells at 45, 50 and 70 days. There was an early necrosis of the marrow and complete degeneration at 24 days. At 50 days there was beginning organization which was completed at 70 days. The inner layer of the articular cartilage showed a beginning shrinking of the cells at 10 days which was more marked at 38 days. At 50 days there was some proliferation of the cells and at 70 days there was evidence of resorption of the cartilage. In the cases where the patella was cut into two pieces the cartilage showed some necrosis on the surface due to the trauma.

While the present work was being completed the following articles appeared and they will be reviewed in the order of their publication.

Von Tappeiner (8) performed three reimplantations and eight homotransplantation experiments on dogs, at the ages of one and one half and four and one half months. In the reimplantations he found no changes in the articular cartilage. The marrow of the epiphysis and diaphysis showed fibrous changes at first, after which regeneration occurred. The trabeculae at first degenerated and were then reformed. There were practically no changes in the epiphyseal cartilage line even after six months. The cortex at first degenerated and then was regenerated. There was no disturbance in the normal growth. These findings in reimplantations are entirely at variance with those of the present article both as regards the normal microscopical appearance of the epiphyseal cartilage line and the normal longitudinal growth of the bones which he reports. As his experiments were performed under exactly the same conditions it is difficult to explain

or offer any reason for such wide variation in the results. His microscopical descriptions on homoplastic transplantations correspond closely to the autoplasmic experiments described in the present paper. He ascribes some power of the epiphyseal cartilage line to increase in length even after homotransplantation again disagreeing with the findings of the author.

Obata (9) has made a very complete study of the transplantation of the epiphysis in his work on joint transplantation. He performed reimplantations, autotransplantations and homotransplantation of the metatarsophalangeal joint either with a part of or the entire metacarpal and phalanx. He found a disturbance in growth in every instance the greatest being in the case of homoplastic transplantations. The transplanted joint cartilage maintained its normal form but appeared cream white and in later stages erosions appeared on its surface. The union of transplant with the host was normal in every case except in homoplastic transplantations where there was a pseudo-arthritis. In general the above macroscopic findings agree with those of the present investigation except that Obata did not find such a marked failure of length growth in his reimplantations. In Obata's microscopical findings on reimplantation, he describes degenerative changes in the articular cartilage as early as 9 days which were more marked at 35 days then regenerative changes at 50 days and again degeneration in the middle part at 70 and 100 days. At 104 days he says it is in normal condition. It is difficult to analyze these changes and he offers no explanation for the variations in the processes. He also described a progressive degeneration of the epiphyseal cartilage line until the fiftieth day after which there occurred a partial degeneration followed by a regeneration. He ascribed almost normal functional properties to this regenerated epiphyseal cartilage line. At 70 days he described an extensive degeneration of the epiphyseal cartilage line. It is difficult to explain the discrepancies in his findings in that there was an extensive degeneration at 35 and 70 days while at 50 days the cartilage was so well maintained. It is possible that

under some especially favorable circumstance the transplanted epiphyseal cartilage line did not undergo the usual rapid degeneration as in the other cases. In comparing Obata's findings on reimplantation with those of the present work there is a considerable uniformity except that he describes extensive degeneration of the articular cartilage while in these experiments the articular cartilage proved to be the most resistant of any of the transplanted tissues. This difference might be due to the fact that he transplanted the entire joint with the intact capsule which perhaps prevented the early inflow of nourishing fluids as is possible in the case where only one half of the joint is utilized. Neither is there an agreement as to his statement that the epiphyseal cartilage line can regenerate so as to continue the length growth of the transplanted bone. In the autotransplantation he likewise describes much more extensive changes in the articular cartilage than is found in the present work. Otherwise the changes correspond fairly well to the changes that are described in this series of experiments. In Obata's homoplastic experiments he found changes to be more extensive in the cartilage than in reimplantation or autotransplantation with very little evidence of regeneration. There was also less tendency to regeneration of the marrow trabeculae and cortex. In case of non related animals the degenerative processes were more rapid and extensive. In the homoplastic transplantation of the head of the radius he found the same degenerative changes throughout the transplant as in the other cases. The epiphyseal cartilage line underwent a progressive degeneration with practically no regeneration. Thus he does not agree with Kehn and Wakabayashi who performed similar experiments and described complete retention of structure and function of the epiphyseal cartilage line.

Heller (10) performed reimplantations and homotransplantations of the distal epiphysis of the ulna of rabbits and goat. He found the least amount of shortening in reimplantation while the greatest amount was in homoplastic transplantation in non related animal. He concluded that a practical use

of the epiphyseal cartilage line with a more or less large piece of bone attached could not be utilized in reimplantation and certainly not in homotransplantation. He said that in reimplantations there was some regeneration of the epiphyseal cartilage line and a not in considerable amount of bone apposition but nevertheless the bone growth was retarded. In homoplastic transplantation he found some perichondrial regeneration but that there was no tendency for a physiological utilization of this in the epiphyseal cartilage line. The larger the animal the less favorable were the results and the more rapid and extensive the resorption even to complete disappearance of the transplant. He predicted that it might be possible by using very thin pieces of the epiphyseal cartilage line to obtain some successful result and in a short note at the end of his article intimated that he had obtained favorable results by the use of thin sheets in autotransplantation. The finding of Heller agrees fairly well with those described in this paper except that he reports more or less growth after reimplantation. The use of the distal end of the radius and ulna on account of the bending of the extremity does not offer so favorable an experimental method as does the use of the metacarpal or the metatarsal bones.

Minoura (11) transplanted the metatarsophalangeal joints either intact or split longitudinally of two months-old rabbits into the back subcutaneous tissue liver or abdominal cavity of the same or different animals. In some cases the joint was placed in Ringer's solution before transplantation or was removed from a dead animal. These experiments do not correspond to those of the present work because the transplant was placed under unnatural conditions but on account of a certain agreement of the early histological changes they will be reviewed. He found that the transplanted joint became encapsulated by the tissue of the host and that the healing was always the same whether it was in the muscle subcutaneous tissue or abdominal cavity. In the longitudinally split bone the organization took place more quickly than in the entire bone and there was little difference in the processes if the joint was

allowed to remain in Ringer's solution before transplantation. The joint cartilage remained intact for a considerable time and always showed a cartilage-cell regeneration on the periphery. The marrow degenerated and was substituted by fibrous tissue and later by fat. The trabeculae of the epiphysis degenerated and later were substituted by new formed bone which however was not permanent. The epiphyseal cartilage line underwent necrosis and absorption only the parts of the proliferating zone near the periphery showed multiplication of the cartilage cells. The periosteum always showed new bone formation in the inner layers but the new formed tissue finally underwent absorption. In these experiments there was no possibility of the bone of the host playing a part in any of the regenerative processes. The findings agree very well with those of the present work except that in Minoura's experiment there was not the extensive regeneration and there was a lack of permanency of the new formed tissue. Thus it shows that there are certain regenerative processes that can take place in a transplant without the aid of the host, but in order to have lasting qualities some additional elements from the host are necessary. The changes in homoplastic transplantation were similar to those of autotransplantation although they were not so marked nor so permanent. In none of the experiments was there any increase in the length of the bone after transplantation.

Gill (12) reports eleven experiments performed on full grown animals in which he made autotransplantations of the entire metatarsal bones. Infection occurred in most of his experiments but in spite of that fact, he says five of the transplanted bones were practically normal at the end of eight months. He found no evidence of dead bone on microscopic examination in these experiments in which there was only slight infection. In comparing Gill's results with those of similar experiments in the present paper there is a considerable variation in the findings. In practically every case in the present experiments there was macroscopic and microscopic evidence of degenerative changes after the transplantation of an entire

bone. The changes took place earlier and were more extensive in the young animals.

SUMMARY

1. The epiphyseal cartilage line ceases to functionate after reimplantation and autotransplantation either when transplanted by itself or with a small or a large piece of adjoining diaphyseal or epiphyseal bone or even when transplanted as an entire intact bone. The longitudinal growth ceases in every case. The first change after transplantation consists of a fragmentation of the cartilage columns near the epiphyseal ossifying layer. Later there is a disappearance of these cells. Then there is fibrous substitution of the remaining parts, and finally ossification occurs as in the adult animal. The only evidence of regeneration is near the periphery beneath the perichondrium which part seems to retain its property of producing cartilage. This new cartilage possesses none of the length-producing functions of the normal epiphyseal cartilage line. The epiphyseal cartilage line is the least transplantable of any of the components of bone.

2. The articular cartilage undergoes practically no changes after reimplantation. In autotransplantation there occurs at times evidence of degenerative and regenerative changes. In some of the experiments of longer duration there is a partial substitution by fibrous tissue. The articular cartilage offers the greatest possibilities of successful transplantation of the various parts of a bone.

3. The marrow of the transplant appears to undergo an early complete necrosis. It is possible that some of the cells persist because of better conditions for nourishment, or have a greater resistance and are later the source for the regeneration of the marrow. After the necrosis of the marrow the spaces are filled with fibrous connective tissue. At a still later period scattered marrow-cells are found in the fibrous tissue and there is then a gradual reformation of the marrow. The exact method of regeneration cannot be definitely determined. Whether it bears any relation to the newly formed capillaries or arises from the persisting marrow-cells of the transplant, is difficult to ascertain.

4 The trabeculae show early evidence of degeneration as is indicated by the loss of staining property of the nuclei. The first indication of regeneration is seen on the periphery where a layer of osteoblasts are found. The later stages show a proliferation of these cells to form osteoid tissue which gradually replaces the old bone to form the new trabeculae. It is impossible to determine definitely the origin of this new tissue but it is probable that the osteoblasts on the surface of the trabeculae on account of better conditions for nourishment have persisted and with the re-establishment of the capillary blood supply are able to proliferate and re-form the bone or they might bear some relation to the fibroblasts. The process is the same in both reimplantation and autotransplantation of parts of bone or entire bones.

5 The cortex shows an early loss of nuclear staining. Later there takes place a new formation of osseous tissue from both the periosteum and the endosteum and with a limited amount of new osseous tissue in the region of the haversian canals the cortex is completely regenerated. Even in the transplants that are in contact with the bone of the host the new tissue is formed independently of that source. It seems as though this new bone is lacking in some property by which it may continue to exist and in order to endure some additional stimuli or osseous elements are necessary to establish the permanency of the transplant. This additional factor might be in the nature of certain stimulating fluids from the normal bone or an emigration of definite osseous forming cells.

6 Following the first operation in the two stage autotransplantation of the epiphyseal end of a bone there is a considerable disturbance in the function of the epiphyseal cartilage line even though the epiphysis is not separated from the surrounding tissue. The loss of growth is most likely due to the interference with the main vascular supply from the diaphysis to the epiphyseal cartilage line. After the second operation in which the epiphysis is separated from the surrounding tissue and the epiphyseal vessels destroyed there is a complete cessation of growth. The loss of function occurs in spite of the

fact that the transplant is united to the host and that a part of the diaphyseal blood supply is re-established. The importance of the direct vascular supply to the epiphyseal cartilage line is forcibly demonstrated in this experiment.

7 The vitality of the various components of bone after transplantation is directly related to the ability of that part to withstand the loss of its vascular supply. The least dependent the part is upon its blood supply the greater is the possibility of a successful transplantation as in the articular cartilage while on the other hand the more dependent the part is upon its vascular connection the less likely is the possibility of a successful transplantation as in the epiphyseal cartilage line.

8 From these experiments and the results in general on transplanted bone the following conclusion is offered regarding the fate of bone after transplantation. Although each part of transplanted bone possesses the power to regenerate independently and without the aid of neighboring bone the autonomous newly formed tissue does not possess that property which is necessary for a continued existence and it will ultimately entirely disappear. Some additional stimulus is needed and such conditions are only obtained when the transplant is in direct contact with normal growing bone. Therefore when there is failure of such connection the transplanted bone at first shows evidence of regeneration but it a sufficient time allowed to elapse it will ultimately entirely disappear. However if it is united with the cut surface of normal bone it will continue to live because certain necessary additional stimuli and new elements will be supplied by the host. It is possible that certain chemical or physiological stimuli are supplied by the living intact bone after which the regenerated bone on account of these additional factors is able to persist permanently. Undoubtedly some definite osseous elements from the bone of the host invade the transplant and either replace the temporary bone or give to it certain requisites for its perpetuation. Although function may play a factor in the development of bone it is not of prime importance in determining the permanency

of that tissue. The differences of opinions of the various investigators is in part due to the failure to allow sufficient time to elapse before drawing final conclusions, as well as to take into account the influence of different environmental conditions on the transplant from both young and old animals.

In conclusion, I wish to extend my thanks to Professor Ophuels, of the Pathological Laboratory under whose guidance the above work was performed, for his interest and suggestions also to thank Professor Blaisdell of the Surgical Laboratory for his assistance in the operative work.

Since this article was submitted for publication the following paper has appeared: *Neue Experimente zur Frage der homoplastischen Transplantationsfähigkeit des Epiphyseknorpels und des Gelenkknorpels*. He gives the results obtained from sixteen homoplastic transplantations performed upon the upper epiphysis of the radius of rabbits. He reports two successful instances one of which was not only anatomically but physiologically efficient. He is unable to explain the variation in the results, but suggests that it might be on account of the less poisonous reaction of the body fluids. Like all experiments on the upper epiphysis of the radius they are open to criticism and a careful an-

alysis of his descriptions are not entirely convincing as to the absolute success of these experiments.

TRAUMAS OF THE BACK AND SPINE

B. FRANK E. PIERCE MD FACS CHICAGO

IN my experience with traumatic surgery I have met with no more interesting series of cases than as represented by the title of this paper and having frequently to pass judgment upon the seriousness of such injuries, the responsibility attached there to is not always a light one. The actual conditions present are often so veiled by exaggerated imaginary or simulated symptoms that one must be very careful in making a diagnosis and prognosis not to overlook or underestimate serious injuries or to consider too seriously the minor ones.

This paper is based upon the records of 758 cases. Of these, 51 were under my personal observation while the balance are collected from my file of reports from men associated with me in railroad surgery. I have been in close touch with the conditions in all of the cases so reported have received frequent reports in the more serious ones have examined many of them and have been able to direct the line of treatment. The list includes only those injuries which have been diagnosed as a contusion or sprain, together with their complications. No cases

are included except where the period of disability has exceeded one week and I have also excluded all cases known to be complicated by a fracture or dislocation.

By a contusion we mean those direct traumas received either over the spine itself or as more frequently happens to one side of it and involving the muscles and other soft tissues of the back. Looked upon by many as injuries of minor importance from which the victim promptly recovers they are nevertheless in some instances serious in character and the disability produced is an extended one.

The contusions are included with sprains because it is almost impossible at times to distinguish one from the other particularly so when the contusion has been directly over the spine. In those cases not seen by me I have a rule accepted the diagnosis as made by the attending surgeon but my personal experience with this class of cases leads me to believe that the diagnosis has been in correct in many instances and that cases reported as contusions are often sprains and some of the so called sprains are no more than contusions.

In contusions the trauma varies from a moderate bruising of the soft tissues to a laceration of the dorsal muscles a stretching or tearing of muscular attachments to the spine injury to spinal nerves and injury to internal organs as the kidney. In the milder cases there may be no external evidence of an injury while in more serious ones there will be a swelling with or without discoloration and large deeply lying hematomata may form from extravasated blood and serum. Rarely a groove or depression may be felt between divided muscle bundles.

From a total of 74 cases 83 or 9 per cent were located in the lumbar region 45 or 16 per cent in the dorsal region and 10 per cent occurred in both the dorso-lumbar and sacral regions. In 62 or a little over 20 per cent the location was not specified and from the figures above it is proper to assume that a majority of these occurred below the dorsal region. A period of disability in the mildest cases in this list averages from two to three weeks while a disability of from two

to three months is not at all uncommon. Contusions in which recovery is more delayed and which run from four to six months or a year have some complication as sprain a possible fracture nervous symptom or there is intent on the part of the patient to try and secure a large settlement.

A sprain may be considered a bending or twisting of the spine and a stretching of the spinal muscles and ligaments to a point beyond their physiological range of motion. Constructed and supported as it is the spine will withstand a considerable amount of jarring and bending without symptom of injury following. Its elasticity is dependent upon the articulations between the vertebrae the intervertebral cartilaginous discs or buffers the spinal and intervertebral ligaments and the spinal muscles. The elasticity and pliability present lessen very materially the shock produced by all kinds of traumatism. The cord itself is further protected against injury by being suspended within the spinal canal covered by its layer of membranes and the cerebrospinal fluid and supported to a further extent by the spinal nerves. The space between the dura and the walls of the canal is filled with loose cellular tissue and the venous sinuses. The cord can therefore be injured only by a narrowing of the bony canal as by fracture or dislocation by hemorrhage within the canal or in the cord itself or produced by a shock or strain of some character. From the latter cause arises the condition described as spinal concussion a trauma defined by Dr. Murphy as an impairment or loss of function of the spinal cord due to an injury which is not sufficient to produce gross anatomic changes. Though denied by many surgeons I am convinced that this condition does not infrequently occur as a result of some contusions and direct sprains.

Sprains are the result of either a direct or an indirect force. They occur directly as in contusions from a fall or blow and indirectly from falls upon the feet or buttocks from carrying heavy weights upon the head or shoulders from jumping slipping twisting of the spine and from over exertion in the act of lifting pulling or pushing.

The spinal muscles are undoubtedly at fault in a large number of the cases, about 80 per cent as near as I have been able to estimate, while the articulations and ligaments are involved in the remaining 20 per cent. This relative proportion is probably due to the fact that many of the more severe sprains are often complicated by a fracture and such cases are classed as fractures. The sprains have been grouped according to their origin from direct or indirect causes it having been found impossible to separate satisfactorily those involving only the spinal muscles from those affecting also the articulations and ligaments. One point of differentiation which cannot however be too much depended upon is that pain upon straightening the spine indicates a muscular involvement while pain in bending the spine indicates involvement of the ligaments. Although the mobility of the spine is greatest in the cervical region where the vertebrae are smallest and there is less muscular protection to them sprains occur most frequently in the lumbar region where the vertebrae are larger stronger and more protected.

Out of the 481 cases classed as sprain 420, or 87 per cent, were due to indirect causes and of these 200 or 47 per cent involved the dorso-lumbar and lumbar region. Of 61 cases due to direct trauma, 29 or 47 per cent involved the same region. If we add to these a proportionate number of those cases in which the locality was not specified we have involving this region 58 per cent of all the cases. Cervical sprains the next in frequency were reported but 31 times, twice as due to direct and 29 times from indirect cause. Direct contusions and sprains in the region of the coccyx were reported 20 times and a few of those developed a coccydynia which persisted for months. Those sprains involving the muscles alone are usually caused by lifting pulling or pushing too heavy weights carrying loads upon the head or shoulders, or due to a sudden twisting of the body as from slipping. The ligamentous sprains are usually the result of a fall upon the feet or buttocks or upon the back and shoulders. Numerous cervical sprains have occurred in sleeping cars, where as a result of sudden stopping of

a train one has been thrown up against the head board of the berth thus causing a forced flexion of the head.

The symptoms in contusions and sprains are similar and as has been stated one cannot always be distinguished from the other. In the milder cases there is localized pain and tenderness with some muscular rigidity more marked on one side of the spine in contusions and involving both sides in sprains. In both the pain is much less when the back is kept at rest and is increased by all bending or twisting movements. There is more muscular rigidity or muscular spasm in sprains this being Nature's method of enforcing rest to the strained ligaments and articulations. Some of the rigidity is voluntary from fear of pain as has been described by Page. The patient assumes at all times the position which gives him the greatest relief from pain and in all attempts to rise from a sitting position or in lying or sitting down uses the arms and legs to assist in the movement while holding the back very rigid. The reflexes of one or both legs are usually increased. Hyperaesthesiae and paraesthesiae are often present. Disturbances of the bowels and bladder are not infrequent in both contusions and sprains. In this series 22 patients complained of increased frequency or inability to urinate and in 17 cases bloody urine was passed for from a few hours to several days. Eighteen cases involving the lumbar and lumbosacral regions complained of particular pain over one of the sacro-iliac articulations.

Contusions and sprains are frequently so complicated by other symptoms of nervous disorder paralyses, etc. that our chief concern may be regarding the complication rather than injury itself. In the series 27 cases developed a traumatic neurosis 3 developed hysterical paralyses one a traumatic spondylitis and an epileptic convulsion occurred in one case one month after an injury to the back though the previous history was entirely negative. Eleven cases were classed as malingerers. Two cases suffered from hemorrhage one extradural and the other within the cord as a result of strain due to lifting.

The period of disability in sprains averages

longer than with the contusions. The muscular sprains are usually recovered in from two to three weeks. The milder ligamentous sprains disable one from four to six or eight weeks while the severe type will average from four to six months. In some cases pain is present off and on for several years. Those complicated by a traumatic neurosis average from six months to a year or longer.

In making a diagnosis great care should be taken not to overlook a more serious injury, as a fracture or dislocation. This has been done in a number of cases of which I have record. X-ray plates must be obtained in all doubtful cases and these will at times show a fracture or other lesion which cannot be positively demonstrated in any other way. Owing to the great danger in handling a patient suffering from fracture or dislocation we must exercise great care in conducting the examination. A valuable point in differentiating sprains from dislocations particularly in the cervical region is that in sprains all the normal movement can be obtained though very painful while with a dislocation certain movements are not possible but the effort to make them is not particularly painful. For this reason all manipulative movements should guard against the danger of inflicting more damage to the cord structure in case a dislocation or fracture is present. The necessity of such care is emphasized by a case reported to me several years ago as a sprain of the back. Several days after receiving the report a supplemental report stated that upon attempting to turn the patient upon his side in order to make a more careful examination a sudden marked deformity occurred due to a fracture dislocation at the level of the seventh dorsal vertebra. No difficulty should be met with in diagnosing the ordinary contusion or sprain but many errors are made in separating the muscular from the ligamentous sprains.

The prognosis depends upon the actual injury sustained and the complications which arise. The period of disability is no true index to the severity of the injury and nervous symptoms may be present in minor as well as severe cases. One must ever be on the lookout for malingerers or damage

seekers. The settlement of a claim for damage often has a most beneficial psychic effect upon a patient and recovery takes place rapidly though there may be nothing in the case to suggest an intentional exaggeration of symptoms.

I shall make no attempt to describe treatment of these cases in detail. Contusions should be treated the same as when they occur in other regions. In general the treatment of sprains depends upon whether the muscles are at fault or if the ligaments and articulations are also involved. Those cases in which the muscles alone are affected should be given rest for a few days followed by massage and a gradually increasing amount of gymnastic or setting up exercises. The ligamentous sprains require rest and the spine should be supported by adhesive strapping or other more effective means to secure this. Except for pain and tenderness at first massage and moderate exercise of a strained muscle or group of muscles should give relief but if after such a treatment the pain is increased and no temporary relief is felt then we should assume that the ligaments are involved and treat accordingly. Complications should be treated according to their symptoms. Environment sympathy of friends and members of the family, visions of permanent disability or invalidism, business worries, etc., all tend to bring on or increase nervous symptoms and thus delay recovery.

ILLUSTRATIVE CASES

Spinal concussion. CASE 1. L. J. G. switchman injured December 2, 1903, account of being thrown from the top of a box car to the ground and striking upon the back and right shoulder. Was unconscious for five to ten minutes. When examined at the hospital he was unable to use the right arm and could not move either leg. Sensation not disturbed and reflexes present but slightly exaggerated. Slight motion returned in legs in a few days and by January 11, 1904, he was able to return to work.

CASE 2. J. G. switchman age 48 injured April 17, 1910. On account of defective grab iron he fell from the side of a box car to the ground striking upon the back. Symptoms as reported were a motor and sensory paralysis of the arms and all below the level of the first dorsal vertebra. A report of May 1, stated there was a little return of motion in one hand and returning sensation in the other also a little motion in the legs.

The reflexes were also returning slowly. Bladder and rectum still completely paralyzed. Three X-ray plates were all negative as to fracture. Diagnosis made was hemorrhage into the cord cervical region, followed by transverse myelitis and due to severe spinal concussion. The patient died May 29 1910.

In speaking of isolated injuries to the cord without injury to the spine, Leyden states that from concussion a paralysis may follow at once or soon and may be fatal. The cord shows itself to be lacerated together with free hemorrhage or extravasation of blood in the vertebral canal or it may show no gross or microscopical changes. The real changes he states, are probably a direct traumatic necrosis of axis cylinders. If a patient lives recovery may follow quickly but in all cases where an effusion of blood has occurred a chronic myelitis is to be feared.

C. Injuries with paraplegia. CASE 3 H R W brakeman single, age 26 injured March 1903. While standing in the open door of a baggage car he fell backward out of the car and struck upon wood rail protecting some signal wires. He was taken home and I saw him within the next hour or two. He had a severe contusion over the region of the left kidney and was suffering from intense pain in the back. The first urine passed following the injury contained a considerable amount of blood and continued to contain blood for several days after which it became clear. He returned to work in about six weeks, but pain continued off and on for a number of years.

CASE 4 M C laborer age 35 injured August 1909, account of falling from a gravel car to ground and landing upon his back. He was taken to the hospital by ambulance and remained in the hospital under my care up to April 1910 then was kept under observation until May 1910. Examination showed contusions all along the back and spine. Pain was most severe in the muscles on the left side. Hyperaesthesia present from the mid dorsal region downward. There was a spastic paralysis in both legs, more particularly the left, and a marked increase in all the reflexes. No bowel or bladder disturbance was present. Improvement was very slow but more in the right than left leg. On January 1911 examination of right leg showed muscular spasticity still present reflexes exaggerated but ankle clonus diminishing no Babinsky sensation nearly normal. The left leg showed more muscular spasticity and very much diminished voluntary movements of the leg due largely I felt to fear of increasing pain in the back. All bending movements of the spine were avoided as much as possible. X-ray plates were negative. Not entirely satisfied with the slow recovery and fearing that

a more severe injury had been overlooked I had him examined by D J B Murphy on February 13 and my diagnosis of contusions of the back with some sprain was confirmed. Our line of treatment was unchanged but the amelioration was followed by more rapid recovery than at any other time due to the improved mental condition of the patient. With the added assurance that no serious injury was present he made more effort to get around and soon found that the increased activity did not increase his pain but rather lessened it. He reported back to work about June 1910.

Sprains of the lumbar vertebrae followed by spinal hemorrhage. CASE 5 J J freight handler age 35 injured October 1905. While engaged in lifting a heavy casing he experienced a sensation of something giving way as he spread it something snapped in the back. He was at once disabled and was taken home where he remained without medical attention until the 31st when he came to my office for examination. He complained of pain over the third fourth and fifth lumbar vertebrae and especially at the point where the spine crossed below the level of the iliac crests. He had had no bladder or rectal disturbance and there was no motor or sensory disturbance in either leg but the pain in the back had been continuous. His symptoms were all subjective and there were no objective findings upon examination. The diagnosis was muscular sprain and he was instructed to do no certain muscular exercises and given massage treatment for two weeks. He reported November 1905 that he was much improved and intended returning to work in a few days.

CASE 6 F W H tire agent age 34 married, injured August 1907. Previous history negative. While in the act of lifting a heavy propeller blade he experienced a sensation of something giving way and of an immediate weakness in the lumbar region and through the hips. He rested for about half an hour then resumed work, but did not attempt to do any heavy lifting. He experienced no unusual symptoms that night and was at his office the following day. He had no real pain, but did not feel right. He went to the White City park that evening and spent several hours walking about. He slept well that night and had no uncomfortable symptoms. The following day the 20th, he was at the office and did some work at the warehouse as on the 24th. He was restless that night and did not sleep much, but was not painful. The next day the 27th, he did not feel right but spent all day at the office. That night he could not sleep or rest in bed on account of pain across the lumbar region of the back and distressed feeling through the hips, and he walked the floor until about 6 a.m. the following morning. About this time the pain became less and, feeling very tired and weak, he went to bed and slept for about two hours. When he awoke he was unable to get up on account of a complete motor paralysis of both legs. Called in day or two later I found upon examination a motor paralysis of both

PIERCE TRAUMAS OF THE BACK AND SPINE

legs but no marked disturbance of sensation. The patellar and plantar reflexes were absent. There was no ankle jerk and no Babinski reflex. There was no involvement of the bladder or rectum except for slightly diminished sensation which returned to normal within the next week. Examination in February 2, 1908, showed improvement. The muscles of the legs were greatly atrophied but had retained some size through the use of massage and electricity. It was noted at this time that he felt a little more strength in the muscles in the anterior surface of the right thigh but there was no comparison. There has been no material improvement since then. He still has a complete paralysis of both legs but retention of the bladder and rectum. Sensation is practically normal. I have never been able to satisfactorily elicit the reflexes in this case but believe to be located in the cauda. The most interesting features of the case are the equal involvement of both legs below the level of the lumbosacral ligament with loss of sensation of bladder and rectum and the presence of practically normal sensation.

CASE 9. W. C. Smith, harness maker, injured January 5, 1910. In letting go of a heavy piece of iron which he was lifting he felt a sudden pain in the chest and back. He was almost immediately disabled and when examined at the hospital was found to have a motor and sensory paralysis of both legs and of the bladder and rectum. He complained of severe pain in the spine. Two days later sensation and some motion returned to the right leg but the left was unchanged. February 11, it was reported that sensation was normal in the right leg but that there was less motion than a week before. Anesthesia on the left side extended nearly to the lower border of the scapular arch. I examined the case February 10 and found both legs paralyzed but sensation present in the right. All the reflexes were absent except the plantar reflex in the right leg. Bowel movement was involuntary and there was incontinence of urine. The bed men were his distant land and right from the outer margin to the hips, both sensation and being present at times and absent at times. Later there was more loss of sensation in the left side. He stated that he could move the right leg some the first day after injury but not since then. No muscular atrophy was present at this time but there were a number of small local ecchymoses. On March 1, sensation was present in the whole right side and some extent in the left foot. There was a little return of motion in the left foot. The symptoms improved slightly from then on but he gradually lost weight and strength and finally died July 16, 1910. The diagnosis in this case was extradural hemorrhage due to sprain from lifting.

SPINAL TRAUMA WITH LOCAL SYMPTOMS
CASE 10. F. W. Witham, glass injured November 20. Admitted to hospital on account of injury to the lumbar region. He stated that he had been carrying a heavy box on his back and that he had been

healed and talked at random. No paralysis was noted. On November 22 he sat up in bed for the first time and was up each day until the 6th when he complained of feeling bad again and remained in bed. Later in the day he got up and left the hospital. I next saw him on January 4, 1908. At this time he claimed to have been struck in the back by a tree trunk and knocked down. He was brought to the hospital where upon examination we found a complete left-sided paralysis and some limpity. He felt no pain at times. Motion returned in the right leg the next day and the remaining symptoms cleared so that he was up on the 14th. He was discharged from the hospital January 15. The same night I was called to see him in another hospital on account of an injury sustained through being struck by an engine. Examination at this time revealed a complete motor and sensory paralysis below the level of the fourth lumbar vertebra. There was rectal anesthesia and retention of urine for several days. No loss of reflex. Complaint of diplopia for first 4 hours also complained at times of an unnatural feeling in the hind foot. Expressing a desire to go home we put him in a stretch and on a train bound for Ohio with out waiting for his recovery. I next heard from him on account of an injury received November 1908. He was in a hospital in Ohio suffering from a paralysis of both legs due to railroad accident. The attending surgeon learned of two more alleged injuries between January and the one of November and while making an examination of one of the paralyzed feet stuck a needle well into the foot. This met with a shout of pain and upon being ordered to get up and leave the hospital the man promptly died. A man answering the same description and of the same name was picked up and taken to a hospital in Canton, Ohio on December 12, 1908, where it was reported he was completely paralyzed from the hips down. I did not hear the outcome of this attack. This man undoubtedly was suffering from a hysteroneurosis the paralytic attacks being easily precipitated by a slight injury to the back and this knowledge was being used by him to defraud corporations.

CASE 11. J. M. E. Hostler injured October 3, 1908. He was reported to me as having been struck in the back by a baggage truck and knocked down. Examination showed a complete paralysis from the hips down with no local evidences of any injury. The diagnosis was hysterical paraplegia. He recovered sufficiently to leave the hospital two days later. The history of this case developed that he had been treated for the same condition on numerous other occasions following falls from the cars or railroad tracks and once from shaking the grates in an engine.

CASE 12. Mrs. N. C. House injured February 1910. Claimed that a sudden top of a train threw her back against a set and injured the back. She had severe pain in the back and down the right thigh. She was taken to the hospital in a

negative. She was examined by a neurologist, who found nystagmus, exaggerated reflexes, ankle clonus, and loss of corneal and pharyngeal reflexes. Diagnosis: traumatic neurosis of hysteroid type.

CASE 1. A. E. L. merchant, age 35, injured February 2, 1903. Claimed to have been lying in berth when sudden stop of train threw him up against head of berth, causing contusion of head and sprain of muscles of neck. A neurologist in Cleveland who examined him the day of the injury found no motor or sensory disturbances, no inco-ordination, normal reflexes, and no objective signs of injury. The man stated he felt all right until some hours after the injury. Subsequently he was examined by seven or eight prominent surgeons and neurologists on account of pain in the neck and the usual nervous symptoms found in a traumatic neurosis. In all cases the diagnosis was the same. This man was still complaining for more than a year following injury.

Fall cases. **CASE.** O. W. helper injured September 20, 1909, by falling into a pit. Was

picked up unconscious. He sustained a severe contusion of the spine over the upper dorsal region. Confined to hospital up to October 22. A report under date of November 1 stated that the man walked well with use of a cane for two weeks after he left the hospital, then began using crutches and complained very much of pain in the back. The case was settled shortly afterward and four days later the man discarded his crutches and desired to resume work.

CASE 3. T. E. L. conductor, age 43, injured April, 1903, through fall from the top of a car to the ground. He complained of pain in lumbar region, but no mark of injury was found on examination. He consulted several different physicians about his back but on May 1 was examined by a neurologist, who stated that the man was either a poorly instructed malingerer or he might have a traumatic neurosis with marked exaggeration of signs and symptoms. This case was settled, and immediately after the man went on a drunk lasting three days.

ABDOMINAL PREGNANCY

B. BETHEL SOLOMONS, M.D., F.R.C.P. (LOND.), L.R.S. (LOND.)

Gynaecologist to Women's Hospital, Examinator, Mother and Child Hospital.

ABDOMINAL pregnancy which may be defined as the development and growth of the foetus in the abdominal cavity may be either primary or secondary. The fact that primary abdominal pregnancy may occur is denied by some authorities although Parvin (1) gives Kleinwachter's explanations of its occurrence as follows:

1. The ovic sac may rupture so far from the ampulla that the current caused by the movement of the cilia cannot carry the ovule into the tube.

2. A temporary abnormal position or movement of the abdominal organs may obstruct the passage of the ovum.

3. The end of the tube may be completely closed in consequence of former inflammation, and the ovule be impregnated by semen coming through the other tube.

4. The tubal orifice may be so narrow that while permitting spermatozoa to pass, the ovule enlarged by impregnation cannot pass.

5. The tube may have lost its cilia from disease and the current fall so that the ovule is not carried to the tube.

6. Old exudations or pseudomembranes may either obstruct the orifice of the tube, or be in the way of the ovule reaching the orifice.

7. Abdominal pregnancy may occur when both tubes are normal. The ovule impregnated at one tube may pass out into the abdominal cavity and then cross to the other tube but the latter will not admit it because meantime the ovum has become too large.

This last is certainly a most ingenious explanation. The condition may also arise from an ovum escaping through the scar following a caesarean operation or through the fistula in the cicatrix of a cervix remaining after the performance of subtotal hysterectomy. With all these possible explanations it seems difficult to exclude the occurrence of a primary abdominal pregnancy. There are very few definite cases reported. Among them those of Béhier (2) and Calloway (3) bear close investigation. Many experimenters on animals prove from their experiences that primary abdominal pregnancy is to be considered a very possible occurrence. Blair Bell (4) concludes that because it is common in a rabbit

anesthetic, I asked Dr. Glenn, consulting gynecologist to the hospital, to see the case with me. He agreed it was impossible to diagnose definitely that there was some marked abnormality and that the best policy was to open the abdomen.

To touch on these diagnostic points of the case in comparison with those points which I was able to gather from my study of the subject.

- 1 Sensitiveness was present though not extreme.
- Intermittent contractions were not noticeable. This does not seem to be a very distinguishable sign for while these contractions are valuable diagnostic points when present their absence does not contraindicate pregnancy.
- 3 There was marked irregularity of outline.
- 4 The child was not directly under the skin.
- 5 Heart-sounds were not directly under ear.
- 6 Retroversion was present.

On January 8 I opened the abdomen by a medial incision from the symphysis to 6 inches above the umbilicus. A tumor hemorrhagic in appearance stretching a little beyond the umbilicus was seen. In separating the adhesions of the tumor which were numerous and were chiefly to the intestines, omentum, posterior pelvic wall and uterus, in the left iliac region the finger entered the sac and a fresh fetal foot was extruded. There was some old blood on the right side and there was much fresh hemorrhage from the separated parts of the sac. It was necessary to remove and dissect off omentum in several places while the rectum for two or three inches required overlying where the placenta was removed. There were several pieces of tissue removed during the operation which consisted possibly of some kind of sac. While the operation was in progress the patient was given saline subcutaneous pituitary extract 2 cc., strychnine sulphate, gr. 1/3 etc. When the fetus and placenta had been removed it was apparent that the right tube had been taken away from the mass. The uterus left tube and both ovaries were left *situ*. The diagnostic difficulty was here made apparent for the uterus lying retroverted without retroflexion was practically imbedded in the mass which filled the pelvis. It was impossible to investigate further for the patient was much blanched, was pulseless, the period of the operation and it was necessary to close the abdomen as quickly as possible and to get the woman to bed where continuous rectal saline and other usual restorative measures were carried out. On the sixth day cystitis developed which persisted for seven days. On the fourteenth day she passed per rectum a wash leatherlike piece of material which Dr. Wigham reported to be cast of the rectum. This phenomenon was marked proof of the irritation to which the bowels had been subjected. The long abdominal wound healed by first intention and she was discharged from the hospital in good health on the twenty-sixth day.

The history of the treatment of abdominal pregnancy is interesting. Firstly there were

the days when the condition was always found post mortem. Next when treatment was postponed until after the death of the child (19) or when the child was removed and the placenta left (20, 21, 22). In those days gynecologists were vying with each other to find the best infanticide. Barnes (23) injected into the sac atropine and strychnine. Friedrich (24) morphine while Thomas, (25) and many others were using the electric current. Barnes inoculated the mother with syphilis to kill the child. Generally speaking the results of these measures were disappointing.

The pathological report does not throw much light on the subject. The specimen consisted of a 5 to 6 months fresh fetus and placenta. On the maternal surface of the placenta is seen an area which on microscopic examination proved to be blood-clot and which probably is the place where it was implanted on the rectum. Sections from various sites showed nothing abnormal. A search was made for tubal tissue but none could be demonstrated. Much omentum was removed and a microscopic examination of portions of this failed to show the presence of decidua cells. Outerbridge (26) has proved that decidua like cells are found in the omentum in cases of intrauterine pregnancy. This has been noted by Schmorl (27), Kinoshita (28) and Shaviodskundis (29). They have also been found on the peritoneum covering the posterior surface of the uterus, the anterior wall of the rectum, in the appendix (30) in a parovarian cyst (31) and in the vagina (32). It is strange that in my case there was no decidua reaction in the omentum removed.

The most probable explanation of the case is as follows. That there was a very slight rupture of the tube at 2 to 3 months that the ovum remained attached partially to the tube and that as it grew the placenta attached itself to rectum, omentum, and posterior pelvic wall etc. that this caused irritation which predisposed to a connective tissue proliferation thus surrounding it with a vascular sac. The patient evidently sought Dr. Ryan's opinion shortly before the time I first saw her on account of the pain caused by the enveloping sac which was much stretched, this latter fact was clearly demonstrated during the

operation. If no operation had been performed what would have been the result? She might have progressed to full term. She might have shown symptoms of distress earlier. Cases are on record where the dead foetus has been carried for many years in the abdomen. Heskell (13) reports a case of 40 years duration. In the present case it seems most probable that hemorrhage or other dangerous symptoms would have appeared soon.

The following are important points in connection with abdominal pregnancy.

1. The fact that the cause of abdominal pregnancy has not been definitely established.

2. The extreme difficulty in definite diagnosis.

3. From a review of the literature and of my own case (though not wishing to argue from one experience) the rational treatment seems to be to remove foetus and placenta and to stop the hemorrhage. This hemorrhage can be stopped therefore it is bad policy to leave the placenta *in situ*.

RHABDOMYOMA OF THE PROSTATE

B. J. HENTLEY SQUIER AND F. A. C. S. NEW YORK.

(The or (Depo rth u d l obay N York Post G dca 11 April 1

THE number of reported cases of carcinoma of the prostate gland which have been microscopically examined and well authenticated is very few and the number of rhabdomyomata fewer.

With reference to rhabdomyomata Kaufmann recorded three cases only. It is possible however that some of the spindle cell sarcomata of the prostate may be more properly classified under rhabdomyosarcomata but this can never be proved except by re-examination of the pathological material of the old reported cases—a condition now impossible to meet. It is certain however that rhabdomyomata are most frequently found in

and about the urogenital system as for example in Wollenberger's collection while there are no cases reported as from the prostate yet out of 63 cases of rhabdomyoma 38 involved the urogenital system.

KAUFMANN CASE 1. A child nine months of age had symptoms of bladder trouble with partial retention and pain for six weeks. He died in the hospital without operation. At post mortem an oval tumor was found occupying the region of the prostate. It measured 5x5x4 cm. The surface was smooth and covered by a fibrous true capsule. Neither the ureter nor the seminal vesicles were involved in the growth but there was a right testicular hydropneumosis and a left testicular pyelonephritis. The wall of the bladder was thick and irregularly

Fig. Embryonic type of muscle-fibers.

Fig. Muscle fibers from fetus of 10 months, showing low resemblance of the fetal fiber to the irregular fibers in Fig. 1.

The tumor was almost completely extra-canal, the lumen of the rectum being nearly closed by the tumor. There were no metastases either in other organs or in the lymph-nodes of the neighborhood. On section, the tumor was found to be firm, hard and divided into irregular areas by bands of connective tissue. On microscopical examination the tumor gave the impression under low powers, at least of spindle-cell sarcoma but more careful examination of the individual cell-forms under higher powers showed that in many cases the spindle-shaped cells which resembled those of sarcoma were in reality more or less rudimentary muscle

Fig. Longitudinal section of striated fibers more highly developed than those in Fig. 1.

fibers. In some of these fibers rows of striations could be easily made out. The muscle fibers of most parts of the tumor assumed bizarre shapes, the clubbed ends and numerous fibers some of which being almost peripheral others draw out into long tapering strands of ellipsoid form. Some of the longer fibers had rows of small pink granules arranged in a regular space the portion of the cell and the long terminal sprout which give striations. It was, however, many cases difficult to differentiate among the muscle fibers from connective tissue of similar size when the difficulty in differentiating this tumor from sarcoma. Kaufman thinks it probable that this tumor should be classified with the rhabdomyosarcomas because of the large number of cells which could not be definitely determined as muscle fibers though the tumor did not involve the surrounding true rectum and other enteric metastases.

CASE. The patient, a 9-year-old boy, the history of urinary retention was found to have a very large tumor of the bladder which projected into the vesical encephalon and also into the rectum. He died of suppuration of the bladder with bilateral pyelonephritis. At autopsy the growth was found to be the size of a fist. It involved the prostatic region as well as the seminal vesicles and the vasa deferentia. Although of this large size it was still movable through the pelvis. The chief portion of the tumor projected widely over the anterior portion of the bladder and projected into the lumen of this organ in regular lobules from the ureters were also involved especially the right. On cross-section the tumor was soft, smooth, in some places jelly-like and was histologically a sarcoma. Microscopical examination showed in some areas soft myxomatous tissue

FIG. 4. Field of spindle cells with poorly developed muscle fibers.

FIG. 5. More mature part of tumor.

ther also normal structures containing numerous spindle cells and a moderate number of fields in which poorly developed muscle fibers with cross-striation could be demonstrated. Because of the large number of spindle cells this tumor must be called a rhabdomyosarcoma although no metastases were found in any of the litterer organs or in the lymph nodes.

The third patient was a 20-year-old man suffering from pain in the perineum and without urinary symptoms. The tumor was evidently malignant. It involved not only the bladder and the prostatic region but also the wall of the pelvis and metastases were found in the left lungs, pleura, the muscular membrane of the stomach, the thyroid gland, the external and internal ureters of the dura. There were numerous metastases scattered throughout the bones. The tumor in the lung and dura were lined. The microscopic examination of the tumor showed a massive cellular mass in which could be found bundles of embryonal muscle fibers showing all the characteristics of striated muscle. The tumor was however much more cellular than those previously described. In the metastases especially in the dura mater the embryonal cellular growth will be found with a characteristic of muscle cells in the primary growth. The presence of numerous metastases, pleural effusion, metastasis in the lungs, the primary tumor and the presence in the lumen of the tumor. The region of the striated muscle tissue in the congenital rhabdomyosarcoma of the perineum due to the group must be laid to an embryonal epithelial metastasis from the epithelium arising from the pharyngeal muscle with the mouth. The epithelial tissue must therefore not be considered as a primary epithelial tumor.

The case which I desire to add to the already reported presented the following history:

The patient a male 40 year of age was examined in September 1915. He was tall, athletic, palely nourished but in excellent general condition. For a period of three months he had suffered from a painful hematuria. The blood would appear with the last portion of the urine voided. With certainty of urination blood was absent but at some time every day it would be present. Increased urinary frequency existed. His health had been excellent and he had had no serious illness at any previous time in his life. Physical examination of the heart, lungs and abdomen was negative.

Local examination of the prostate by rectal palpation revealed a smooth, symmetrically enlarged gland of almost flinty hardness. It felt about as large as a hen egg and no periprostatic infiltration could be appreciated. Cystoscopic examination showed marked trabeculation of the bladder wall. The prostatic urethra was injected and bled from instrumental trauma. There was no intravesical prostatic projection and no residual urine. The urine was negative except for the presence of blood.

The diagnosis was made of early prostatic neoplasia and operation advised. This the patient accepted.

On September 11, 1915, under general anesthesia a radical extirpation of prostatic bladder neck and seminal vesicles was performed.

The prostate was exposed through the perineal incision. After division of the muscularous urethra, close to the apex of the prostate the prostatic neck and neck of the bladder was pulled down and amputation of the esophagus in the pelvic region to the prostate. The seminal vesicles were removed.

en masse with the prostate ligation of their blood supply and vasa being first accomplished.

An anastomosis was then made between the urethra and the neck of the bladder by approximation over an indwelling urethral catheter. Closure of the wound, with gauze dressed down to the urethro-vesical anastomosis, completed the operation.

The specimen removed was about the size of an egg. It had been removed easily and nowhere seemed adherent to surrounding structures. The growth was localized within the lateral lobes and did not seem to involve the urethral port on the gland or to have extended outside of the capsule.

The patient's convalescence from operation was most satisfactory. The indwelling catheter drained the bladder for four days, when it was removed.

The perineal wound healed well; the gauze drains were removed the fifth day. After removal of the indwelling catheter urine was voided through the perineal wound as well as urethra but by the thirteenth day the perineal wound was tight and the patient had no urinary incontinence. He left the hospital on the twenty-second day after operation.

The material removed to operation was submitted for study to the Pathological Department of the Post Graduate Hospital, to Dr. F. E. Wenden and to Dr. F. C. Wood. The diagnosis received from all was rhabdomyosarcoma.

The examination of the gross tissues showed irregular fragments of ragged outline measuring about 7.5 x 5 x 5 cm. A portion of the mass was smoothly encapsulated and the thus encapsulated part were attached remnants of the seminal vesicles. The hardened tumor as reconstructed was flattened oval mass, smooth white and firm on section. In some areas dilated prostatic gland tubules filled with yellowish material could be made out. A few dark colored areas showed hemorrhage at the time.

The microscopic examination showed three different structures.

A very glandular somewhat inflamed prostatic tissue the myeloid bodies were scanty and some of the lveoli contained pus-cells.

Dense fibrous tissue and glandular structures commingled with fibrous tissue, smooth muscle fibers, and large numbers of striated muscle fibers, some very large long and branching others irregular in shape with numerous nuclei some club-shaped fibers also were present. The fibers showed all the peculiar morphological appearances of the striated muscle-fibers seen in rhabdomyosarcoma of the testicle and in the striated muscle of the foetus (Fig. 2 and 3). Cross sections of the fibers showed the usual circular or oval outline with a large nucleus in the spot in the middle of the fiber. Transverse striation of the muscle were so well marked in many places that there could be no question as to the nature of the fibers (Fig. 4). In some areas of this portion of the tumor there was in addition to the glands and the striated muscle fibers a small amount of spindle-cell tissue, looking like newly formed or embryonic cell-tissue but not sufficiently characteristic to permit of the diagnosis of sarcoma.

In the portions of the tumor there was third variety of tissue—pure spindle-cell sarcoma with very little oligogenous material between the cells, the nuclei of which were large rich in chromatin and showed mitoses (Fig. 5).

Thomas W. has here glandular hyperplasia of the prostate with the development of rhabdomyosarcoma.

The subsequent course of the case follows.

He remained in the hospital for some time, received all X-ray treatments were instituted after operation as possible and against recurrence six weeks after operation irradiation could be appreciated by rectal examination. Two months after operation recurrence of the disease appeared in the perineal area and pelvic region but the return became distant and then the disease has rapidly tended to the next stage approaching

EVENTRATION OF THE DIAPHRAGM AND DEXTROCARDIA

WITH A CASE REPORT

B. H. C. WOOD, M.D. (CHICAGO, ILL.)

A CASE of diaphragmatic eventration and associated dextrocardia has recently come to my notice. This condition I feel of sufficient rarity to make its publication desirable.

Apparently eventration was first described and named by J. L. Petit when he reported a case in 1790. This term has been in com-

mon use ever since. In 1913 in his paper on

Diaphragmatic Hernia (1) Dr. H. Z. Giffin pointed out the fact that the term eventration would apply equally well or even better to a true diaphragmatic hernia in the commonly accepted sense. By reason of its common acceptance however the term eventration has been continued in this article. In sup-

Fig. 1. Skiaogram, lateral view of patient p on 4. H rt had in right thorax. B left half of diaphragm rising to the level of the third rib.

Fig. 2. Skiaogram, posterior view of patient p with buttock elevated and head down. H rt had in right thorax. B left half of diaphragm. In (C) with (D) fat mass (C) which is filled with barium (D) and the gas bubble (E) in the posterior portion.

port of Petit's nomenclature it may be stated that he believed the case he reported to be one form of true diaphragmatic hernia.

In the recent English literature on the subject the most extensive article is one by Sailer and Rhein (2) and to this paper I am indebted for most of the cases mentioned. Since 1900 the *Index Medicus* lists only a short brief of an article by Dr. Hermann Fisher (3) under the title "Relaxation of the Diaphragm." He reported a case.

The history of the case I report is as follows.

Patient is a female, 8 years of age. Family history unimportant. Personal history. At age 8 years the patient fell from second story and struck in sitting posture. No serious result was noted at the time. Three years ago she had typhoid fever. Menstruation normal. She had had several paroxysms of nasal obstruction.

(Check up list: 1) Dyspepsia (2) epigastric pain (3) abdominal bloating and belching (4) palpitation (5) cyanosis.

History. The patient left school in 1924. She has worked in a garage but has never been in the hospital with her condition. Symptoms.

but for at least ten years has been bothered by an upward pressure in chest, especially if she ran or walked up hill. She felt as though her heart was pressed upon and asked after the examination if her heart was not on the right side. She said she always thought it was. She cannot remember whether these symptoms were present before injury or not. She has never been very strong but was always able to indulge in the usual recreations of her friends and the symptoms at present complained of have appeared or have been aggravated within the last year.

She has been very nervous for a year and during this period of time has had much soreness in the epigastrium with abdominal bloating also gas belching which relieves these symptoms. She craves sour food and acids which cause no distress heavy and greasy food aggravates the symptoms (to 3 hours postprandial) and (4) better in very light diet but no food seemed to occasionally help. Nausea and flatulence common. The above symptoms were intermittent until the past month. Also intermittent cyanosis several weeks and palpitation very noticeably only palpitation noticed in very palpable when the cyanotic symptoms are present. These are aggravated by a

heartily meal and also when she lies down. The patient eats very rapidly and is always hungry but does not bulge. Her weight is about normal. There is soreness across lower abdomen when she menstruates. The bowels are regular. She has occasional frequency of micturition (octurnal, 3 times) but never pain. *Phys. Exam. g.* Height 5 feet 4 inches, weight 90.5 pounds (normal). Nutrit. fair. Systolic blood pressure 88, diastolic blood pressure 74, pulse 86, temperature 98.8, hemoglobin, 77 per cent. Urinary findings negative. *Inspection.* Expansion equal, precordial impulse perceptible at the fourth interspace at right margin of sternum. Slight lateral scoliosis. *Pericardium.* Cardia dullness. Left margin of sternum at point 5 in to right of 4. Left supraclavicular and infraclavicular region anteriorly slightly hyperresonant, not tympany over precordial area at level of third interspace. *Respiration.* Breath sounds over left upper lobe higher pitched than on right. Gurgling heard at tympanic area at base of both lungs. Heart sounds normal. Heard most clearly to right of sternum. *Radiography.* *Roentgenogram* showed eventration of diaphragm and dextrocardia (see radiograph).

In all about 500 cases of hernia and eventration have been reported but Fischer was able to find only twenty-three of eventration and Sailer and Rhein in 1903 could collect only twelve definite cases besides their own though there were several discarded because of insufficient data.

We may safely assume that the condition is very much less common than diaphragmatic hernia with which it is most apt to be confused. Fischer defined eventration as a thinning out and fatty degeneration of the muscular fibers of the diaphragm and bulging upward of the same to the level of the second or third rib. Sailer and Rhein define it as an abnormally high position of the left half of the diaphragm with dislocation upward of the abdominal viscera especially of the stomach with hypoplasia of the left lung and dislocation of the heart to the right.

The etiology is uncertain.

1. Some writers consider it as a true hernia.
2. Others believe that it is secondary to hypoplasia of the lung.
3. It is considered also the result of dextrocardia.
4. Some think it is due to a primary congenital defect of the diaphragm.
5. Again, it is regarded as a result of acquired lesions.

Of the 13 cases reported in 1905, 1 was found in a foetus, one in a newborn baby, and 11 in patients ranging in age from 19 to 75 years of age. On these cases there were twelve post mortems and one patient was still living. Two of the cases died of peritonitis, one of pneumonia, 1 of typhoid and 1 of a carcinoma of the tongue. In at least 6 the condition was found accidentally at post mortem. Two cases were reported as dextrocardia. Apparently an abnormal condition of the diaphragm was suspected in only four or five.

The clinical symptoms were very irregular. One patient complained of asthmatic attacks, relieved by eating, one of vomiting and gastric disturbance and one had hematemesis and from the symptoms an incarcerated diaphragmatic hernia was suspected and an operation performed at which time an eventration was found.

I have also seen a case of intestinal fistula of the left thorax, in which the patient had been operated upon under the supposition that an empyema was being dealt with and instead of which there was a true diaphragmatic hernia.

One case is reported in which the symptoms appeared after pneumonia. In one case an adult male after a severe shock there was a sense of something giving way followed by cough, dyspnea and pain in left chest. At post mortem an eventration was found.

Fischer also mentions a case in which the condition seemed to develop following pneumonia and after a time cleared up. Here a diagnosis of paralysis of the left phrenic nerve was made. Sailer and Rhein believe it is the result of a hypoplasia of the left lung together with a hypoplasia of the left half of the diaphragm. The majority of cases are undoubtedly congenital and this hypothesis is true in many cases.

In some however that appear to be congenital in origin there is no hypoplasia of the left lung. In others, again there appears to be a definite association of eventration with an acute infection and in some cases there is found a diffuse fatty infiltration or a fatty degeneration of the muscular fibers of the diaphragm. In one of the cases mentioned and in the one I report, there seems

the aetiological relation to traumatic eventration. Undoubtedly the vast majority of cases are due to congenital defect of the diaphragm or to trauma, but both other conditions must be considered as it appears that acute infectious, traumatic and injury to the left phrenic nerve are occasionally etiologically factors.

The case here reported is of special interest as the clinical findings and the history of previous trauma would lead one to expect that it was dealing with a diaphragmatic hernia. In fact, with out the radiographic findings I did not believe that a diagnosis of eventration could be made. The chief difficulty is always in distinguishing between these two conditions. It is also stated that pneumothorax cavitation of left lower lobe and subdiaphragmatic pyoneumothorax must be differentiated. I did not feel that the latter condition is a much diagnostic difficulty.

A pyneumothorax should present characteristic physical findings and there would be bulging of the intercostal spaces and immobility of the left thorax while in eventration or hernia the respiratory movement appears normal.

It is not conceivable that cavitation of sufficient extent to be mistaken for eventration could exist with out a previous history and sufficient clinical evidence of pulmonary disease to make the diagnosis clear. Both of the above conditions could at once be positively diagnosed also by a radio-copic examination. Subdiaphragmatic pyoneumothorax is also stated to be a condition to be distinguished. I have seen one case as well as several of subdiaphragmatic abscess and in none of them was the possibility of eventration or hernia considered. These generally result from a rupture of diseased gall bladder or the perforation of a gastric or duodenal ulcer. They also are occasionally the result of infection following abdominal operation. The history of the case together with the clinical evidences of sepsis present should be sufficient to exclude eventration or hernia.

The condition that offers serious difficulty in differentiating from eventration is diaphragmatic hernia. These conditions may present identical clinical manifestations and

can be differentiated only by a careful roentgenoscopic examination. In many instances a radiogram or a fluoroscopic examination will satisfactorily differentiate the two, though occasionally a combination of the two methods is necessary. In the present instance the first plate is sufficient to clear the diagnosis. Occasionally however the air bubble in the upper part of the stomach leads to a false line appearing below it which has been mistaken for the diaphragm and because of this a mistaken diagnosis of hernia is made. This mistake can be avoided by filling the stomach with barium sulfate and taking a plate with the patient supine, the bubble elevated to fill the cardiac portion and to force the air bubble to the pyloric end. The same result can be attained by fluoroscopic examination after giving barium and palpating the abdomen so as to thoroughly fill the cardiac portion of the stomach.

Another important diagnostic point is the fact that in hernia there is fixation of the diaphragm and in eventration the respiratory excursion appears normal. This is best determined by the fluoroscope. In the present case there is normal mobility of the diaphragm. A lack of movement would also be found in eventration resulting from a phrenic paralysis and the association of an eventration with a fixed diaphragm would suggest the latter condition.

The extreme importance of differentiating between eventration and diaphragmatic hernia is due to the fact that hernia is a surgical condition and operation is followed by good results, while eventration is not so considered.

In this connection a point of much theoretical interest is: What would be the result of a plication of the diaphragm? Such an operation should be attended by no greater risk than the operation for hernia. The result would be dependent upon the ability of the diaphragm to withstand the increased abdominal pressure. It is possible of course that this would lead to a further stretching of its attachment and a recurrence of the condition. This point could possibly be cleared up by an experimental plication of the

diaphragm in dogs though it is questionable whether an experimental eventration could be produced by section of the phrenic nerve. Unless such an artificial eventration could be produced before plication the experimental proof would not be conclusive.

Many cases of eventration suffer little discomfort, and of course in such the risk of operation is not warranted. If however the condition is attended with sufficient symptoms to interfere seriously with the patient's physical well being I believe that a plication is a procedure to be seriously considered.

In conclusion it may be stated that—

1 Eventration is attended by no definite train of symptoms, and is in fact often symptomless, though it is probable that a careful investigation of a series of cases would show that they were all below par physically as in the case reported.

2 That it results from congenital defects in the left half of the diaphragm or the left lung or of both. That a small percentage of cases are undoubtedly the result of trauma, or follow acute infections, as a result of degeneration of the muscle fibers of the diaphragm or injury to the phrenic nerve.

3 That the physical findings are often identical with those of hernia, and a differential diagnosis can be made satisfactorily only by means of radioscopic examination though

a history of sudden onset of symptoms following injury is very suggestive of diaphragmatic hernia, rather than eventration.

4 That the most important and only uniform physical findings are heart dullness to the right of the sternum tympany on percussion and gurgling heard over the precordial area. These symptoms are the same in hernia and eventration.

5 Rupture with hernia of the diaphragm is undoubtedly much more common than eventration but it is probable that more cases of eventration are being overlooked than in the former condition because of lack of symptoms and also because of the fact that hernia is generally associated with severe trauma and severe physical disability which often ends in death and the condition is found at post mortem. In cases that do not die the resulting disability and history are more apt to direct attention to the condition present than in eventration.

6 The finding of dextrocardia should always call for a careful examination to exclude the possibility of eventration.

GANGLIONEUROMA

B. RICHARD J. BEHAN, M.D. PITTSBURGH

BECAUSE of its great rarity and the paucity of information in the English literature a brief review of the known facts concerning neuroma seems to be of value. Neuroma is seldom diagnosed before operation. This frequently is due to a lack of knowledge on the part of the surgeon as to the prevalence of this tumor. Perhaps if knowledge in regard to it were more general and slightly greater care were exercised in diagnosis, we would find the tumor to be much more common than is supposed.

At first, the peculiar white glistening encapsulated tumors found in close relation to the adrenals and the sympathetic nerve-cords were thought to be sarcomata by the American and English observers (Dalton, Pitt, Orr, Parker, Pepper, Amberg, Richards, Hutchinson, Tileston and Wohlbach). They were supposed by some to arise in the suprarenals. Kuster however found that the intercellular substance was fibrillary and did not stain the same as the intercellular substance of sarcoma but did give the same stain.

ing reaction a glia, so because of the peculiar
cigarettes similar to those found in glioma and
the characteristic staining reaction he grouped
the tumors as gliomata.

While most of the author agreed that the tumors were composed of nerve-tissue there was following the publication of Kutter's paper considerable discussion between European pathologists as to the origin of these tumors. Finally J. H. Wright settled the controversy by proving definitely that they were of sympathetic germ-cell origin. Wright called these tumor neuroblastomata. He accounted for their presence in various locations by the accepted teaching that nerve cells not differentiated have a tendency to wander out of the embryonic nervous system and form not only nerves and ganglia but also the components of the sympathetic nervous system.

However it was Lick and Bielschowsky who first prominently emphasized the close relationship between these tumors and sympathetic nerve elements. They named them sympathoblastomata or embryonic sympathetic gangliomata.

According to Poll this relationship of the tumors to the sympathetic may be diagrammatically shown in the following outline

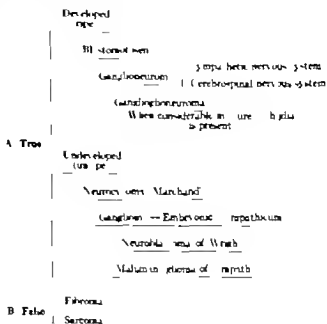

Tumors are known consisting of one or all types (except the phaeochromoblastoma) of the above cells. These tumors in turn are but a subdivision of that great class of tumors called neuromata.

Neuroma which is a general name for the entire class of the tumors under discussion is divided into (1) true and (2) false.

The true neuroma is derived from perineuritic nerve tissue and is the result of hyperplasia of ganglion cells or of the new formation of ganglia. The false is not a neuroma at all but is rather a sarcoma or a fibroma.

According to Pick and Biedschwsky a neuroma consist of nerve-cell originating either from the sympathetic nervous system or the cerebrospinal nerves and ganglia. When the glia tissue is in abundance it is spoken of as a glioneuroma. Under the latter are included (1) pure celled neuroectoma of the cerebro-spinal ganglia (Marchand) (2) ganglioma embryonic sympatheticum (3) large celled form of the area of the Tuberosen Hirn-kerosa (4) neurinome (Verocay)

The relationship of the different classes of nerve-element tumor is shown in the accompanying diagram.

The first ganglioneuroma was described by Loretz in 1890. It occurred in an epileptic 33 years of age and was found on the left side of the second and third thoracic vertebra. It was an egg shaped smooth hard tumor which evidently arose from the sympathetic. On autopsy however no communication with the sympathetic was observed. It is probable that Loretz did not recognize the definite relationship of his tumor to the nerve elements although he described the tumor as consisting of two layers (a) the outer dense of connective tissue (b) the inner soft consisting of numerous ganglion cells partly separate and partly grouped.

In structure the ganglioneuroma is alveolar in type with septa of connective tissue

separating various sized masses of cells poor in protoplasm but containing nuclei rich in chromatin. In some cases these collections have a rosette form and the cells are separated by a fine fibril intercellular substance. This intercellular fibrillary substance as is shown by Pick has its origin in the cells, several of the fibrils having been traced to individual cells. The more the fibrils and the cells become differentiated the closer will be the resemblance to tumors of glia, and then of fully differentiated nerves the neurofibroma.

The following varieties of tumors have been described:

a. The sympathoblasten (Marchand and Hecht)

b. The group containing bundles of fine fibrils separating the cells (Lick Landau)

c. The combination of the fibril masses with ganglion cells and nerve fibers (Martius)

d. The ganglion cells with nerve-fibers.

If the intercellular substance is not markedly fibrillary then the tumor resembles a small round-celled sarcoma and so it frequently happens that the tumor in the neighborhood of the kidney which has little intercellular substance is mistaken for a sarcoma.

In the tumor mass, small cells similar to lymphocytes are seen in conjunction with very large cells. These small cells are (according to the views of Wright Landau Marchand etc.) the immature ganglion cells which later develop into the larger cells.

Vascularity. The tumor as a rule has but slight vascularity so that it may be removed with but slight bleeding.

Location. Ganglioneuromata seem especially frequent in the lumbar region where they originate from the embryonic cells of the suprarenal body. As is known the chromatin substance of this body is of sympathetic origin so that reasoning from analogy we would expect to find tumors of ganglion cells in locations where the ganglion cells are abundant and have a tendency to become highly differentiated and specialized. This we do. They are found originating from the sympathetic ganglia (Landau Pick) also from the sympathetic cords (Shilder Landau) in the coccygeal gland (Alexais Imbert)

According to Friedlrich ganglioneuromata are most numerous in the sympathetic cords and ganglia of the abdominal cavity. Next are the sympathetic ganglia and the medulla of the suprarenals.

They also have been found in the brain (Schminke Pick and Bielschowsky) in the cord (Pick) in the dura mater at the superior orbital fissure (Haenel) in the gasserian ganglion (Marchand and Rissel) in the retrobulbar part of the optic (Perko) in the capsule of the knee (Hagenbach).

Incidence. Ganglioneuroma is more frequent on the left side of the body than on the right 13 out of 16 cases. As a rule it is only a solitary tumor however in some instances metastases have occurred and in one case Henecke found more than 160 tumor nodules. In another case (Miller) metastases were found in the neighboring lymph glands and in another metastases were found in the liver (Jakobsthal).

Ganglioneuroma is more frequent in women than in men (63 per cent) and in the first 20 years of life. The following is a summary of the age in incidence:

t. years	8 cases
to 30 years	6 cases
30 t. 35 years	4 cases
35 t. 40 years	6 cases
40 t. 50 years	1 case
Over 50 years	4 cases
The oldest as 76 years (Weichselbaum) The youngest as 3 months (Busse and F. bra.)	

Symptoms. There are few if any clinical symptoms of ganglioneuroma the tumor being most frequently discovered on autopsy after the patient has died of some other disease. However in many instances the tumor mass has produced symptoms by pressure on the neighboring organs and nerve trunks. In one case (Williamson's) the tumor was located on the sacrum and caused dysmenorrhoea—at the same time the uterus was displaced and ante flexed. In a case of Busse the tumor filled the entire pelvis and reached to the margin of the ribs, so that involuntary passage of feces and urine occurred. Most of the tumor except a small piece under the ribs was removed. In five years there was no return. In the case of Braun the aorta was torn during the

Fig. 1 (left) Cross section of the tumor removed
Fig. 2 Cross section of the mass $\times 5$ magnified
Fig. 3 Cross section of the mass $\times 5$ magnified

Fig. 3 (right) Cross section of the mass $\times 5$
Both reinserted as masses of comparison with Fig.

removal of a large abdominal ganglioneuroma which was supplied by four large arteries from the aorta. The aorta was resected, the two ends united, and uneventful recovery ensued. In a case reported by Peters the tumor had pressed the kidney upward.

In the three cases in which post operative collapse occurred Celner believed that a sympathetic shock with a vessel paralysis had occurred with a consequent bleeding into the abdominal vein.

Especially characteristic of ganglioneuroma are the congenital origin, the occurrence in very early life, and the variation in malignancy. It generally occurs as a single tumor although multiple tumors have been described by Knuss, Kredel, Benek, and Risel.

Prognosis. As a rule there is little tendency to malignancy though Landau believes that the younger the individual the greater is this tendency. The malignancy seems to be reduced in those cases which show a great variety of cellular elements. The greater the tendency to infiltrate and the less the differentiation of the cell the greater is the malignancy. Metastases may occur in neighboring lymph glands or in the liver (Jakobsthal).

Treatment. The only treatment is free and complete removal. If the entire mass cannot be removed without danger to the patient as much as possible should be cut away. Cures sometimes follow such removals.

My case of ganglioneuroma was referred to me by Dr. H. The patient was a well nourished female

infant of 10 months. The chief complaint was a swelling in the left lumbar region which appeared six months previous and followed by erysipelas. The infant was otherwise normal.

The mass was seen to vary in position during respiration becoming more prominent during inspiration and less prominent during expiration. On palpation the mass was felt as a tumor about the size of a small apple could be pushed up under the ribs, and was not tender or elastic. On crying the mass was again pushed down. The vertebrae were apparently normal, no kyphosis or scoliosis and no tenderness. The abdomen apparently was normal.

Diagnostic remarks. From the history and physical findings it was extremely difficult to make a diagnosis. The most probable hypotheses were that the mass was either a lumbar abscess connected with the kidney or a tumor of the kidney itself. In view of the rarity of tumors in the adrenal or of the kidney (with the exception of the cystic degeneration) in children we naturally were inclined to think more of the possibility of an encapsulated abscess. Incision was made into the mass and only a very minute quantity of straw-colored fluid was removed. Examination disclosed some amorphous crystals. This result rendered rather more vague and indefinite the diagnostic conclusions so that the patient was finally referred for operation with the diagnosis of lumbar tumor probably connected with the kidney.

Operation. May 11, 1915. Ether anesthesia. Incision three inches long and parallel to an inch fourths inch from the last rib on the left side. Incision was made through the latissimus dorsi and subjacent fascia. A small nodular mass presented through an opening between the quadratus lumborum and the abdominal muscles. The peritoneal fold was attached to the anterior part of a presenting tumor. The growth was evidently immediately posterior to the peritoneum and its development had pulled the peritoneum down with it. After careful dis-

difficulty because of the dense adhesions, the mass was freed from the adjacent structures. It was touched rather loosely by an apparently fibrous band of tissue beneath the transverse process of the second lumbar vertebra. This adhesion was separated. Ligatures were required as there was but little bleeding. This mass as capsulated and was about two inches in diameter. Neither the kidney nor the spleen were palpable. The wound was closed by catgut approximation sutures, the skin by silkworm gut and gauze drainage was introduced.

On June 19, 1905 the patient was in good condition. On July 1st the drain was removed, there was a slight red thin discharge (retained blood). The wound discharged a thin serous fluid for about one month. At the present time the patient is perfectly healthy and is gaining in weight.

Through the kindness of Dr. Klotz of the Pathological Department of the University of Pittsburgh I am able to furnish the following report on the specimen submitted.

On macroscopical examination the specimen is seen to consist of a lobulated mass of tissue 5.4 x 5 cm. The specimen was flattened the surface being more or less lobulated and apparently covered by capsule. The opposite surface was clean cut by the knife and did not present the natural characteristics. The capsule was quite thin, the cut surface showed glistening grayish-pink structure in which a glassy looking central fibrous tissue existed at the periphery. The tissue showed a fine granular material between the fibrous tissue which further more showed small grayish specks or granules. The tissue did not appear very vascular nor was it friable.

On microscopical examination the sections of the tissue showed very interesting tumor. There was a great deal of fibrillar material which was pink staining and was arranged in tracts or columns. These tracts when closely examined showed many fibrils very closely arranged. In such tract only occasional small mononucleated cells were found. These cells had round nucleus, fair amount of protoplasm, and occasionally fibrils could be seen attached to them. The tracts of fibrils when cut in

cross section consisted of granular looking areas or fine tipping indicating the cross section of individual fibrils. In areas other than these tracts there was also a ground substance of pink staining fibrils, which however were scattered numerous cells of irregular shape and size. In general these cells were unusually large having one or more nuclei and clear homogenous protoplasm. Some of the largest cells contained twelve or more nuclei. Some of these cells were round others pear shaped, while still others were irregular. From the pointed protoplasm of the cell long processes could occasionally be made out. Some of these appeared to continue into fibrils.

Scattered among the cells were also seen homogenous hyaline bodies of circular contour. Here and there calcified masses were found in the stroma. By Mallory's method it was demonstrated that the connective tissue was relatively small in amount while an intricate staining of reddish staining fibrils could be seen in large quantities. The intimate association of large cells of the tumor mass with the numerous fibrils could also be demonstrated. There was no evidence of the presence of myelin sheaths about the fibrils. The diagnosis was ganglioneuroma.

THE APPLICATION OF THE BONE-CRAFT IN THE TREATMENT OF PARTIAL OR COMPLETE AVULSION OF THE ADOLESCENT TIBIAL TUBERCLE (COMMONLY REFERRED TO AS OS GOOD-SCHLATTER'S DISEASE)

A NEW OPERATION

B. ROBERT E. SOUL, M.D., FACS, NEW YORK

Address: 125 West 42d Street, Post Office Box 1111, New York City. Hospital: New York City Hospital, New York City. Hospital: St. Vincent's Hospital, New York City. Hospital: St. Vincent's Hospital, New York City.

THE object sought in the treatment of partial or complete avulsion of the adolescent tibial tubercle is the early encouragement to ankylosis of the fractured portion of the tubercle back to the tibia which I have accomplished by pinning the broken fragment of the beak directly to the tibia by a bone-graft pin. The simplicity of application, the great shortening of the usual necessary period of treatment, and the certainty of an early cure of the condition lead me to offer this method as one which has served me most satisfactorily.

This condition is always the result of trauma either by direct injury as in falling on or striking the tibial tubercle or by indirect violence through a sudden powerful contraction of the quadriceps muscle as might occur in the various athletic sports where a sudden and severe strain would be placed on the quadriceps muscle in an effort to maintain the leg in extension when it might be experienced in the all jumping, wrestling, etc. The condition is always found in adolescence but is not associated with the tibial beak and tibia hypertrophy. An injury simulating the laceration of the ligament will not if a direct rupture of the patella ligament which is rare. The fracture of the patella itself is more common. The lesion is sometimes mistaken for a dislocation of the tibia or a tubercular necrosis of the tibia.

The quadriceps muscle one of the most powerful of the body is attached to the tibia about the patella from which it runs a rough tendonous tubercle and passes into the strong band of the patella tendon joining the patella to the tibia in the form of a very strong band of tendonous fiber a portion of which fiber are attached

directly to the tubercle the praved out fibers being attached to the roughened bony ridges of the upper anterior surface of the tibia. Somewhat overlying the direct fibrous attachment of the patella ligament to the tibial tubercle is a bursa in and about whose walls pass some of the direct tendonous fiber of this patella ligament as they pass to their attachment to the tibial tubercle. As a sudden over strain to the quadriceps muscle is felt first by the direct patella ligament fiber these are the ones to become ruptured first or if their bone attachment is not sufficiently osified the portion of the patella ligament at the epiphysis of the tibia is partially or completely separated producing a partial or complete fracture of the tubercle.

Upon the degree and extent of the strain produced by the contraction of the quadriceps muscle depend the amount of the rupture of these fiber and the partial or complete avulsion of that portion of the ununited or partially injured beak of the epiphysis of the tibia. Where the strain has been sufficient only to break the attachment of the central or direct fiber the power of extension of the leg by the action of the quadriceps muscle may still be maintained through the unruptured lateral fasciculi of the patella tendon remaining attached to the tibia about the tubercle and the X-ray will show only a partial separation of the whole tubercle or the breaking out of only a small portion of it. But where the violence has been particularly severe a complete fracture and avulsion of the tubercle back upward take place severing the continuity not only of the attachment of the direct fiber of the patella tendon but also of its lateral strong praved out fiber.

The incomplete separation of the patella

Fig. Photograph of case before operation showing prominence over tibial tubercle break as the result of fracture.

tendon from its attachment is by far the most common and results only in partial disability to the limb. An important factor associated with this condition and one which would seem to be the chief cause of the pain and discomfort experienced in many of these in complete cases of avulsion lies in the traumatism to the bursa overlying the tubercle. This bursa I have found at operation enlarged and tensely distended with bursal fluid. Pressure over this tense bursa before opening always produces pain accompanied at times by a slight increase of local heat as is associated with bursitis. This tenderness lasts longer than would be experienced from the simple rupture of tendon fibers or the separation in continuity of a portion of the tubercle. Then again the local swelling is greater and persists longer than would be looked for in such a trauma. So it would seem from these findings that a low grade inflammation of this bursa is produced kept up by the attempted use of the limb until the fixation of the ruptured fibers is had the contraction of the quadriceps stopped or the ankylosis of the fractured tibial tubercle to the tibia completed.

The consensus of the findings in these cases as to recovery from the injury places the time from six months to two years. If the milder degree of damage has taken place and the diagnosis is made shortly after the injury a few weeks of local treatment suffices

such as fixing the leg in extension with strong compression over the tubercle by crossed adhesive strapping. In the most severe cases where partial or complete fracture of the tubercle has taken place and in cases of late diagnosis symptoms of pain tenderness and partial disability having persisted for several weeks or months, or in spite of local treatment then more radical measures should be resorted to.

There was referred to me the Post-Graduate Hospital case of boy T. C., 4 years of age, who previously had fallen, striking the left knee on a stone. Pain localized tenderness and swelling were the following the injury. No particular attention was given to the injury other than rest of the joint. The condition improved but was not entirely relieved. It was noted that there was a decided localized limp and tenderness on pressure which persisted. He was unable to kneel, the affected knee did not bear a limp in walking and I got up and he experienced pain and tenderness in the knee. He was unable to run with the freedom he had formerly and he stated the left leg seemed decidedly weaker than the right.

My examination in October of 1935 one year after the injury revealed the localized enlargement of the site of the tibial tubercle tenderness pressure weakness and discomfort in attempting voluntary strong extension of the leg slight limp in walking slight increase of local temperature perceptible no joint involvement. The X-ray showed the separation of portion of the beak of the tibial tubercle. As the local symptoms had persisted for so long time and as relief by the conventional methods heretofore adopted promised no speedy cure I decided to apply a new method that of pinning the injured beak of the tibia by means of a tenuous bone pin to stimulate osteogenesis and furnish medium through which earlier bony union of the beak of the tibia could take place and thereby strengthen the tibial tendon attachment which operation I performed in October of 1935.

A curved skin incision about the flexed knee was made and the flap of mediotomy exposing the bursa and tendons of the tibial tubercle. The bursa was found tense and distended and upon incision the bursal fluid escaped as if under pressure. The bursal walls showed increased thickness. Carrying the dissection through the bursa down through the tendinous structures the bone with a 2-inch drill attached to the electric motor hole was made about 3/4 inch deep penetrating through the broken beak into the tibia. Through skin in incision 1 1/2 inches long over the tibia internal to the tibia of the same leg bone trip one inch long was made out with the motor in saw separated 1/4 inch from one another and cut at each end by small motor circular saw to free the bone

Fig. 1. Roentgenogram of leg before operation. Noting tubercle the bent bone substance hanging between the tibia and the femur.

Fig. 2. Roentgenogram of leg after operation. Noting bone graft in position uniting the tubercle to the diaphysis of the tibia.

Operation. This strip of cortical bone was lifted out of the tibial surface by the aid of a thin osteotome and then run through the electric dowel shaper to form a peg $\frac{1}{8}$ inch in diameter to fit the hole previously drilled. The bone peg graft was driven into place and the ends cut off with the small motor saw flush with the bone surface. The skin wound was closed with plain catgut without drain-

age. No fixation dressings to the knee joint were employed. The wound healed by first intention and the patient was up on crutches in two weeks. In three weeks all tenderness on pressure was relieved and the patient was walking in six weeks with all symptoms relieved. The leg has regained its normal strength and usefulness and the patient remains entirely free from all symptoms.

CYLINDROMA OF THE TONGUE

WITH A REPORT OF TWO CASES

B. ROBERT H. BAKER, A. B. A. ARTHUR MICHU

Staff Assistant in Pathology, Pathological Laboratory, University of Michigan

CYLINDROMA characterized by hyaline formations of typical arrangement has been described in the text books as having the following clinical characteristics. It is located about the head especially about the orbit, the salivary glands, nose, antrum of Highmore, and the mucous membranes of the cheek and gums. Its growth is slow, recurrences are frequent, but there are no metastases. Except for some forms described that seem to include a distinctly sarcomatous element, the tumor seems to be relatively benign. Some confusion exists from the fact that some quite different tumor forms have displayed some of the same hyaline characteristics, and also because of the lack of agreement in denoting the term cylindroma and endothelioma.

Several cases that may be described under the title cylindroma have been discussed in the literature. In general the majority of observers have classed the growth as an endothelial form of connective tissue tumor. Some difference of opinion exists even on this point, some men choosing to explain the hyaline structure to be described later as a product of mature connective-tissue element. Others like Lubarsch (1) believe the form originates not from the endothelial but from the perithelial cells of the blood and lymph vessel. The most widely held opinion is however that the tumor is an overgrowth of endothelium lining lymph and blood vessel, and that the hyaline so generally described is either a degeneration product or a secretion product of these cells. This latter point has not been so widely discussed.

In 1911 Dr. Oberlin (2) in a concise and thorough review of the cylindroma question reported three cases from this laboratory, which he described as cylindromata. In that report she considered all the literature to date stating the prevailing theories of origin, development, and classification of the rela-

tively rare form. Two of the three cases which she reports came from the head with a history of 15 to 30 years growth. These she describes as endotheliomata. The third case from the uterus, of rapid growth, exhibits a mixed type with a sarcomatous element. In 1914 Baumgartner (3) in discussing *la pathogenie du cylindrome* takes this view that the cylindroma is a mixed tumor consisting of epithelial and mucoid elements existing side by side and with a predominance of the mucoid material. A further discussion of his views will be considered later in this report.

The especial interest attached to the two cases in hand is the fact that in all cases described in the literature to date none has been mentioned as coming from the tongue. Both tumors were received at the Pathological Laboratory of the University of Michigan within a period of less than two months and present nearly identical features.

Case 1 (4) must be discussed only in the light of its microscopic appearance as no history was obtainable. Case 2 (5) occurred in a woman age 30. Two years previous it began as a thickening on the right dorsum of the tongue. It grew slowly until about three months before removal at which time it became painful and grew more rapidly. No adenopathy occurred with the growth and it was removed entire with its capsule.

In the gross Case 1 appeared somewhat lobbed with a dimension of about eight millimeters in its two smaller diameters and twelve in its greatest dimension. Case 2 was somewhat larger and existed as a single mass. Neither of the tumors was received in fresh enough state to express the hyaline tubes as has been described by some authors. Both tumors gave the hyaline glassy appearance usually described in the section of such growths, the descriptive name cylindroma coming obviously from the appearance of the

hyaline cylinder and ball on section in the gross.

Microscopically the specimens present the following features. Enclosed within a thin but quite definite connective tissue capsule within the muscle of the tongue is to be seen the characteristic arrangement of curved and twisted hyaline strands which in serial section would form the cylinders and knob described in the gross. In some part of the tumor the hyaline patches are seen to include small nests and cords of cells which appear to be of the endothelial type—flat with rounded and ellipsoidal nuclei containing in some apparently the most recently formed cells a rather limited amount of chromatin material. These cells vary quite markedly in size averaging somewhat larger than the endothelial cells lining normal lymph spaces. The same type of cells is noticed in greater abundance arranged in nests and cords extending between the hyaline cylinders. The somewhat radial arrangement of these cells in reference to the hyaline cords is due I believe to contraction of the latter substance. A noteworthy feature is that the hyaline areas are almost exclusively bounded by these cells suggesting the origin of the hyaline. A much less conspicuous element is the mature connective tissue cell which with some small blood and lymph vessels serves to make up the rest of the tumor. Special staining by Kresyl-Echt-Violett gives no staining reaction for amyloid or mucin. Van Gieson stain gives the deep rose red reaction characteristic of connective-tissue hyaline to the non-cellular glassy material and no reaction for mucin is obtainable.

Under higher magnification certain quite distinct markings within the hyaline material suggest the outline of large flat cells from which the nucleus has degenerated. This conception is further substantiated by finding here and there a definite cell inclusion within the hyaline showing the complete cell outline but with the pale vacuolated and contracted pyknotic nucleus at one side. By careful search such cells are seen in all stages of disintegration even to the point where the nucleus has lost its contour and only a remnant of chromatin remains within

a cell boundary. The same cell may have an imperfect wall and may enclose what appears to be a beginning infiltration with the hyaline which I assume to be a secretion of this or other cell about it.

The connective tissue element in both the tumors at hand shows a marked hyaline degeneration but it is quite impossible to trace the relation of this tissue to the hyaline of the cord. The tumor however shows small blood vessels with markedly sclerotic walls while others farther removed from the hyaline cylinders are quite normal in appearance. One of these tumors presents a somewhat different picture *en masse* than the other a difference which I interpret as representing a younger stage of the growth of this peculiar tumor form.

In the first case one is struck by the profuse vascularity of the growth the conspicuous element being the large number of dilated lymph and blood capillaries and spaces. The ramification of the capillaries is easily made out as they stand out sharply often containing a line of red blood cells. The hyaline cords are not in this case so large or so definitely circumscribed as will be described in Case 2. The connective tissue element is much less conspicuous as they are so scattered among the lymph spaces and have not in this younger stage of the tumor undergone the same degree of sclerosis and hyaline change which is so much more evident in the second case as a result of the restriction of blood and lymph supply. One is impressed however by what seems to be a significant fact. In certain areas where the sections show most clearly the curling and branching of capillaries in a single plane one can see between the unbroken endothelium and the connective tissue which makes up the framework of the tumor small areas of the hyaline which from its very relation suggests that it is a secretion product of the endothelium. Where the mixing of this material is more marked one sees that the lumen of the spaces is correspondingly restricted until we have in some field the small cell inclusion referred to above. The peripheral distribution of hyaline I believe to be but a chance one in this field and one equally attractive

by the fact that the hyaline strands are definitely included within a single line of endothelium and contain no cell inclusions the hyaline substance here being quite certainly a secretion within the lumen of the capillaries.

In the second case one is struck by a more characteristic appearance of the hyaline tubes. Here we have the same cellular elements as described above but in somewhat altered proportion and arrangement of these. There are seen definite trabeculae of connective tissue to form a framework including capillaries of large caliber. Both these factors are markedly sclerotic. Within the enclosure of these trabeculae is seen the much twisted and whirl-like arrangement of the hyaline cords. The structure here is not essentially different from that in Case 1 but we notice a relative lack of connective tissue fibers and of capillaries and lymph spaces seen above. But here the hyaline cords are larger and do not show the earlier stages of cell degeneration. The distribution of hyaline too is generally one of secretion within the lumen as evidenced by the external lining which these cords show.

The interpretation to be made then from these observations is this:

1. That the tumors in question arise from abnormal proliferation of blood and lymph capillaries and spaces.

2. That the endothelial lining of these capillaries and spaces gives rise to a secretion of some material which gives the staining reaction of connective tissue hyaline.

3. That this hyaline substance receives a chance distribution centrally or peripherally to the secreting cells.

4. That the excessive proliferation of the vascular elements meeting the resistance of the former connective tissue framework and of the increasing resistance of the hyaline material tends to assume a much twisted curling convoluted structure.

5. That the increasing tension within these convolutions from proliferation and excessive hyaline formation causes first a shutting off of the vascular supply to the tissue and ultimate necrosis of the endothelial cells and tends also to restrict the nutrition of the connective tissue elements with resulting sclerosis and hyaline degeneration.

That the tumors are not of connective tissue origin I think is proved in that they quite clearly are associated with endothelial structures and in all stages show no relation to the connective tissue elements they enclose. Any degeneration of connective-tissue stroma which may be demonstrable in these tumors, I believe to be but secondary to a primary change in the endothelium in contradistinction to the view of Ewetsky (6).

That the hyaline secretion is not perithelial in origin as Lubarsch states I believe to be evidenced by the fact that these hyaline inclusions are seen to be within an endothelial boundary in the greater part of the growth.

Baumgartner following the view of Malassez thinks the cells composing the main part of this form to be epithelial. He further thinks these cells exist in conjunction with a mucoid substance. The preponderance of this latter element he explains as due to the greater vitality of the mucin over the epithelium. He further explains the growth as centrifugal in its course. That the cells are epithelial he attempts to prove by the fact that they do not seem to him to have any connection with the blood vessels. He describes them as being atypical in the center but showing the characteristics of cuboidal and columnar cells at the periphery of his sections. They do not show signs of being secretory so therefore he concludes that the mucoid substance is not a secretion of these cells nor is this substance a degeneration or a vegetative development of these cells. By staining reactions he is satisfied that the material is not myxomatous but true epithelial mucin in nature. In a review of 400 cases described as cylindroma he chooses 83 as true to the type. Seventy four of these are described from the head, three from the sacral region. He explains the presence of mucoid tissue as an embryonic remains similar to the vitreous of the eye and cites the existence of 23 cases from the orbit to substantiate this relation. The description of cylindroma like areas in teratoids lends further weight to his theory of the embryonic origin of this substance. That the epithelial relation of the cells in these tumors is not valid I can only combat with the evidence which I have offered.

Fig. 1. Cylindroma of the tongue (low power) showing the relation of secretory tissue stroma to the basal cell cords and the hyaline tubes. (Note basal keratin.)

Fig. 2. Cylindroma of the tongue (high power) showing the relation of secretory tissue stroma to the basal cells and hyaline tubes and the intimate relation of the basal cell cords to the endothelium of capillaries and lymph spaces.

Moreover following the analogy of this mucoid substance with the vitreous we must look for a cell matrix which will be the origin of this mucin just as the vitreous takes its origin in the epithelium of the posterior zone of the ciliary body. That the substance is not mucin is certain in these two cases and that it is a secretion of the cells seems a logical conclusion though the secretory power of these cells cannot be proved. The underlying idea of Baumgartner and others that these tumors are possibly embryonic in origin and assume a development during extra uterine life is a conception which seems quite tenable.

That the cylindroma may be described fully as a tumor entity I believe is justifiable because of the fact that several of the cases described under this title have shown no clinical or pathological relation to either carcinomata, sarcomata or enchondromata as believed to be the case by Foerster (7), R. Volkmann (8) and R. Maier (9). A recent report by Richard Weil (10) of a parotid tumor which he has considered as an example of cylindroma gives evidence of the frequent mistaken identity of this tumor form. The

clinical history of his tumor might fall well within the limits of the cylindroma but his brief discussion of its histological nature and his photomicrograph certainly do not conform to the type of tumor I am describing as cylindroma. It is undoubtedly such degenerative forms of epitheliomata that have so complicated the exact classification of the cylindroma. Cylindroma is a descriptive term. But the cell of the cylindroma does not partake in character or arrangement of the features of the basal cell. Dr. Oberlin's Case 3 from the uterus is also an example of a malignant growth with degenerative areas of the nature of cylindroma. Such cases should I believe be called sarcoma cylindromatosum to express this resemblance to cylindroma. True cylindromata show few degenerative changes in some cases mucin being demonstrable. On the contrary they seem relatively benign and evidence microscopically only the arrangement and elements described above.

Fig. 3. Cylindroma of the tongue. The dense connective-tissue capsule above encloses the tumor and separating it from the tongue muscle.

The exact nature and origin of the cylindroma which will lead to its final classification among tumors must remain undecided. I believe, however, that the evidence submitted in my cases combined with that of similar reports points to a logical conclusion. In the belief that the endothelium may take part in the formation of sarcomata, the cylindroma should be considered as a variable form of sarcoma according to Borst (11). True cylindroma is not clinically or microscopically of the character of sarcoma, however. The tissue is not sarcomatous and not infiltrating but is sharply circumscribed by a connective-tissue capsule. If then we consider this form as essentially endotheliomatous, in what does it take its origin? From the cases of true cylindroma described in the literature we are struck by the benignity of the form. The clinical history usually is that of a slow growing nodule lasting over a period of years.

The one history which I submit may seem to indicate an exception to this statement. We cannot be certain, however, that the history of more rapid growth in the last three months is not due in this case to some degree of inflammatory infiltration due to the mechanical irritation of the tumor proper. Considering then the long history, the benignity and the simplicity of the tumor-element—a connective-tissue hyaline in a base of capillaries—it seems logical from pathological experience to consider this of the nature of angioma simplex or perhaps hypertrophicum. In the event cylindroma may be described as of embryological origin of a type of angioma assuming its clinical characters usually some time in adult life. The hyaline may be believed in this case to represent some sort of an attempt on the part of the body at a reparative process in the existing angioma.

Further evidence as to the duration of growth, location, clinical manifestations and microscopical characters in young forms alone can give this tumor its definite place in the classification of tumors. Until then it may quite logically be considered under the title of cylindroma, endothelioma, cylindromatosis or angioma, cylindromatosis.

I desire to express my gratitude to Drs. Warthin and Weller for valuable assistance and advice in making this report.

DEPARTMENT OF TECHNIQUE

FLUOROSCOPIC ROENTGEN INJECTION OF THE BLADDER

B. L. H. SKINNER, M.D., KANSAS CITY, MISSOURI

ROENTGENOGRAMS of the bladder filled with opaque emulsion of barium have been frequently reported. Such roentgen examinations are of great value in vesical diverticuli, intravesicular tumors, enlarged prostate, etc.

There are certain advantages to these roentgen examinations if the opaque injection is made under fluoroscopic control. It is extremely simple for the patient to lie upon the horizontal roentgen table with the fluoroscopic screen directly over the bladder area as the opaque emulsion is slowly injected into the bladder through a catheter by means of a large plunger syringe or by the gravity method.

The gradual enlargement of the opaque bladder half was witnessed fluoroscopically, the patient being turned from one side to the other in order to note the location of diverticula upon the posterior or anterior bladder wall. The transverse bladder half may be obtained also and is especially valuable in dilatation of the bladder anteriorly and upward or in cases suspicious of a patent urachus.

In the case herewith reported No. 6345, Mr. O'N. referred by Dr. Denlow, the provisional cystoscopic diagnosis was a diverticulum near the position of the left ureteral orifice which could not be entered with the cystoscope for visual exploration.

The patient lay upon the fluoroscopic roentgen table with the knees slightly flexed over a pillow. The catheter was inserted to the bladder and a large syringe filled with barium emulsion was attached to the catheter. The fluoroscopic screen was placed over the bladder area anteriorly and the roentgen tube focused underneath this area.

As the emulsion was gently forced into the bladder by the syringe the opaque shadow grew apace. After 16 ounces of opaque emulsion had been injected no diverticulum having been observed upon the lateral bladder wall, the patient was rotated to the right and left sides and still no diverticular shadow presented itself. Viewing the patient laterally, he noticed the

projection of the bladder anteriorly and lateral to the symphysis pubis with a serrated outline to the bladder wall but no diverticulum was apparent.

When the patient was returned to the original position upon his back, we noticed a large opaque shadow extending upward from the left superior portion of the bladder half in the usual position of the left ureter. This shadow had extended above the pelvic outline toward the left kidney (Fig. 1).

Röntgen negatives were then taken in several positions and this long shadow interpreted as a dilated left ureter. The opening in the bladder wall which was thought to be the mouth of a diverticulum was no doubt the enlarged orifice of the dilated left ureter.

Fig. 1. Showing opaque shadow extending upward from left superior portion of bladder half in the usual position of the left ureter.

This method of fluoroscopic injection of the bladder is valuable in suspected diverticulosis because so frequently the diverticulum is behind the full bladder shadow and the best position for

radiography can be secured with the fluoroscope thus avoiding unnecessary delay or repetition of the bladder injection as when radiography alone is practiced.

B. D. JOSE EDUQUIL M. D., Philippine I. D.

Assistant Professor of Surgery, University of the Philippines

THE case I am presenting in this paper is not a new one it is however interesting on account of findings met with after the vaginal inc had been opened up. The case history is as follows:

CASE 3548. Perfecto (Mr.) male Filipino age 4 born in Iloilo City came to Philippine General Hospital on April 3, 1935. Complaint right-sided enlargement of scrotum. Habits, smoker 3 cigarettes per day. Family history unimportant. Past history Smallpox and dysentery. Had young occasional fever and cough also al solar bacera and edema of lower extremities fifteen years ago. No venereal disease.

Present illness. Began about fifteen years ago small, soft, fluctuating mass situated at the right side of the scrotum which gradually increased in size until it attained its present volume. This enlargement of the scrotum has never been accompanied the pain

tenderness. The patient never noticed the scrotum to get smaller on lying down, nor to get bigger on standing. Only at times when he is fairly ill developed and emaciated man as he lies in the bed and is able to be up and round, the swelling of importance on examination except the scrotal lesion.

Local examination. Right scrotum is about 15 cm. in size soft and fluctuating. It is oval shape and could be easily moved up and down. (The superficial epididymis prominent and enlarged.) The right testis could not be found. The left testis is apparently normal. On per vaginal touch could be listed above the level of the urethra. The mass seemed to be not entirely filled fluid.

Laboratory studies. Stool, uric acid, urine reaction, and sugar negative. Urinary leukocytes and bacteria few renal epithelial cells, leukocytes and mucus. April 10, 1935.

Operation. April 10, 1935. An incision about 6 cm. long on the anterior surface of the scrotum as made. A mass encountered not touching the stomach. Cum about

Fig. 1 Before operation.

Fig. 2 Before operation.

Fig. 3 After operation.

6 feet of jejunum and duodenum all plastered together. During manipulation one loop of intestine was incised. This a sutured ileum. The appendix was found to be lig and knotted and bound to the posterior surface of the caecum by adhesions. After separating all the adhesions and removing the appendix the entrapped viscera were reduced into the abdominal cavity. The redundant part of the sigmoid was cut off and the remaining trimmed and sutured. A few interrupted sutures were placed behind the testis to hold the edges of the sigmoid sac in position. A loop of the terminal abdominal ring was made to prevent future protrusion of the ileum. Abdominal incision in the scrotal area. The scrotal wall was closed by a separate drainage through a separate count opening.

The accompanying pictures (Figs 1 and 2) show the state of the scrotum of the patient soon after he was admitted to the Urological Service of the Philippine General Hospital Surgical Department. As is seen in these pictures the enlargement of the scrotum is so remarkable that it almost touches the inner and upper part of the knee joint. The veins are beautifully distended that they constitute a net work easily seen with the naked eye. The enlarged scrotum is distinctly fluctuating. The right groin is flat although a little bit more elevated than the left. In the inner aspect of the scrotum and upper part of the same just below the gland penis a small bulging is noticed which corresponds to the left testis. The right groin is also fluctuating although the fluctuation is not so distinct as that of the scrotum. Before the operation a diagnosis of hydrocele of the right testis with possible hydrocele of the cord had been made. An operation was advised and agreed upon.

On performing the operation the writer was surprised to encounter condition beyond expectation as are expressed in the post-operative diagnosis.

A BLADDER SUTURE

B. ALEXANDER HAMILTON PEACOCK, M.D. SEATTLE, WASHINGTON

ALL who have attempted surgery upon the bladder have had more or less difficulty in closing the viscus, either watertight or around a drainage tube.

The causes of this difficulty are (1) the distance it lies from the primary incision (skin); the bladder lying quite low in the pelvis especially in men who have a thick abdominal wall; (2) the fact that in all but cases of a hypertrophied and dilated viscus the bladder cannot be brought up to the initial wound as other pelvic organ can be; (3) that the bladder is a contractile organ and apparently shrinks into the size of a golf ball; and (4) that after the bladder has once been incised the incision is apt to develop into an uncontrollable tear due to the insertion of the speculum instruments, or the fingers of the operator and some bladders tear very, very easily. All these things contribute to making a closure of the bladder at times, slow tedious and embarrassing.

Anchor sutures. The most popular suture has been the preincision anchor suture, one on either side of the median line. They have been a great help serving chiefly as tractors and elevators of the edges of the bladder wound. However, they frequently tear themselves loose and are of doubtful aid in the final closure of the

bladder. To overcome these disadvantages the full wing suture has proved most satisfactory, as it is easy to insert, easy to tie and gives a perfectly tight wall.

Modified purse string bladder suture. A perineal fish hook needle is used as pictured in Fig. 1. Chromic catgut size No. 2 twenty-day absorption is the best suture material. After exposing the bladder retractors are inserted and the peritoneum pushed and rolled back off the upper side of the viscus. No matter whether large or small full or empty the dome of the bladder always shows itself. This is grasped at two points in the median line with toothed forceps. Then a purse string suture is started at the fundus down the right side then turned and run up the left side. It will be noticed that the stitch has a crenelated appearance as each new bite into the bladder wall falls into a different line the object being to avoid bringing all the strain and pull on muscle fibers of the same line and group. We aim at the same result with mattress sutures.

Fig. 1. A. Perineal fish-hook needle. dotted and dashed line crenelated purse-string suture.

Fig. 2. Suture tied around drainage tube. T drainage tube. B bladder. all drawn tight against drainage tube.

The bladder is now ready to puncture. After completing the intravesical work a drainage tube can be inserted or a retention catheter placed in the urethra and the suture drawn tight. A reinforcing suture can be used, but is quite unnecessary as the natural contraction of the muscles of the bladder wall further assist our purse string. A small cigarette drain can be used in the space of Retzius. This suture has been employed for simple drainage, exploration, calculus retrograde stricture operation, resections for papilloma and prostatectomy, all with uniform success and satisfaction.

I can recommend its use for the following reasons:

- 1 It is easy to insert
- 2 It stays in place and does not tear the bladder
- 3 It lessens bleeding from the large veins in the bladder wall
- 4 It saves much time in closing up the bladder
- 5 It makes a tight closure of the bladder possible insuring a drier wound and better drainage

PITUITRIN IN POST-ABORTION CURETTEMENT

By HENRY DAWSON FURNISS, M.D., F.A.C.S., NEW YORK

FOR the past year it has been my practice to give one cubic centimeter of pituitary extract hypodermatically before curetting for incomplete abortion.

The advantages in doing this are that it produces firm uterine contraction which makes the procedure almost bloodless and much more easily done. Because of this contraction the uterine cavity is small and the contracted walls present a resistance to the curette which makes their cleansing less difficult and, I believe, lessens the risk of uterine perforation.

The most favorable time to give the pituitrin is 15 minutes before the actual curettement is

begun. When the interval between the injection and curettement is less the resulting contraction has not been so pronounced and the result not so good. As yet I have not had any post-operative bleeding following the use of the pituitrin but realizing that such a possibility exists it is advisable to pack the uterus and vagina with iodoform gauze which is removed at the end of 24 hours. Should bleeding occur and be troublesome ergotole can be given hypodermatically.

With the use of pituitrin the blood loss is so much less and the curettement so much easier than without that I strongly advocate its general use.

TRANSACTIONS OF SOCIETIES

CHICAGO SURGICAL SOCIETY

REGULAR MEETING HILD MARCH 3 1906 WITH THE PRESIDENT DR. S. C. PLUMMER
IN THE CHAIR

DR. EDWARD H. OCHSNER read a paper entitled
The Bio-Chemistry of Topical Applications as
Applied to Surgery

DR. F. E. PIERCE read a paper entitled Trauma
of the Back and Spine (See p. 332)

DISCUSSION

DR. DANIEL N. EISENDRATH This is an exceedingly valuable paper to everyone of us especially to those who hold important railroad positions. We are indebted to Dr. Pierce for bringing to us his carefully edited list of cases. I believe that we owe it to these patients, both from the standpoint of a defendant corporation and that of a patient not a claimant for injuries, to be exceedingly thorough in our examination and not regard the patient as malingering. We are very apt to examine them hurriedly and pass them along as cases of sprained muscles, etc.

I have had occasion in the last two years to see a number of cases which were diagnosed as minor injuries, and yet the persistence of the symptoms caused me to make a most thorough examination. I wish to speak in this connection of fractures of the transverse processes of the lumbar vertebrae as being frequently overlooked, because we think that such things could hardly be possible from an injury of the back. A roentgenogram ought to be made of every one of these cases not only in the region complained of but of the entire spine, not only in an anteroposterior direction, but also possible in a lateral direction. Some of the cases of fracture of the ribs near the vertebral column are apt to be overlooked, and again there are cases of fractures of the fifth lumbar vertebra, crushing fractures, without any other symptoms than those of pain. There may be no symptoms on part of the spinal cord, hence it is almost impossible to diagnose them without a good roentgenogram.

Finally I would speak of a superficial method we have of examining some of these cases which of the histries reminded me of and that is injuries of the urinary tract. I had occasion about two years

ago to see a patient who had sustained an injury of the kind Dr. Pierce described, from lifting a heavy weight. The patient was from Grand Rapids, Michigan, and had passed from one practitioner to the other with a history of repeated colics. The colics were referred to one side and only by going into the history thoroughly did we find the colic started on one side of the back and radiated down the same as a typical ureteral colic. We made use of a method of diagnosis that I can warmly recommend to you and that is to make a pyelogram and in this case we found a stricture of the ureter an inch and a half below the pelvis of the kidney as the cause of this man's symptoms. Thinking there could be no connection between the injury of the back sustained by flexion or over extension of the back and injury of the ureter, we later proved by a pyelogram at operation that there was hydrocephalus secondary to the injury of the ureter. So I could make an urgent plea for a more thorough examination in these cases, utilizing every method before passing them along as sprains or possible cases of malingering.

DR. FRA. E. PIERCE (closing) I have nothing further of importance to add. I purposely omitted fractures because it is such a large field.

The importance of making a careful examination in these cases as emphasized by Dr. Eisenrath cannot be urged too strongly. I have had a number of cases in which the diagnosis was made of sprain where the X-ray has shown a fracture of the transverse process, or a fracture of an articular process which had caused pressure on the spinal nerves and symptoms which our examination could not bring out except through an examination of the X-ray plate. It is easy enough to make a superficial diagnosis and say it is this or that, but if we are going to do justice to the patient we should be absolutely unprejudiced and give him the benefit of the doubt, if there is a doubt as to the serious nature of his case.

DR. WILLIAM HENRY read a paper entitled
Epyloitis Following Herniotomy (See p. 97)

BOOK REVIEWS

A CRITIQUE OF NEW BOOKS IN SURGERY

BY MAJOR C SEFLIG MD S N L

ONE of the best book reviews I have ever read (written by Walter Lippman) did not even so much as mention any specific book by title. The reviewer suavely granted himself the license to select a volume only to consign it to oblivion by leaving it nameless; then he proceeded to use it as a text from which to preach a sermon on the meaningless mumble jumble of much of our present day politico-sociological literature. And after all why is it not legitimate to do just this very thing? Why not now and then regard a book as the expression of a tendency rather than as a concrete product to be measured and trimmed by the ordinary conventional standards?

At all events this is the spirit that moves me after reading two new volumes by Crie. Both these volumes are louned on the same material that has served as the basis for other books by Crie already reviewed in this department. In these earl er review we ha e expressed rather emphatic dissent both from Crie's philosophy and from his logic. Of course this is after all only a matter of judgment and someone has said wisely regarding judgment. Tis with our judgment as our watches none goes just alike, yet each believes his own. If Dr. Crie himself should take exception to our estimate of his philosophy and logic he surely can not cavil at our unqualified admiration of his tendency mirrored in these two latest and the two or three earlier volumes dealing with anoci association.

But before stating this tendency it would not be amiss to furnish a few descriptive words regarding the two volumes. *The Kinetic Drive* is a short monograph of seventy pages a reprint of the Wesley M. Carpenter lecture published a few months ago in the *Journal of the American Medical Association*. The main thesis is Crile's now well known doctrine that the body is a mass of potential energy and that the potential energy is converted into kinetic energy by various stimuli calling forth adaptive responses. After detailing this so-called kinetic mechanism Crile dilates upon the function of the adrenals and thyroids and then, under separate chapter heads, considers the control of the kinetic drive in kinetic diseases (Graves disease, cardiovascular disease, Bright's disease, and diabetes) and surgical methods of controlling

The Kamae Diet 1 Phosphorus and Control By George W. Cole M.D. Philadelphia and London W. H. Saunders Co. \$5.00
The Alkaline Diet 1 George W. Cole M.D. New York The Macmillan Co.

th Linetti has actually summarized *My
an Adaptive Mechanism* in a summary volume
of three hundred pages. I find the expan-
sion of the lecture that minutes actually in energy
transforming mechanism leaving the la-
th as do other mechanisms. A very little
introduction containing a few large prin-
ciples open to question if followed by a chapter
voted to man's adaptation to environment. Then
follows Part II of the book of 1 to 10. The
mechanisms of Adaptation and finally Part III
Biologic Interpretation of the phenomena of Health
and Disease.

More specific or detailed treatment is not called for since our aim is merely to point out in general what books of this sort are. And I think I may say just this that the man who writes them is thinking briskly along lines somewhat divergent from the current of his main life work. One would like to call them avocative books. They teach us the service of an avocation. Legitimate recreation might be taken to our characterization of such efforts as an avocation but certainly no workaday operating room or urgent library turns out such product. If for the sake of argument we were forced to admit that these two books are distinctly surgical and represent ultimately the opinion of a surgeon on surgical disease, I should say: Then let us have a few more just such volumes. These are days when men have to be forced to think and imagine and Cline furnishes the most impelling stimulus to this end. Finally even if I be constrained to view the books as pure surgery I shall counter with the statement that they represent the artistry of surgery as contrasted with the artistry of the usual book devoted to the more specifically technical subjects of surgery proper.

HERF is a book that speaks for itself and requires no comment from the reviewer regarding the tendency that it manifests. One may be pardoned for entertaining the suspicion that everything everywhere is tending toward war. Thus much I know that within the year I have had to rearrange my shelves several times in order to make room for new war surgery volumes.

It is a book in practically along the same lines
and after the same fashion as the volume by the
Surgeon General, Alfred J. H. R. C. S. in preface by
Sir Alfred E. Webb M.D. Phil. trop. Med. on "New & C.

Frenchman Delorme the English work by Makins the various contributors to the Oxford War Primers, and the treatise by the American La Garde. The difference lies in the fact that this, being the latest volume to appear presents the latest conclusions reached by the English surgeons.

For example the first chapter on The Bacteriology of Wounds in War summarizes very clearly Sir A. E. Wright's studies of wound infections and their treatment and Chapter II on The General Condition of the Wounded summarizes admirably the data of the various collecting and base hospitals. Chapter III on The Treatment of Wounds and Chapter IV on The Treatment of Wounds by Saline Solutions furnish about the only data that may be appropriated advantageously by the civil surgeon in his routine work. The remaining eleven chapters deal with surgery from the regional point of view and although of unusual interest hardly call for detailed comment, save to mention the salient fact that chest wounds are still handled along lines of the strictest conservatism in contrast with wounds of the abdomen which are being treated more and more radically (as regards early operation or exploration) in accordance with the rules that have been followed in civil practice.

There are several contributors to the little volume and they have done their work well. The book is built for the knapsack, and is built admirably for this purpose indeed.

A RECORD of accomplished purposes not easily incorporated in review of this latest product of Mr. Lane or better this joint production of Mr. Lane, Mr. MacCallan, and Mr. James, for the latter two gentlemen contribute chapters on Speech Training and Dental Treatment of Cleft Palate respectively. Judging from the title this book is ostensibly devoted to a consideration of the subjects Cleft Palate and Harelip. As a matter of fact the latter is quite ignored save for a table showing the frequent co-existence of the two conditions, which table in itself sufficiently warrants more than merely casual reference. After a lengthy introduction, Mr. Lane reveals his purpose by emphasizing the twofold point which really represent the sum and substance of the entire book. The first is that cleft palate operations are to be done very early and the second is that his method of operating by fashioning mucoperiosteal flaps is preferable to the simpler one of paring and co-opting the margins of the cleft.

In the light of illuminating experience surgeons very generally incline to accept the latter dictum as correct and concede to Mr. Lane well deserved credit for originating and popularizing so valuable an operation. They may well concur also in the first point to the extent of dividing operation before dentition interferes with the reflection of adequate mucoperiosteal flaps, and before the child acquires permanent speech defects as speech develops. But

it is possible that Mr. Lane presumes a bit in recommending operation upon the day of birth, or as soon thereafter as possible on this basis that the newly born child is always healthy (p. 34). It is well recognized that serious consequences may follow even the much simpler circumcision operation upon even slightly jaundiced babies.

A SHORT span of less than two decades has sufficed to place the problems of internal secretion into the very center of medical interest and to incite countless number of students to devote their energies to this fascinating subject. Virchow's cellular pathology once supreme and all-embracing no longer seems to stand on its former firm foundation and the camp of those who endeavor to establish the old humoral pathology on a new and scientific basis is daily growing larger. That which was once an unconditional defect is, to say the least, premature at the present day will hardly be denied by the majority of medical workers. Yet, the accumulated mass of clinical and experimental evidence is so immense, and only exceeded by the number of more or less plausible theories that it has been extremely desirable to possess a critical summary of our present knowledge of the nature and significance of the glands with internal secretion. Out of this need was born Bledt's monograph work on the experimental physiology and pathology of the ductless glands. This was followed by an equally important treatise by Falt, which first appeared in German in 1913 and now appears in English translation.

Falt has set himself the task to consider the clinical aspects of the diseases of the ductless glands, and his deductions and conclusions are based upon an exhaustive study of the literature and an exceptionally large number of personal observations. The opening chapter is devoted to a general consideration of the normal and pathological physiology of the ductless glands, their reciprocal action, their interrelations to other organs and their influence upon the constitution of the entire organism. There follow nine chapters dealing separately with the diseases of the thyroid gland, cretinism, affections of the parathyroid glands, hypophysis, and epiphysis, lesions of the suprarenal apparatus, the status lymphaticus and hypoplasticus, and finally diseases of the sexual glands. The last named chapter comprises consideration of the interstitial glands and discussion of changes in the generative apparatus. This includes malformations, hypogenitalism (euchooidism), hypergenitalism, chlorosis, and osteomalacia. A short chapter is devoted to pluriglandular diseases, Infantism, dwarfism, rachitic chondrodystrophy and mongolism are united in a chapter on vegetative disturbances that do not depend directly on diseases of the ductless glands. In another chapter the diseases of the insular apparatus of the pancreas and their

F.R.C.S. 2d ed. London, Arnold & Son. 4.

relation to diabetes are treated and the final chapter deals with the different forms of obesity and adipositas dolorosa.

A comprehensive list of bibliographic references at the end of the book covering no less than 60 pages will prove of great advantage to anyone who wishes to study special subjects.

As can be seen from this brief survey of the table of contents the field of study is enormously large and Falta has endeavored to bring order into this existing chaos. His guiding principle has been this: that the diseases of the ductless glands altogether are due to quantitative alterations of the respective internal secretions, that is to say either an increase or a diminution of function. Such a classification which leaves qualitative disturbances of secretions or perverted functions of the glands entirely out of consideration is bound to create objections. Falta himself anticipates such opposition but he meets it by contending that the physiological chemistry of the internal secretions is still in its infancy. The author has endeavored to attack the difficult and complicated problem with strict objectivity. But in a field where our actual knowledge is still incomplete in spite of the imposing material collected there is a great temptation for theories for which the convincing experimental and clinical proofs are still lacking.

In medicine everything is in motion more so in this most modern branch of pathology than in other fields. Falta's book is not the last work; it is only a milestone in the development of the study of the internal secretions. The pathology of the hypophysis and the sexual glands, for instance, is only in its initial stage. The question of diabetes is still *sub judice* and the veil has hardly been drawn from the obscurity of the nature of the pluri-glandular diseases.

Yet the value of the book cannot be overestimated. The astounding erudition, industry and ingenuity of the author fill the reader with sincere respect. The work represents a permanent acquisition for medical literature for it will at times be an inspiring and fruitfulting stimulus upon other scholars to study the clinical aspects of the diseases of the ductless glands.

To have translated this work and to have put it within reach of English speaking students was a laborious undertaking of great merit. The publisher too deserves their fair appreciation. The translator has still further increased the value of the book by collecting recent American and English views in an addendum at the end of an already very chapter.

This is the second English edition and it seems more than likely both from the far reaching importance of the subject and the intrinsic merit of the book that a third edition will soon be needed. Under these circumstances the reviewer cannot refrain from expressing a friendly criticism as to the phraseology of the translation. Typographical errors and misspelled names of foreign authors will of course easily be corrected. The English titles sounds awkward. Disease of the Ductless Glands would seem preferable. More important to my mind is the all too faithful rendering of the German text. It seems unnecessary that the fact of its being a translation should be made so painfully obvious through an almost photographic reproduction of the involved German sentences and the *genius linguae* is often led off for instance the German *Krankheitsbild* appears better as a disease picture. Differentiation is surely superior to delimitation. A literal translation of *Lebersteine* should be excretory rather than upper length. A connection between two phenomena may be not clear or obscure but not unclear and it requires a thorough knowledge of the German language to discover that most misunderstandings merely mean gross misinterpretation. However such defects are not invariable and it may yet be in the power of the translator to make Falta's book an English classic.

A CORRECTION

VERE D. Frank Smithies has kindly called attention to the fact that in the review I have recently published in *Carcinoma of the Stomach* the error in stating that he did not mention the postprandial differentiation between pernicious anemia and pernicious anemia. The differentiation is given in Table of differential diagnosis in his *Textbook of Internal Medicine* (pp. 403-45).

THE CLINICAL CONGRESS OF SURGEONS IN PHILADELPHIA

It is quite apparent at this time that the limit of attendance for the Philadelphia meeting will be reached some weeks in advance of the date of the meeting so that those surgeons who wish to attend the meeting but who have not sent in their registrations are urged to make application immediately to the Secretary General Dr. Franklin H. Martin, 30 N. Michigan Ave., Chicago, Illinois. When the required number of registrations has been received no further applications can be accepted.

A careful survey of the operating amphitheatre, lecture rooms and laboratories of the several medical schools and hospitals in Philadelphia as to their capacity for accommodating visiting surgeons has been made and the limit of attendance based upon this survey. The popularity of these clinical meetings has become so great that the plan of limiting the attendance and requiring advance registration was decided upon to prevent overcrowding. This plan assures accommodations at the clinics for all who hold membership cards and has worked satis-

factorily at the two previous meetings in London in 1914 and in Boston in 1911.

MEMBERSHIP—REGISTRATION FEE

The Constitution of the Congress provides that all subscribers to the official journal *SURGERY, GYNECOLOGY AND OBSTETRICS* are members of the Congress and that such other legally qualified practitioners as are in good standing in their own communities may become members upon registering at an annual meeting. A registration fee is required of each member attending an annual meeting there being no annual dues for members of the Congress. The registration fees provide funds to meet the expense of preparing for and conducting the annual meetings so that no financial burden is imposed upon members of the profession in the city entertaining the Congress.

THE CLINICAL PROGRAM

The schedule of clinics and demonstrations to be given by the clinicians of Philadelphia during the week of October 3d as published in these

pages is a tentative one and is to be amplified and corrected so that the final program will properly represent the clinical work of the Philadelphia surgeons. The Committee on Arrangements has planned for a complete showing of Philadelphia's clinical facilities in every department of surgery including gynecology obstetrics genito-urinary surgery orthopedics, surgery of the eye ear nose, and throat together with many demonstrations on borderline subjects.

HEADQUARTERS

Headquarters will be established at the Bellevue-Stratford where the Ball Room Clover Room Red Room, Green Room and adjacent foyers and smaller rooms have been reserved for the use of the Congress. These rooms are located on the second floor of the hotel and provide ample space for registration rooms and ticket bureau bulletin boards, etc. the Ball Room being used for the evening meetings.

Headquarters will be open on the afternoon of Saturday October 21st and on Sunday the 22d, for the registration of members. The program

of clinics and demonstrations for Monday will be bulletined on Saturday afternoon and on each afternoon beginning on Monday the complete program for the next day's clinics will be posted on bulletin boards in headquarters. A printed program will be issued each morning and special tickets for all clinics and demonstrations will be issued to members at 8 a.m. each day.

SPECIAL TICKETS

The use of special tickets at previous sessions has fully demonstrated the efficacy of this method of providing for the distribution of members among the various clinics. To prevent over crowding tickets for any clinic or demonstration are limited in number to the actual capacity of the room in which the clinic or demonstration is to be given. These special tickets will be issued at 8 o'clock each morning for the clinics and demonstrations to be held that day a complete clinical schedule having been posted on the bulletin board on the afternoon of the preceding day and a printed schedule of the clinics distributed early each morning.

PRELIMINARY CLINICAL PROGRAM

GENERAL SURGERY

Monday

CHALES H. FRANKER — University Hospital — 9 to 2.
T. TURNER THOMAS — University Hospital — 3 to 4.
GEORGE G. ROSS — German Hospital — 9.
A. D. WHITING — German Hospital — 10.
JOHN B. DEAYER — German Hospital — 11.
E. G. ALEXANDER — Episcopal Hospital — 12 to 1.
HARRY C. DEAYER — Episcopal Hospital — 1 to 3.
W. W. YEE BARCOCK — Samaritan Hospital — 9 to 10.
M. BRENNER — Jewish Hospital — 10 to 5.
KATE W. BALDWIN — Women Hospital — 9.
LEVI J. HANWOOD — Methodist Episcopal Hospital — 10.
W. O. HERMANCK — Polyclinic Hospital — 10.
MORRIS BOOTH MILLER — Polyclinic Hospital — 10 to 11.
LEWIS H. ADLER — Polyclinic Hospital — 10 to 3.
JOHN B. ROBERTS — Polyclinic Hospital — 4 to 5.
FRANCIS T. STEWART — Jefferson Hospital — 4.
MELVIN M. FRANKLIN — St. Joseph Hospital — 1.
W. HERBERT THOMAS — Medico-Chirurgical Hospital — 9 to 11.
JOHN A. BOGER — St. Mary's Hospital — 1.

Tuesday

H. R. OWEN — Philadelphia General Hospital — 10 to 11.
H. R. LOUX — Philadelphia General Hospital — 10 to 4.
J. B. CARRUT — University Hospital — 9 to 10.
A. C. WOOD — University Hospital — 10 to 11.

W. WAYNE BARCOCK — Samaritan Hospital — 9 to 10.
ALFRED HEDENBERG — Mt. Sinai Hospital — 1 to 2.
LEON BRIDGEMAN — Mt. Sinai Hospital — 1 to 3.
A. P. C. ARNOLD — Episcopal Hospital — 9 to 10.
L. H. HUTCHESON — Episcopal Hospital — 10 to 4.
N. TRAMER GREENBERG — Jewish Hospital — 9 to 12.
WILLIAM H. T. ELLER — Jewish Hospital — 10 to 5.
J. M. BALDWIN — Methodist Episcopal Hospital — 10 to 11.
SAMUEL MCCLARRY III — Oncologic Hospital — 1 to 4.
CHARLES H. FRANKER — University Hospital — 9 to 12.
C. P. MOYLE — University Hospital — 10 to 11.
E. G. ALEXANDER — Episcopal Hospital — 10 to 11.
HARRY C. DEAYER — Episcopal Hospital — 10 to 3.
ALFRED HEDENBERG — Mt. Sinai Hospital — 10 to 3.
N. TRAMER GREENBERG — Mt. Sinai Hospital — 10 to 4.
M. M. FRANKLIN — Jewish Hospital — 9 to 12.
WILLIAM H. TELLER — Jewish Hospital — 1 to 5.
W. B. VAN LEE — Hahnemann Hospital — 10 to 11.
JOHN SPEER — Polyclinic Hospital — 9 to 11.
JOHN H. JONES — Polyclinic Hospital — 10 to 11.
JOHN H. GREEN — Jefferson Hospital — 10 to 11.
JAMES A. KELL — St. Joseph Hospital — 10 to 11.
J. F. Y. JONES — St. Joseph Hospital — 1 to 4.
A. C. WOOD — Howard Hospital — 10 to 30.
F. L. ELLISON — Howard Hospital — 10 to 30.
ERNEST LAPLACE — Medico-Chirurgical Hospital — 9 to 12.
JOSEPH H. ROSS — St. Mary's Hospital — 1.

ROENTGENOLOGY

GEORGE E. FRANKLIN—Medico-Chirurgical Hospital—to 30 to 35. Roentgenotherapy in the treatment of deep-seated malignant disease.
 W. B. NEWCOMB—Presbyterian Hospital—to 3. Bone lesions. Sinus cases (in conjunction with D. Stauffer)

CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA

Tuesday

- DAVID R. BOWEN — Pennsylvania Hospital — 1 to 2 Fractures.
 FREDERICK C. HUTTON — 438 N. 5th St. — 0 to 12 Organic lesions of the stomach and duodenum.
 W. F. MANOVS — Jefferson Hospital — to 3 Pyelocopy and pyelography.
 W. S. NEWCOMET — Presbyterian Hospital — 2 to 3 Bone lesions. Sinus cases (in conjunction with Dr. Stauffer).
 A. G. MILLER — German Hospital — to 3
 GEORGE E. FRAHLER — Medico-Chirurgical Hospital — 23 to 31 Roentgen diagnosis of gastric and duodenal lesions. Lantern slide demonstration.

Wednesday

- W. F. MANOVS — Jefferson Hospital — to 3 Fluorocopy of the gastro-intestinal tract.
 A. G. MILLER — German Hospital — to 3
 W. S. NEWCOMET — Presbyterian Hospital — to 3 Bone lesions. Sinus cases (in conjunction with Dr. Stauffer).
 GEORGE E. FRAHLER — Medico-Chirurgical Hospital — 30 to 33 Roentgen diagnosis of gall-stones.
 DAVID R. BOWEN — Pennsylvania Hospital — 1 to 3 Bone and joint diseases.
 M. K. FISHER — Stetson Hospital — Joint diseases and radiography of the urinary tract.
 JACOB W. FRANK — Hahnemann Hospital — 9

Thursday

- DAVID R. BOWEN — Pennsylvania Hospital — 1 to 3 Surgical diseases of the thorax.
 SIMPLY FELDSTEIN — Jewish Hospital — 3 to 4 Tuberculous of the lungs.
 FREDERICK C. HUTTON — St. Mary's Hospital — 3 to 5 Intestinal pathology.
 A. G. MILLER — German Hospital — to 3

- W. F. MANOVS — Office — 2 to 3 Brain tumor and intracranial lesion.
 W. S. NEWCOMET — Presbyterian Hospital — 1 to 3 Bone lesions. Sinus cases (in conjunction with Dr. Stauffer).

Friday

- DAVID R. BOWEN — Pennsylvania Hospital — 2 to 3 The management of small and medium-sized hospital roentgen laboratories.
 W. F. MANOVS — Office — 1 to 3 Roentgen examination of teeth as an aid to logical diagnosis.
 W. S. NEWCOMET — Presbyterian Hospital — 2 to 3 Bone lesions. Sinus cases (in conjunction with Dr. Stauffer).
 A. G. MILLER — German Hospital — 1 to 3
 GEORGE E. FRAHLER — Medico-Chirurgical Hospital — 30 to 33 Electro-coagulation in the treatment of malignant disease.
 M. K. FISHER — Stetson Hospital — Joint diseases and radiography of the urinary tract.
 JACOB W. FRANK — Hahnemann Hospital — 9

Saturday

- A. G. MILLER — German Hospital — 1 to 11
 DAVID R. BOWEN — Pennsylvania Hospital — 1 to 3 The management of small and medium-sized hospital roentgen laboratories.
 W. S. NEWCOMET — Presbyterian Hospital — to 3 Bone lesions. Sinus cases (in conjunction with Dr. Stauffer).
 Days to be Announced
 HENRY K. PANCOAST — University Hospital — 9 to 10 Radium therapy 3 to 4. Gastro-intestinal tract.
 W. S. NEWCOMET — Oncologic Hospital — Deep roentgen therapy and radium therapy in advanced cancer cases.

GENITO-URINARY SURGERY

- L. T. A. HICKEY — Hahnemann Hospital — Tuesday 11
 H. M. CHRISTIAN — Medico-Chirurgical Hospital.
 H. R. LOUX and staff — Jefferson Hospital — Thursday 9
 T. R. NEWCOMET — University Hospital.
 L. T. A. HICKEY — Women's Hospital — Tuesday 11

- E. H. SITER — Philadelphia General Hospital.
 E. H. SITER and staff — University Hospital.
 B. A. THOMAS — Polytechnic Hospital — Tuesday and Friday 4 to 6
 A. A. URLE and WILLIAM MACKINLEY — German Hospital — Monday and Friday 4 to 530

LABORATORY DEMONSTRATIONS

- DAVID R. BOWEN — German Hospital — Monday and Friday 4
 V. L. L. — German Hospital — Monday and Friday 4
 DR. S. P. O. F. L. B. T. T. and V. L. L. — Hahnemann Hospital — Wednesday and Friday 9
 I. F. SWIFT — German Hospital — Wednesday 9
 Tumor of the thyroid gland diet
 C. B. L. — Oncologic Hospital — Monday and Thursday 43
 Demonstration of photographic, photo-micrographic and color work with special reference to hospital photography.
 C. J. S. — Oncologic Hospital — Wednesday and Friday 4
 Laboratory technique especially in the development of the Abderhalden reaction.

- P. O. L. LEWIS, R. E. L. L. RICHARDSON and H. S. NEWCOMET — Pennsylvania Hospital — Daily Demonstrations in pathology and bacteriology.
 JERRESON MEDICAL C. L. L. L. — Pathological Museum — Daily 830 to 5
 A. HENRY — Polytechnic Hospital — Thursday 4
 Experiments with small mammals on cancer. Preservation of anatomical material. Methods of injection of eye by metallic wire.
 B. A. THOMAS — Polytechnic Hospital — Thursday 4
 Indication of elimination of indigocarmine as a guide to kidney sufficiency.
 JAY F. SCHAMBER — Polytechnic Hospital — Friday 4
 Laboratory and clinical aspects of salivary gland pathology.

SURGERY OF THE EYE

Monday

WILLIAM CAMPBELL POSEY — Howard Hospital — 2.

ALEXANDER RANDALL — University Hospital —
 CHARLES P. GRAVE — Medical College Hospital —

PRELIMINARY PROGRAM OF EVENING SESSIONS

CENTRAL SURGICAL DIVISION—In the Ball Room of the Bellevue Stratford at 8 p.m.

Presidential Meeting Monday October

Address of Welcome ROBERT G. LECONTE M.D. Philadelphia, Chairman of Committee on Arrangements
 CHARLES H. MAYO M.D. Rochester Minn. Address of retiring president
 Inauguration of President FRED BATES LUND M.D. Boston and Vice Presidents JAMES HALPENNY M.D. Winnipeg and S. M. D. CLARK M.D. New Orleans
 Presidential address by FRED BATES LUND M.D. Boston The Indications of Cholecystectomy
 J. M. T. FINNEY M.D. Baltimore Drainage of the Gall Bladder
 CHARLES H. MAYO M.D. Rochester Minn. Cholecystostomy vs. Cholecystectomy
 Discussion J. C. D'ACOSTA M.D. and JOHN B. DEWEY, M.D. Philadelphia

Tuesday October 4

DEAN LEWIS M.D. Chicago Fat and Fascia Transplantation.
 Discussion FRANCIS T. STEWART M.D. Philadelphia.
 J. BENTLEY SQUIER M.D. New York City Kidney Surgery
 WILLIAM F. BRAASCH M.D. Rochester Minn. Recent Method in Kidney Diagnosis.
 BRANFORD LEWIS M.D. St. Louis Diagnosis of Ureter Diseases with Their Surgery
 J. T. CERAGHTY M.D. Baltimore Diseases of the Bladder
 EDWIN BEER M.D. New York City The Treatment of Benign Vesical Papillomata Including Endoscopic and Operative Methods
 Discussion EDWARD MARTIN M.D. Philadelphia.

Wednesday October 25

- THOMAS S. CULLEN M.D. Baltimore Methods of Draining Where Pelvic Infections Exist
 Discussion E. E. MONTGOMERY M.D. Philadelphia
- J. WHITRIDGE WILLIAMS M.D. Baltimore The Abuse of Cesarean Section.
 Discussion EDWARD P. DAVIS M.D. Philadelphia.
- GEORGE G. WARD JR. M.D. New York City Treatment of Inaccessible Vesico-vaginal Fistule
 Discussion JOHN G. CLARK, M.D. Philadelphia.
- C. JEFF MILLER, M.D. New Orleans Surgical Treatment of Puerperal Pyemia
 Discussion BARTON C. HIRST M.D. Philadelphia.
- THOMAS J. WATKINS, M.D., Chicago Cystocoele and Prolapse
 Discussion BROOKER M. AMSPACH M.D. Philadelphia.

Thursday October 26

- C. A. PORTER, M.D. Boston Surgery of the Peripheral Nerves
 Discussion CHARLES H. FRAZIER, M.D. Philadelphia, and JOHN H. GIBSON M.D. Philadelphia.
- WILLY MEYER, M.D. New York City Cancer of the Breast
- WILLIAM J. MAYO, M.D. Rochester Minn. Cancer of the Stomach
 Discussion FREDERICK W. PARHAM, M.D. New Orleans.
- GEORGE E. ARMSTRONG, M.D. Montreal, Canada Cancer of the Large Bowel
 Discussion STUART McGUIRE M.D. Richmond and E. WYLLYS ANDREWS M.D. Chicago
- HOWARD A. KELLY M.D. Baltimore Treatment of Cancer by Radium.
- JAMES T. CASE, M.D. Battle Creek, Mich. Treatment of Cancer by X ray
 Discussion GEORGE E. PFANTER, M.D. Philadelphia.

DIVISION OF SURGICAL SPECIALTIES—At the Bellevue Stratford at 8 p.m.

Friday October 27

Symposium on Ophthalmic Surgery

- ARNOLD KNAPP M.D. New York City The Present Status of Extraction of Cataract in the Capsule.
- WALTER R. PARKER, M.D. Detroit Corneoscleral Trephining Usually Known as the Elliot Operation.

Wednesday October 25

Symposium on Rhinological and Laryngological Surgery

- CHEVALIER JACKSON M.D. Pittsburgh Some New Developments in Bronchoscopy
- R. CLYDE LYNCH, M.D. New Orleans The Technique of Suspension in Bronchoscopy and (Esophagoscscopy
- HARRIS P. MOSHER, M.D. Boston The Webs and Pouches of the Upper End of the Esophagus
- Discussion D. BRADEN KYLE M.D. GEORGE M. COATES, M.D. CURTIS C. EVES, M.D. Philadelphia

PUBLIC MEETING Friday October 27 in Witherspoon Hall, at 8 p.m.

Under combined auspices of the Philadelphia County Medical Society the Department of Public Health and Charities, and the Clinical Congress of Surgeons of North America.

- WESTON A. PRICE, M.D. Cleveland Care of the Teeth. (Illustrated by lantern and cinematograph.)
- JOSEPH C. BLOODGOOD, M.D. Baltimore Diagnosis of Cancer
- ROBERT W. LOVETT M.D. Boston Description and Illustration of Curable Deformities and the Importance of Their Proper Treatment.

SEPTEMBER 1916

International Abstract of Surgery

SUPPLEMENTARY TO
Surgery, Gynecology and Obstetrics

PUBLISHED IN COLLABORATION WITH

Journal de Chirurgie Paris

Zentralblatt fuer die gesamte Chirurgie und ihre
Grenzgebiete Berlin

Zentralblatt fuer die gesamte Gynaekologie und
Geburtshilfe sowie deren Grenzgebiete Berlin

EDITORIAL ANNOUNCEMENT

The Editorial Board of the INTERNATIONAL ABSTRACT OF SURGERY has desired for some time to present a comprehensive review of the work done on surgery of the eye. In this branch of scientific endeavor there is work being accomplished which is of the utmost value to the patient which has reached the height of technical proficiency and which is virtually unknown except throughout the relatively small group of men devoting their efforts to this so-called minor specialty.

Perhaps at this time no subject is of greater interest to the ophthalmic surgeon than that of glaucoma, the literature concerning which has become at once extensive and valuable. In this maze of competition the interested reader finds a wide divergence of opinion. Partly to clarify this confusing situation and in part to give ophthalmic surgeons a broader scope in our columns we have secured a collective review on the surgery of glaucoma from the pen of Dr Emory Hill of Chicago. While a discussion of this subject at the present time may lack finality Dr Hill's experience as a student and surgeon has enabled him to present the matter broadly and with such decision as may safely be arrived at today.

Other collective reviews to be published during the next few months are

Mechanism of Fractures	EMMET RICHFORD, M.D. San Francisco

INTERNATIONAL ABSTRACT OF SURGERY

SEPTEMBER 1916

COLLECTIVE REVIEW

CONGENITAL MALFORMATIONS OF THE NECK

By GEORGE DE TARNOVSKY, M.D., F.A.C.S., CHICAGO
A Consulting Surgeon, Cook County and Rushmore Hospitals

HISTORIC

ACCORDING to A. Funk (8) to Ascheron in 1832 must be given the credit of first discovering that congenital cysts and sinuses of the neck had a definite connection with aberrations of fetal branchial clefts. Somewhat later Roser and Koenig reinvestigated the same subject and confirmed Ascheron's findings. Lillenthal (11) and DaCosta (22) credit Mayer in 1833 with the first comprehensive report on carotid body tumors although Luschka in 1862 so popularized the subject that this body is now very generally known as Luschka's gland. After a most careful perusal of the literature the reviewer has failed to find the original authors who first classified cystic hygromas, lymphatic cysts, hemorrhagic cysts or teratomata of the neck among tumors of congenital origin. Exact knowledge of these malformations appears to have been acquired through a slow process of medical evolution. Giacomo (32) believes that Wegner should be given credit for describing cystic hygromata of the neck in 1877.

FREQUENCY

Burke (1) makes the statement that thyroglossal cysts occur with comparative frequency. Dowd (51) in looking over the records of the New York Surgical Society found no report of a complete branchiogenic fistula thus indicating its comparative rarity. The records of the Cook County Hospital of Chicago from 1909 to 1916 reveal 5 cases classified under the heading of congenital malformations of the neck. A

careful analysis of these 5 cases compelled the reviewer to reject 6 of them; the clinical history, operative findings and lack of pathological report all speaking against their embryologic derivation. One case, a doubtful branchial cyst, was a fluctuating circumscribed swelling the size of an almond lying subcutaneously over the center of the right sternomastoid muscle. At operation the tumor was found within the sheath of the muscle but there is no mention of any obliterated duct proximal or distal to the tumor and no pathological report is attached to the case history. The eighth case was an undoubted thyroglossal cyst. McKenty (1) reviewing the records of the Royal Victoria Hospital for ten years (1904 to 1914) was more fortunate being able to tabulate 15 branchiogenic cysts, 5 branchiogenic carcinomata, 9 thyroglossal cysts and 1 carotid body tumor—a total of 30 cases. Collison and McKenty (9) were able to collect 60 cases of carotid body tumors in the literature up to 1913. Of these 60 cases, 4 had merely been accidentally found at autopsy and 2 had been examined post mortem; the nature of the growth not having been recognized ante mortem. Dowd up to 1913 collected reports on 91 cases of cystic hygroma of the neck, and only 35 cases involving the axilla or pectoral regions.

From a careful analysis of cases reported to date it becomes self-evident that in general the diagnosis of congenital malformation was only arrived at after the operation. In the case of congenital cysts only a microscopic examination of the epithelial or endothelial lining of the cyst

wall will reveal the true nature of the tumor. Clinically, a definite diagnosis of congenital fistula can only be made when it is either complete i.e. extending from the pharyngeal wall or foramen cecum to the lateral or anterior surface of the neck or of the incomplete internal or incomplete external types i.e. opening either on the surface of the neck or in some portion of the pharynx. A pre-operative differential diagnosis between a true branchial or thyroglossal cyst (closed at both ends) and a hygroma cysticum colli, would appear to be impossible.

CLASSIFICATION

The classification of embryologic malformation has never been placed on a firm basis. Each author has apparently been content to work out his own scheme, with little or no regard to previous publications. Thus O. C. Smith (6) in his otherwise splendid classification of tumors of the neck, includes aneurysmata, hygromata, and dermoids of the neck under neoplasms and not among embryologic malformations. Murphy (3) classes the above under the proper heading but includes carotid body tumors among malignant diseases of the neck. He also classes hygromata as bursal cysts. Smith classifies carotid body tumors under the heading "tumors of special organs." Branchiogenic cysts are classified by the same author under two heads: (1) congenital (2) malignant, which is needlessly confusing. Kirmisson (14) divides all congenital cysts of the neck into (1) serous (2) dermoid (3) mucoid. His serous cysts are evidently hygromata, for he describes them as large multilobulated extending from the lower jaw to the clavicle and from the median line almost to the spinous processes of the vertebrae. There may be as many as 100 pockets in one tumor. These tumors have a tendency to penetrate muscles (pseudo-malignant); they may even pass under the clavicle and form axillary cysts, or under the manubrium to the anterior mediastinum. He considers the etiology of serous cysts under two headings: (1) venous, because of their frequent intimate connection with the interior jugular vein and the clinical fact that the contents of the cyst is frequently bloody; (2) lymphatic, because of the dilatation of surrounding lymph channels. Dowd (10) writing on the subject of cystic hygromata of the neck, states that three types of growths have been included in some of the descriptions (in medical literature): (1) cystic tumors which have endothelial linings and which grow with much power through the tissues of the neck or downward under the clavicle into the

axilla or pectoral region; (2) lymphangiomas; and (3) branchial cysts. He correctly maintains that only those of the first type should be called hygromata.

The following classification based on embryologic, microscopic, and clinical data, has been compiled from the case reports to date:

1. Branchiogenic
 - (a) Complete fistula (branchial fistula of Roser) patent both ends
 - (b) Incomplete fistula

(Cystic fistula)	{	Internal
		External
 - (c) Branchial cyst closed both ends open in intermediate portion
2. Thyroglossal
 - (a) Complete fistula (extremely rare)
 - (b) Incomplete internal (rare)
 - (c) Incomplete external (rare)
 - (d) Thyroglossal cyst (usual type)
3. Aberrant thyroid gland.
4. Supernumerary thyroid.
5. Lymphangioma (lymphangioma simplex and cavernosum).
6. Hemorrhagic cysts (hemangioma congenitum).
7. Hygroma (hygroma cysticum colli congenitum).
8. Dermoid cysts (in parotid gland near floor of mouth in thyrohyoid or submaxillary region) Kirmisson (14).
 - (a) Primary benign
 - (b) Secondary malignant.
9. Carotid body tumors
 - (a) Primary benign
 - (b) Secondary malignant.

EMBRYOLOGY

Branchiogenic fistula or cyst. In the development of the anterior part of the digestive tract there are formed bilaterally symmetrical lateral diverticula which pressing aside the lateral mesoderm of the head, come into apposition with corresponding invaginations of the ectoderm. The endodermal diverticula are termed pharyngeal pouches, while the ectodermal invaginations are known simply as branchial grooves. By pressing aside the mesoderm the ectoderm and the endoderm for a time come in contact and fuse forming the epithelial closing membrane which breaks through in all forms that have a branchial respiration. The branchial grooves and pharyngeal pouches thus become continuous and together form the branchial clefts. Under normal conditions this fusion and breaking through does not occur in mammals. Between the branchial clefts are the branchial or visceral arches, each of which contains a skeletal rod, the cartilaginous branchial arch, its muscular

ture an aortic arch and a nerve trunk. The branchial arches are named in succession the mandibular hyoid and branchial arches proper. The first branchial cleft is also known as the hyomandibular cleft (Keibel and Mall 57).

In a four week-old human foetus there are four branchial clefts which correspond to the gills in the fish. All these clefts should become completely obliterated or in other words the arches or bars separating the clefts should coalesce (with the exception of the first cleft which forms practically speaking the canals opening into the pharynx) leaving the neck perfectly smooth. The auditory canal develops at the site of the first cleft (52-53). The eustachian tube the middle ear and the external auditory meatus would really form a complete fistula but for the membrana tympani which represents the thinnest portion of the cleft and contains two layers of epithelium one from the ectoderm and one from the endoderm. This near fistula is really very similar to the real fistulae which sometimes exist in the neck at the site of the second cleft. When maldevelopment of the first cleft occurs it is apt to show itself by tabs in front of the ear or defects of the ear itself and occasionally is associated with defective formation of the mouth (Dowd 10). If nature fails in any of these particulars there is produced a congenital fistula a cyst or both (Funk 5).

The region that corresponds to the outer opening of the second branchial cleft is to be found at the anterior border of the sternomastoid muscle. The second pharyngeal pouch corresponds to the tonsillar depression the openings of the third branchial cleft (pharyngobranchialis) are to be looked for near the larynx. A fistula of the second branchial cleft must lie if the development of the vessels be normal between the external and internal carotids and anterior to the glossopharyngeal and vagus nerves a fistula of the third cleft between the common carotid and vagus as well as between the glossopharyngeal and upper laryngeal nerves while a fistula of the fourth cleft must bend around the subclavian artery on the right and the arch of the aorta on the left. In these are derivations of the fourth aortic arch. So far only fistulae of the second branchial cleft have been recognized with perfect certainty.

4. Thyroglossal fistulae or cysts aberrant or supernumerary thyroids. Almost certainly associated with the formation of the first pharyngeal pouch there appears the anlage of the thyroid gland. This anlage is recognizable before the first pharyngeal pouch has become intact

Fig. Incomplete internal branchial cyst fistula (De Tarnowsky collection.)

with the ectoderm as a prominence in the ventral wall of the pharynx. It then becomes constricted to form a stalked vesicle and its stalk whose lumen becomes obliterated persists for some time as an epithelial cord. The hollow stalk of the vesicle is the thyroglossal duct (57).

In a human foetus of five weeks we find this small vesicle on the back of the tongue. By the eighth week the first trace of glandular tissue appears. This is the developing thyroid gland which begins to secrete as early as the fourth foetal month. The gland slowly passes down to its normal resting place through the thyroglossal duct and this passage is obliterated behind it. Normally nothing remains of this duct except the foramen caecum but when nature fails to do her duty a congenital abnormality is developed. If some of the thyroid cells are dislodged from the gland and remain along the duct these may develop into accessory thyroid. The thyroglossal duct may fail to be obliterated either partially

phleboma. (Johnson, Surgical
Diagnosis, Vol.)

or totally, causing the existence of a fistula or cyst (8).

5 Lymphatic cysts (lymphangioma-cysticum). The first evidence of the formation of the lymphatic system is the development of symmetrical sacs in the neck, which have been called jugular sacs. These are first found in the human embryo as endothelial lined sacs just lateral to the internal jugular veins. These jugular sacs become bridged or cut into by bands of connective tissue, this being the process by which each sac, originating from a plexus of blood capillaries, is reconverted into a capillary plexus lymphatic in character. Out of these lymphatic capillaries chains of lymph-glands are evolved. The jugular sacs and thoracic duct may be termed a primary system; the secondary or peripheral lymphatics grow out from the primary system (Sabini 58). Many of the lymphangiomas are found in connection with the sutures and fissures of the body. Thus we recognize macroglossia (tongue), macrocheilia (gums, lips), nevus lymphaticus (skin), etc.

6 Hemorrhagic cysts. Since the human embryo like that of all other vertebrates, possesses a row of definite gill bars or visceral arches, separated distinctly externally by clefts, internally by endodermal pockets or pouches, so also its primitive vascular system is in conformity with this fundamental plan, and strong branches, connecting the dorsal and ventral aortae—the aortic arches—each course in a visceral arch. Six of these aortic arches are recognizable in a human embryo 5 mm. long. Our present knowledge of the vascular system in the human embryo points to the fact that normally the first two

aortic arches are lost, as far as their actual arch portions are concerned, but the third and left fourth arches are retained becoming the root portion of the internal carotid and aortic arch respectively. Certain portions of the remaining arches are retained forming parts of the carotids, the pulmonary arteries, etc., the remainder of the arches normally disappear (57). Faulty retrogressive changes in a certain portion of one of these aortic arches account for the presence of congenital hemangiomas. Their situation always corresponds to embryonic lines of fusion such as the facial or branchial clefts (59).

7 Hygroma. Embryologically speaking a hygroma is probably the result of fetal sequestration of lymphoid rests (10). It has also been suggested that its origin may be from the inter-carotid ganglion. Kirmisson (14) thinks its origin may be either venous or lymphatic. On account of their pseudomalignant independent power of growth it has seemed best to consider hygromas as differing from lymphangiomas.

8 Dermoid cysts. Embryologically both sequestration and tubulodermoids may occur in the neck. In the first instance, a portion of surface epithelium becomes pinched off and continues to develop beneath the skin surface. In the latter case a portion of embryonic canal (branchial cleft, thyroglossal duct) remains patent and a mixed dermoid results (60). Batut (23) restricts the use of the term dermoid to tumors of the neck containing ectodermic inclusions, classifying as mucoides those representing endodermic inclusion. Kirmisson (14) also states that dermoids of the neck represent a retention of epidermal cells whereas mucoid

cysts are lined with cylindrical epithelium often possessing vibrissae.

9 Carotid body tumors. There is little uniformity of opinion regarding the embryologic derivation of this body 5 mm. long 3 mm. wide and 2 to 5 mm. thick. Collison (9) states that it is of doubtful embryological derivation of undetermined function inconstantly present but occasionally giving rise to tumors of definite structure Funk (8) believes it represents the remains of the upper part of the thymus anlage.

Many investigators such as Zuckerlandl (38) McMurrich (39) Stilling (45) Kohn (46) Keith (47) and others classify it with the sympathochromaffin system anlage which buds off from the central nervous system. Steide (48) Rabl (49) de Meuron (50) and others maintain that it represents an embryonal rest from the third or fourth branchial cleft while Katschenko (42) Paltauf (43) and Monckeberg (44) look upon it as being a connective tissue structure derived from the perithelium of the carotid arteries. It would however seem to be a well-established fact that this carotid body consists essentially of a loose connective tissue capsule and meshwork, containing chromaffin cells similar to those found in the medulla of the adrenals in the pituitary and in the ganglia of the sympathetic nervous system. Physiologically we have at present very little knowledge concerning this body. Experimentally its action on blood pressure is contradictory. The fact that it is not constantly present indicates that its function—if any—is unimportant. However we must remember that the different parts of the chromaffin system while of common embryology possess different functions. Thus the medulla of the adrenals affects blood pressure its cortex has an influence on the development of the sexual apparatus the pituitary seems to possess a trophic influence etc (9).

PATHOLOGY

1 Branchiogenic fistula (a) Complete The proximal (internal) portion is lined with cylindrical epithelium (hypoblastic) the distal (external) portion is lined with flat pavement epithelium. The hypoblastic portion also contains a layer of lymphoid cells in its wall. The discharge consists of clear stringy mucus or of a thinner milky or turbid fluid resembling thin pus. It may also contain particles of fluid or semisolid food.

(b) Incomplete The lining may be wholly of cylindrical epithelium of flat pavement epithelium or a combination of both varieties.

(c) Cysts. These have a wall of more or less dense fibrous tissue containing lymphoid tissue

if the cyst arises from the inner embryonic layer. They are lined with pavement epithelium or cylindrical ciliated epithelium sometimes with membrane containing all the structures of the skin. They are usually unilocular occasionally multilocular. Their contents varies it may consist of clear serous fluid of mucus of oily material or of fatty material of solid or semisolid consistence. The walls may undergo suppurative or degenerative even malignant changes.

2 Thyroglossal (a) Fistula. The deeper portion of the fistulous tract is lined by ciliated epithelium that part nearest the foramen caecum of the tongue with flat epithelium.

(b) Cysts. They are lined with flat or ciliated epithelium.

3 Aberrant or supernumerary thyroids. In the downward migration of the thyroid gland through the thyroglossal duct from the base of the tongue to its final location some thyroid cells may become dislodged and remain along the duct (8). Occasionally the entire thyroid gland may remain sublingual and its removal be followed by myxedema (Murphy 2). These embryonal rudiments may be multiple giving rise later in life to multiple goiters (Jakubowski 25). In general it may be stated that aberrant or supernumerary thyroids are subject to the same pathologic changes which may occur in the parent gland.

4 Hemangioma (cavernosum). These are always in the nature of fissural angiomas. At first they may appear as simple telangiectases when fully developed they present numerous large vascular spaces or sinuses lined with endothelium, resembling the structure found normally in the penis corpora cavernosa.

5 Lymphangioma. Their structure is in most respects analogous to that of the hemangioma save that the vascular spaces contained therein are lymph channels instead of blood vessels. The supporting stroma in which the vessels are embedded may be fibrous fatty or mucous. In the cavernous variety the lymph channels are very numerous and much dilated so that the structure on section has a somewhat spongy texture. The supporting stroma is scanty thin delicate and transparent. Cysts varying in size from that of a pea to that of a walnut or larger may be produced. As in the case of hemangioma the lymphangiomas of the neck occupy or originate at the site of the branchial clefts.

6 Hygroma. These are usually large multilobulated containing as many as one hundred pockets in a single tumor. The cyst walls are thin and consist of endothelial cells supported by a loose connective tissue stroma. They are pecu-

lar in having an independent power of growth sufficient to force them into the surrounding tissues (Dowd 10). Some of them extend from the lower jaw to the clavicle and from the median line almost to the spinous processes of the cervical vertebrae. They have a tendency to penetrate muscles (pseudomalignant) many of them even pass under the clavicle and form an axillary cyst or under the manubrium to the anterior mediastinum (Kirmisson, 4).

7 Dermoid cysts. The majority of cases of dermoid cysts reported were due to imperfect closure of the second branchial cleft. As a rule they are lined with stratified squamous epithelium without other skin structures (epidermoid cysts) occasionally the cyst wall will also contain hairs, glands, and fat (dermoid cysts).

8 Carotid body tumor. From a histologic point of view these tumors resemble endothelioma or perithelioma of the suprarenals (Lillenthal, 11). Their normal size varies from that of a grain of rice to a grain of corn. They reach a certain size when from 20 to 30 years old remain stationary for a time and then the connective tissue only increases. The interlobular blood vessels thicken, with resulting sclerosis and atrophy.

The consistence varies, but the tumor is usually moderately hard and elastic. In color it varies from a reddish gray to a reddish brown. When present, the carotid body is found most commonly a little posteriorly to the bifurcation of the common carotid artery lying between the internal and external carotids, and more closely united to one or the other of them. It is attached to the one on which it lies by the ligament of Mayer through which it receives its blood supply. The nerve supply is abundant and is connected with both the cranial and sympathetic nerves. It receives branches from the vagus and glossopharyngeal superior laryngeal and superior cervical sympathetic ganglion.

Fibers pass from the vagus, glossopharyngeal, and sympathetic, to form a plexus in the angle of bifurcation just in front of the carotid body. Many fibers from this plexus penetrate the capsule of the organ.

These tumors may remain quiescent for many years. Lillenthal's case (11) was that of a woman 60 years of age who had noticed the tumor for 35 years. When malignant changes occur the growth of the tumor and infiltration of the carotid sheath and surrounding tissues may be very rapid. Funk (8) reports a tumor 8x5 cm. with pressure upon or involvement of the superior cervical sympathetic ganglion, causing contraction of the pupil on the affected side.

SYMPTOMS

Subjectively there are absolutely no symptoms in the vast majority of these cases. If old enough, patients suffer from a varying degree of mental distress caused by the visible presence of a disfiguring tumor or fistula they may complain of a sense of tightness in the neck, increased by excitement or overexertion. In the case of multilobular bygromata they have reported a gurgling sound on coughing (due to compression of one cyst by the sternomastoid forcing the fluid content into a neighboring cyst). Fistulae or cysts may however become inflamed or infected, giving rise to the common subjective findings of acute or subacute inflammation.

In a case recently operated upon by the reviewer the patient a woman 72 years old, with an incomplete internal branchial fistula (see Fig 1) had all her lifetime been obliged, after each meal, to evacuate the contents of her cystic fistula into the pharynx, semisolids and liquids being forced into the sac during each act of deglutition. Notwithstanding this repeated traumatism, it was only within recent months that the fistula had become infected occluding its lumen with subsequent putrefaction of the contents of the cyst. The inflammatory symptoms alone, brought her to the operating table. Of special interest are the subjective symptoms of imperfect closure of the upper portion of the thyroglossal duct forming what might be termed an exaggerated foramen caecum. Dr T W Lewis of Chicago has reported (but not published) several such cases. The patients suffered from spasmodic cough and irritation of the pharynx which was relieved only by cauterization of the foramen usually to the depth of one-half to three-quarters of an inch. In every case reported by Doctor Lewis touching the opening of the foramen caecum with the tip of a probe invariably produced an attack of severe spasmodic coughing.

Even carotid body tumors give rise to few subjective symptoms until they begin to infiltrate the carotid sheath producing pressure symptoms on the vagus, superior laryngeal, and superior cervical plexus of nerves (disturbances of phonation, dysphagia, dry cough, deafness, conjunctivitis).

Objective (a) Fistula. If of the second branchial cleft, the external opening lies in the skin of the neck, between the anterior border of the sternomastoid muscle and the median line anteriorly and between the greater cornu of the hyoid bone and the sternoclavicular joint of the same side. The external opening is usually very

small often so small as only to admit a filiform guide or a bristle. The inner opening lies in the neighborhood of the tonsil in the lateral wall of the pharynx, or near the pillars of the fauces. In the complete fistula it is sometimes possible to inject fluid through the external opening into the pharynx the passage of the fluid into the pharynx may be recognized by the patient by its taste or by the surgeon by its color (strychnine quinine milk or methylene blue solution) (60).

The discharge from a complete fistula is a thin clear mucus that of an incomplete external is thicker and more turbid while the incomplete internal variety discharges a thick mixture of mucus and epithelial or endothelial elements admixed with particles of more or less decomposed food.

A fistula of the thyroglossal duct is always median between the lower margin of the hyoid bone and the sternal notch. Branchiogenic cysts are single soft freely movable not tender (unless recently inflamed) and are never in the median line. Thyroglossal cysts are usually smaller and always in the median line. Collison and MacKenty (9) describe the objective findings of a carotid body tumor as follows:

(1) Early. A tumor varying in size from a kernel of corn to a robin's egg situated under the sternomastoid or at its anterior margin. It is egg-shaped single discrete firm elastic moves easily laterally but not vertically is pulsating (but not expansile) and may give a bruit on auscultation.

Late. Paralysis of vocal cords (due to involvement of recurrent laryngeal nerve while its fibers are still within the vagus) difficult phonation and deglutition congested larynx irregular pupils with no reaction to light on the affected side lessened mobility of tumor loss of weight and progressive cachexia (10).

F. S. Mathews (11) reports a case in a man years old of presenting hemiatrophy and paralysis of the tongue in addition to other classical findings. The left side of the pharynx was pushed inward and the left tonsil occupied a position near the median line.

DIFFERENTIAL DIAGNOSIS

O. C. Smith (6) has worked out a very exhaustive outline of tumors of the neck which the reviewer appends in full.

1. Inflammatory

(1) Acute

Parotitis submandibular adenitis
Cervical lymphadenitis
Furunculosis
C. rhinoid
Anthrax cymomyces
Echinococcus

(2) Chronic

Chronic lymphadenitis
Tubercular syphilis ad
Hodgkin disease
Mikulicz disease

2. Embryologic malformations

Branchial cysts
Thyroglossal cyst

3. Neoplasia

(1) Benign

Lipoma fibroma chondroma
osteoma sebaceous cyst
angioma
(1) Hemangioma
(1) Lymphangioma
Hidradenoma
Teratoma
(1) Dermoid cyst
(1) Medulla thyroidalis

(2) Malignant

Carcinoma (epithelioma)
Sarcoma
Lymphosarcoma

4. Tumors of special organs

(a) Thyroid

(1) Phylloides hyperplasia at puberty
menstruation and from
(2) Colloid adenoma glandular with
out cysts
(3) Parenchymatous hyperplasia
(4) Follicular adenoma
(5) Malignant disease

Carcinoma
Sarcoma

(b) Carotid body tumor

(c) Aneurysm of a carotid artery

(d) Tumors of larynx

The true nature of a fistula of the neck can be ascertained readily by inquiring into the history of the case. Only branchial or thyroglossal fistulae are congenital. Tubercular adenitis late carcinomata or sarcomata and lymphangiomata or hygromata (the last two only as the result of exploratory puncture or traumatism) may give rise to fistulae. Cysts of the neck must be differentiated from the following: (1) cervical lymphadenitis (2) carcinoma (3) sarcoma (4) fibroma (5) lipoma (6) Hodgkin's disease (7) syphilis (8) aneurysms (9) aberrant or supernumerary thyroid (10) carotid body tumor.

TREATMENT

The correct treatment of congenital deformities of the neck is to leave the benign cases alone unless their removal is desired for cosmetic reasons or on account of inflammatory pressure symptoms and to remove early and radically growths having a malignant or pseudomalignant tendency such as lymphangiomata hygromata and carotid body tumors. It should become axiomatic for instance that a solid tumor of long standing situated in the anterior triangle of the neck at or near the level of the lower border of

DIFFERENTIAL DIAGNOSIS OF CONGENITAL

Tumor	Age	Location	Single or Multiple	Consistency	Superficial or deep	Mobility	Fluctuates
Branchial cyst	Congenital	Anterior triangle of neck	Single	Soft	Superficial; may extend deeply	Movable unless infection has occurred	Present
Thyroglossal cyst	Congenital	Median line below larynx	Single	Soft	Subcutaneous	Freely movable	Usually present
Lymphadenoma	1 month	Anterior or posterior triangle	Multiple as rule, often matted together	Hard at first, later softer	Fork as rule	Slight or absent	Absent early
Carcinoma	Adult	Depends on site of primary focus	Multiple nodes	Heavy hard except in late cases; skin may form tumor	Deep	None	
Sarcoma	Youth or middle life	Angle of jaw sternomastoid	Multiple nodules	Softer than carcinoma	More superficial than carcinoma	Early mobility	
Fibroma	20-45	Very rare in this location	Usually single	Hard	More superficial	Freely movable	
Lipoma	Any age	No anatomic boundaries; not uniform	Single or multiple	Doughy or waxy soft	Superficial	Movable in all directions	
Hydatid's disease	10-40	Posterior rule	Multiple in chains or discrete	Softer than any other tumors; harder than tuberculous glands	Feel like lipoma; but are more deeply seated	Movable	
Syphilis	Any age	Submental or submandibular; look for chancres	Single or multiple	Hard; painless adenitis	Both	Early hard	
Hygroma	Congenital	Inferior angle to clavicle; may pass in axilla or anterior axillary line	Multiple; there may be one or two pockets	Soft	More superficial than carotid body tumors	None	May reach enormous size long
Anastoma	Middle age especially	Carotids especially	Single; usually fusiform	Soft	Deep or rule	Usually none	None
Carotid body tumor	20 to 50 in 1st 2nd 3rd 4th 5th 6th 7th 8th 9th 10th 11th 12th	Under sternomastoid or at its anterior border	Single, egg-shaped discrete	Firm but elastic	Deep	Lateral mobility but no vertical mobility	None

the thyroid cartilage, should be looked upon as a possible carotid-body tumor and removed before it involves the surrounding structures—particularly the carotid sheath. The general modus operandi is essentially that of the radical removal of tubercular glands of the neck. Bearing in mind the probable embryologic derivation of the fistula or tumor one should resort to a careful dissection of the growth while constantly bearing in mind the tissues and structures which are to be avoided. In the extirpation of hemangioma, the reviewer has made use of couglene Kocher Fonio in order to minimize hemorrhage (6r). A 5 to 10 per cent solution is injected around the base of the angioma just prior to its excision. Extirpation is much facilitated thereby. The radical extirpation of a complete branchio-genic fistula requires painstaking care. A small probe or urethral catheter (Dowd 5r) may be

passed through the external opening as far up as possible. A circular incision is then made around its external margin so as to leave a disk of skin around the stoma of the fistula. This is followed by the usual oblique incision parallel to the anterior border of the sternomastoid, including skin superficial fascia and platysma. The sternomastoid is retracted outwardly and the dissection will proceed easily as far as the bifurcation of the carotids. From this point on no sharp or pointed instruments should be used. The final dissection—up to the pharyngeal wall—becomes a slow process of teasing out the fistula from the surrounding tissues. With the patient's mouth held open and using a head mirror tugging on the fistulous tract will cause a dimpling in below the tonsil or on the lateral pharyngeal wall. Having freed the entire tract one of three procedures may be employed to

MALFORMATIONS OF THE NECK

Gurgling	Pulsation	Bract	Specific reaction	Fistula	Course	History	Causes	Variation
Noise	Noise	Noise		May be present easily open in mouth or externally	Slow	Congenital		Clear or turbid fluid
				Rarely present	Slow	Congenital		Clear thin light fluid
Noise			T. bercula	Lat broken down areas	Sub cuts	T. berculous		F. in lat
				Only in terminal stage	Rapidly progress	Primary focus	Prest	
				Only in terminal stage	Progress		La	
					Chronic			
					Chronic			
			Blood picture splenomegaly		Progressive	Irregular progress	Lat	
			W. ascending point			Chronic et		
				Only in terminal stage	Fairly rapid et. tends but not facial layers esp	At begin side of be spreads rapidly		Clear thin fluid
Present	Expire in left in 1 normal artery pulse on affected side	Present	W. ascending point		Fairly rapid	Syphilis		F. lat
	Present but not esp side	Present			Long history of slow growth	Rather sudden change in malformation	Only in lat	

complete the operation Von Hacker (54) cuts off the fistula three-quarters of an inch from the pharyngeal wall. An eye probe or small catheter is then pushed through the fistula into the pharynx and sutured to the distal end of the tract. By traction through the pharynx, complete inversion is obtained. The stump usually separates or tears away readily from the mucosa. The opening thus left is sutured with catgut. Wishing to preserve the entire cyst and tract in one of his cases the reviewer proceeded as follows: Having dissected the tumor up to the pharyngeal wall two clamps were placed on either side of the tract in such a manner as not to occlude its lumen. A third clamp was then placed squarely across the neck of the tumor just distal to the guy clamps and the mass removed *in toto*. The remaining fistula was then cauterized with pure carbolic acid and a catgut ligature thrown

around the guy clamps proximal to them and tied. The clamps were then removed and the incision closed without drainage. The result was perfect. For those cases where adhesions to the carotid sheath make complete dissection impossible or extremely dangerous Koenig (53) has devised an ingenious method of treatment. He frees the distal end of the fistulous tract as far as he can and then passes this free (distal) end through the mucous membrane in front of the tonsil and stitches it there thus leaving a curved sinus with an internal opening at each end—the posterior one pharyngeal the anterior one buccal.

Thyroglossal fistulae or cysts should always be injected with methylene blue and every particle of stained tissue removed. The usual procedure has consisted in shelling out the cyst as far as the hyoid bone. Inasmuch as the tract invariably passes either through or behind this

bone, cures have only been effected in those cases where the duct is represented by a fibrous cord proximal to the hyoid. Recurrences have been the rule. McKenty (13) mentions one case where three successive operations were necessary, even then he does not state whether the third operation was a permanent success. Chiseling or drilling through the hyoid bone, followed by cauterization, is recommended in obstinate cases.

The extreme thinness of the walls of a hygroma makes a clean dissection of the entire tumor almost a surgical impossibility. Portions will tear and remain behind, leading to extremely rapid recurrences. Dowd (10) operated on a girl not quite three years old removing the cyst as far as the sternum. It promptly recurred and at the second operation he was obliged to extend his dissection as far back as the scalene muscles. This case died on the tenth day from shock and hemorrhage. A preliminary injection with methylene blue is absolutely indicated in these cases.

The operative mortality of carotid-body tumors is formidable. Collison and Mackenty (9) collected 60 cases up to the year 1913. Of these, 54 were operated upon. In 4 cases, the operation was merely exploratory in nature in 31 the common external and internal carotids were ligated in 7 only the external carotid was ligated in 15 cases the tumor was dissected away from the blood vessels or dissected away from the internal carotid or the common carotid after ligation of the external. Recurrences occurred in 6 of these 15 cases whereas only 2 recurred after complete removal of all the carotids. Immediate death occurred in 11 cases of the 43 who convalesced 4 had prompt recurrences and in 6 other cases speedy deaths were in prospect from recurrences known to have existed when the cases were reported. We thus have an operative mortality of 25 per cent and a prospective mortality of 40 per cent, a far from encouraging outlook. Desgouttes (1) reports the successful removal of a tumor *en bloc* with the internal jugular vein and the pneumogastric, the internal carotid being saved. He has also successfully removed the pneumogastric the sympathetic plexus, the internal jugular and the internal carotid in another patient. He does not state however whether or not either of his patients succumbed to recurrences. Lillenthal (2) ligated and resected, above or below the tumor mass, the internal jugular and all three carotids, saving the pneumogastric. Twenty-four hours after the operation his patient developed central

aphasia and right hemiplegia. There was no aphonia but the left eyeball softened and its pupil contracted. All symptoms except the contracted pupil disappeared in a few days. He ascribes the pupillary contraction as probably due to injury of the superior sympathetic cervical ganglion. It is therefore self-evident that a large percentage of these tumors will be considered inoperable by conservative surgeons. If seen early dissection away from the carotid bifurcation leaving the vessels *in situ* has been suggested (9) in all other cases if operation is undertaken, the mass should not be dissected away from the blood vessels but the carotids and internal jugular vein should be removed *en masse* after freeing the pneumogastric.

SUMMARY

1. The pre-operative diagnosis of congenital deformities of the neck is all too seldom made. A careful history and examination of the deformity oftentimes aided by the injection of either bitter tasting or coloring substances, will enable the surgeon to make a correct pre-operative diagnosis.

2. No operation should be undertaken unless the surgeon is prepared to carry the same to a complete conclusion. Partial removal of a secreting wall is worse than leaving it *in situ*.

3. The desirability of operating on carotid-body tumors must depend on (1) a very early diagnosis, while the tumor is still benign (2) in late cases, on the desperate nature of the patient's symptoms (paralysis of vocal-cords stenosis of pharynx, hemiplegia, hemiatrophy paralysis of tongue, etc.)

ABSTRACTS OF CURRENT LITERATURE

GENERAL SURGERY

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE

Grant, W. W. The Immediate and After Treatment of Railway Injuries. *South. M. J.* 9:6 11, 357

The circumstances, conditions, and environment of railway injuries are unfavorable to the best treatment so that tentative measures only should be used until the patient is in more favorable surroundings. The immediate application of hydrogen peroxide and iodine with dry sterile gauze is recommended for wounds. Fractures should be temporarily immobilized.

Hemorrhage is a common condition in railway injuries and many times is incorrectly treated. Pressure to stop the hemorrhage should be used for as short a time as possible as tissue necrosis and subsequent sloughing may result from prolonged anemia of the parts.

Shock is frequently unscientifically treated and its presence many times disregarded. No serious operation should be performed in the presence of shock. Combat shock, dry heat applied to the body, hypodermoclysis, rectal saline, and sugar solutions are recognized agents.

Fractures should be treated if possible without the open method, especially should all compound fractures be left alone as regards surgical approximation of the fragments, for at least ten days or two weeks following the accident.

Conservative surgery as regards feet and hands is very important. Ragged wounds should be left open to allow free drainage. Muscles, tendons, and nerves should be carefully sutured. Skull fractures should be carefully explored and all fragments and bone debris should be removed.

J. H. SUMNER.

Barclay, A. E. Preliminary Note on New Method of Bullet Extraction. *Arch. Radiol. & Electrotherap.* 9:6 11, 359.

Barclay's method is an elaboration of the scheme of marking the location of foreign body by inserting a large needle into the tissues until the body is reached, using the fluoroscope to guide the needle. Instead of inserting a needle he uses two prongs, one longer than the other, the point of the shorter prong fitting into the depression near the point of the longer one to make the insertion easier. The outer ends

of the prongs have handles arranged at right angles to avoid the screen and made like scissors so they can be opened and closed. He has also arranged his instrument electrically so that a bell rings when metallic body is in contact with the prongs. Fourteen cases are reported in which the foreign bodies were removed with a small skin incision and without the mutilation of tissue usually required in such cases.

J. O. BURN.

Cathcart, C. W. Methods of Preparing Sphagnum Moss as a Surgical Dressing. *Lancet, Lond.*, 9:6 11, 830.

A description is given of a simple and economical method of sterilizing sphagnum moss. The absorbing qualities of the moss are superior to cotton wool. The moss is first picked clean of grass and leaves and suitable quantities are placed in small flannel bags which are immersed in bichloride solution so that the moss is impregnated with one-fourth of one per cent of bichloride of mercury. The bags are then hung up to dry in a room heated with a slow combustion stove. They are then compressed by an ordinary clothes wringer and are ready for packing. Care must be taken in shipping that the moss is not exposed to moisture, otherwise it will swell and burst the packing boxes.

H. G. SLOAN.

Tovey, D. W. The Nerve Supply of the Lower Abdominal Wall as Related to the Pfannenstiel Incision. *Am. J. Surg.* 9:6 11, 145.

Special care should be taken in any abdominal incision not to injure the nerves supplying or crossing the cut structures, since such nerve injury predisposes to hernia by causing paralysis of muscle or atrophy from disturbed nutrition or loss of sensation.

The course and distribution of the nerves of the lower abdominal wall are described, especially those which may come in the field of a Pfannenstiel incision, principally the anterior divisions of the twelfth dorsal and the hypogastric branch of the first lumbar.

In the Pfannenstiel incision, after the aponeurosis has been separated from the muscle and the linea alba divided and the upper flap retracted, two or sometimes four large nerves can be seen coming up from the recti about an inch from the median line.

and piercing the anterior fascia. These are the anterior divisions of the twelfth dorsal nerve. They are often half as thick as a match, double and accompanied by a blood vessel. They should not be cut as in retracting the upper flap they can be drawn out sufficiently in nearly all cases. The cutting of these nerves according to Tovey may account for the reported cases of hernia following the Pfannenstiel incision. LUCIAN H. LUDWY.

MacLennan. A. The Prevention and Treatment of Some Obscure Conditions Complicating Convalescence After Gastro-Enterostomy. *Glasgow M J* 1916 lxxxv 3 3

MacLennan considers the undesirable sequences of gastro-enterostomy and describes an operation by the adoption of which these sequelae may usually be prevented. The steps are as follows:

1. Except in infants the new stoma is made on the pyloric side of the lowest point of the great curvature.

2. The colon is raised so as to display the mesocolon—that area which is free of vessels yet contiguous to the selected spot on the stomach wall is divided vertically to the necessary extent.

3. The stomach is drawn through the slit in the mesocolon and clamped perpendicularly, occasionally with a slight inclination toward the pylorus but never with the inclination toward the left. The omentum and colon are then returned into the abdomen.

4. The bowel to be attached is emptied by digital pressure and clamped when flat.

5. One continuous Lambert suture (silk) unites the two surfaces along the line which is sickle-shaped at the lower end and which is just off the free edge of the bowel. At the end of the line the thread is hitched under the last loop and caught lightly in a pair of pressure forceps, so applied that the serrations of the forceps cannot cut the silk.

6. The stomach is opened and a small circular section is removed from the entire thickness of the wall corresponding to the curvature in the line of the Lambert suture, making a racquet-shaped opening. The same is done to the bowel, but on no consideration is the mucous membrane of the latter excised in the slit part. The redundant mucous membrane at the upper part of the stoma offers some impediment to the entrance of bile, while the cutting out of a section of stomach and bowel leads to the formation of a gaping hole over the mouth of the efferent jejunum and facilitates evacuation of stomach contents.

7. The operation is concluded by suturing the openings together with catgut and then continuing the Lambert suture, which has been laid aside. A little of the girth of the bowel is taken up as possible. The junction is placed inside the lesser peritoneal cavity by uniting jejunum to the opening in the transverse mesocolon for the greater safety thus gained in localizing possible leakage.

In the author's opinion bleeding from a duodenal

or pyloric ulcer forms the sole indication for closure of the pylorus. Where hemorrhage has occurred all large vessels going toward the site of the ulcer are ligated. Closure of the pylorus has no influence in preventing bilious regurgitation.

Following gastro-enterostomy morphia is allowed during the first twenty-four hours only. The Fowler position is used, rectal saline is given every four hours, a dessertspoonful of brandy and glucose on raulin tea being generally included. During the first twelve hours nothing is swallowed though the mouth is frequently washed out with ice water. During the second twelve hours sips of water acidulated with lemon juice are given every quarter hour. During the next twenty-four hours the water is increased to a half ounce while during the latter part of this time dessertspoonfuls of butter milk are given. On the third day the diet consists of beaten curds, buttermilk, lemon tea, coffee with oat milk, and sugarless stewed apples. On the fourth day calomel is administered (about 3 grains) in one-half grain doses every quarter hour. This is followed by a sudorific enema containing asafetida, quinine or turpentine. Three daily scrambled egg, banana and cream, malted milk or fish cream in addition to the sour milk, apple, etc., is given. Thereafter the diet is gradually increased until at the beginning of the second week fruit (cooked or uncooked), chop, fowl and fish are included. A sour wine may be taken advantageously with the meaty meal, but fresh milk after gastro-enterostomy must be avoided. Bilious regurgitation without vomiting in cases with urgent symptoms requires the stomach tube. After siphoning the stomach should be washed out with warm water and a few ounces containing a tablespoonful of vinegar left in. Small doses of opium or better one twentieth grain of heroin may be given thrice daily to encourage gastric contraction, and retard the secretion of bile.

The mechanism of bilious regurgitation is well called a vicious circle for the presence of bile induces conditions which encourage its continuance. In the presence of alkali the stomach relaxes and the extra weight of the fluid increases the sagging of the organ whose capacity for holding bile is further enhanced. As the overfilled organ sags it inclines to close its exit by obliterating the lumen of the jejunum. The position assumed by the patient then becomes of importance in so far as it may relieve a downward pressure. Under these conditions also vibratory massage is efficient. Heat is comforting and assists in the return of gastric tonicity. In the acute states of regurgitation, champagne to 4 ounces will speedily produce amelioration. A peppermint liqueur is excellent for occasional bilious regurgitation.

ALBERT LURE FRIED

Weeks. A. A Simple Method of Giving Solutions by Bowel. *J Am M A* 1916 10 1

After numerous experiences in watching the routine use of the Murphy drip after operations in various hospitals the author came to the conclusion

that half of the distress complained of by patients is due to the retention in the bowel of gas or too much fluid. This is especially so in little children.

For some time he has used a method which consists of the usual container and dripper supplied by all hospitals with small glass funnel, a funnel holder which will fit on the container and 5 feet of rubber tubing, with a glass tip and an ordinary rubber catheter to suit the case. The funnel hangs on a level with the patient's abdomen. The container is hung so that the dripper will drip into the funnel. The solution is allowed to drip only as fast as it is absorbed, and it is not necessary to keep it warm.

LOW ED L CORNWELL

ASEPTIC AND ANTISEPTIC SURGERY

Emery W D A Standard Method of Testing Antiseptics for Wounds, with Some Results. *Lancet*, Lond., 9 6, cxc, 8 7

The author has aimed to test antiseptics under the same conditions as when they are ordinarily applied to wounds. He uses blood as a medium because of the presence of blood in all fresh wounds, and further because pus which would be the ideal medium is difficult to obtain of a uniform type. Washed corporals were added in an equal amount of serum so that there would be no clotting while the experiments were being carried on.

He used the streptococcus faecalis in testing the potency of the various antiseptics because it is the chief enemy in wounds. It can always be obtained in pure culture, it grows rapidly so that the results can be secured in twenty-four hours and furthermore it readily emulsifies so that there are no masses to resist the action of the antiseptic. In the technique he uses nine parts of blood and one part of 18-hour culture of the streptococcus, containing about 50,000,000 cocci per ccm. This solution was thoroughly mixed with an equal quantity of the antiseptic to be tested on a glass slide. Equal portions of this mixture were then sucked into two capillary pipettes and the ends sealed. Pipettes were then incubated, one for fifteen minutes and the other for one hour and at the end of this time two loops from each pipette were inoculated on the surface of an agar plate. These plates were then incubated and the number of colonies determined after twenty-four hours.

Some antiseptics show fewer colonies after fifteen minutes than at the end of one hour because of their faculty for combining with the protein in the medium in which the bacteria are mixed. This neutralization of the antiseptic with the protein has very nearly passed off at the end of an hour so that the remaining bacteria flourish more at this later period.

Emery found that by this method Dakin's solution was only one-seventieth as powerful as carbolic acid. It was one-fourth as powerful as biniodide solution, one-thirtieth as strong as lysol, and one-two-hundredth as strong as malachite green. Un-

fortunately the action of this last antiseptic on the living cells is too powerful for clinical use.

The end result of any antiseptic, in wounds, is a combination of its action on the infecting bacteria, coupled with its action on the fixed body tissue cells. This latter factor the author has been unable so far to determine accurately but he is working on this problem.

HARRY G SLOW

ANÆSTHETICS

Stanley L. L. Spinal Anesthesia; Analysis of Two Hundred and Eighty Cases. *J Am. M. A.* 9 6, lxxi, 000

In the 80 cases in which spinal anesthesia has been used on the inmates at the San Quentin, Cal., prison tropacocain in 5 gr doses has been the agent employed.

In ordinary operations excepting those in which the abdominal viscera are handled no hypnotic is given to the patient before the operation. The patient walks to the operating room and mounts the table. Within one minute he feels that his feet are becoming warm and he may even feel a tingling sensation in his toes. Within two minutes, sensation is lost about the anus and, as a rule, within about four minutes the loss of sensation is so great that operations for hernia may be done without pain. For operations above the umbilicus the patient is allowed to stay in the Trendelenburg position for six or seven minutes, for apparently it takes that long for the tropacocain to gravitate cephalad to bathe the nerves which supply these segments. For operations about the anus the average Trendelenburg position has been 7 minutes for operations on varicose veins, 5 minutes for operations on the sacrum, 4 minutes for hernia, 3 minutes and for gastro-enterostomy 4 minutes.

The conclusions are as follows:

In this series of 80 cases there has been no fatality.

There has been comparatively little shock.
3. There has been headache in only 8 per cent of cases.

4. There has been no pneumonia following the operation.

5. There have been very few post-operative complications.

6. There have been no permanent paralyses following the anesthetic.

7. The period of convalescence has been short ended.

8. With the relaxed muscles, closing of the abdomen is greatly facilitated.

9. The blood pressure has fallen in most cases but in the average case not to a dangerous degree.

10. The height to which the anesthetic is effective is influenced by the length of time the patient is in the Trendelenburg position.

11. The pulse-rate is not influenced by any marked degree by tropacocain intraspinally administered.

EDWARD L. CORNWELL

Mahn G: *Practical Notes on Local Anesthesia in Otorhinology* (Notes orales sur l'anesthésie locale en oto-rhinologie) *Ann d'otol et de l'oreille* de la Soc. Par. 1916 1: 835

In most interventions in the frontal and maxillary sinuses or in the maxilla not alone must the superficial layers be anesthetized but also and especially the bony walls internally as well as externally trepanation of these cavities being usually followed by curettage. In order to obtain this result the author says that it is necessary and sufficient that the injection should be pushed into the exterior periosteal layer. But the anesthesia will be more perfect if a large part of the periosteal surface enveloping the cavity is injected.

The author uses a novocaine solution and three hours prior to its use he makes a hypodermic injection of pantopon or morphine. His technique is given in detail. W. A. BRENNAN.

Kroenig B and Siegel P W: *Shockless Surgery with the Help of Paravertebral Anesthesia and Scopolamine and Narcophin* *Surg. Gynec. & Obst.* 9: 6 Jan. 5: 4.

Kroenig reports 670 cases of gynecological and obstetrical operations done under paravertebral anesthesia at the University Frauenklinik in Freiburg Germany.

The method consists in blocking the nerve trunks directly at their exits from the intervertebral foramina or from the sacral foramina for the sacral nerves with a one half per cent solution of novocaine suprarenin tablets. A prepared by Hoechst Farbwerke. The anesthesia is preceded by two-thirds to one gram of veronal on the night before the operation and 0.003 gr scopolamine and 0.03 gr narcophin two and one fourth and one and one half hours respectively before beginning the anesthesia, and half a dose of each one half hour before anesthesia if the twilight sleep is too light. For cachectic patients or patients weighing under one hundred pounds the dose is reduced to 0.00225 gr scopolamine and 0.0225 gr narcophin respectively and 0.00075 gr scopolamine and 0.075 gr narcophin for the last dose if necessary. The anesthesia continues uniform from two and one half to three hours and operation may be begun from fifteen to twenty minutes after anesthetization.

The complications noted are of minor importance and may result from the condition of the patient or from the operation itself. No deaths resulting from the anesthesia were noted. An attempt was also made to eliminate post-operative pain by dusting a powder called anesthesin into the wound as it was closed by layers. Apparently a reduction of pain was accomplished in most cases and in some there was a complete elimination of post-operative pain but the resulting edema in the wound and retardation of healing seem to be factors that more than outweigh the slight advantage gained and the use of this powder has been discarded for the present.

1 preceding the anesthesia with scopolamine and

narcophin eliminates the psychical shock due to the preliminaries of an operation and patients often have no recollection of anything from the time they receive their veronal on the night before operation until they recover full consciousness three to six hours after the operation.

The variety of operations done under this form of anesthesia indicates its general applicability in general surgery as well as in gynecology and obstetrics and the success of the Freiburg clinic warrants a fair trial by the profession. The technique is not as difficult as it might seem and requires only a definite knowledge of the distribution of the sensory nerves or working according to the rules applied by experienced users of this method.

With the elimination of the post-operative pain upon which problem the Freiburg clinic still works the method presents the advantages of anesthesia. Its chief advantage lies in the uniformity of the anesthesia obtained in the least serious immediate or post-anesthetic complications.

SURGICAL INSTRUMENTS AND APPARATUS

Thompson G S: *Some Surgical Uses of Celluloid* *Brit J Surg.* 19: 6 Jan. 1906.

Celluloid used for surgical purposes varies in thickness from that of ordinary photographic films to that of thick cardboard. In cases where it is desirable that it become encapsulated it should be perforated with pin holes throughout. When infection does not occur the celluloid does not provoke irritation of the tissue sufficient to cause subsequent sinus formation or the extrusion of the celluloid. The celluloid is sterilized in the autoclave or by boiling. If crinkling is to be avoided the material must not be boiled for a long period. It is not an absorbable material.

Thompson suggests that celluloid might be used to advantage in the various types of hernia. The precautions necessary to be observed in its use are pointed out by the author. In femoral hernia the plate should be triangular in shape and should be provided with a flange on its outer border where it comes into relationship with the femoral vein. The plate for inguinal hernia should be roughly elliptical and should have a gap for the passage of the cord at its lower border. In the skull thick plates are used fashioned to suit the aperture. Perforations are avoided. Celluloid will be found preferable to other material such as transplanted bones—phalanges, pieces of rib etc. in plastic operations on the nose for restoring the bridge. Thompson suggests the possibility of using celluloid caps for the ends of bones after certain operations. For this purpose he suggests that there be kept on hand a series of casts and molds in different sizes corresponding to the commoner joints involved. The celluloid is softened and applied to the cast and it is then worked into shape with the molder. The whole is then placed in cold water to harden.

It is suggested that celluloid be used for medullary pegs after fracture. The advantages claimed for the medullary peg of celluloid are: It is not brittle; it gives perfect alignment; does not interfere with osteogenesis, and therefore does not favor non-union; causes only slight disturbance to parts; causes no discomfort to the patient; it requires only a minimum of trauma for its introduction; the operation is rapid. In the author's opinion the alleged defects of pegs do not exist, and granted correct technique, gratifying results may be anticipated. He believes that this method is destined to supersede the others.

Spina bifida is a condition in which ideal closure of the gap can be made by a properly shaped celluloid plate. A flame-proof celluloid known as "taruloid" is now on the market. IMMORE CORN.

Johnson, C. G. Fracture Splints. *Lancet-Clin* 9 6 xvi, 373

The author uses tin as material for splints, and believes it most practical especially for the country practitioner. The tin splint is most advantageous because it is light in weight, is firm and strong, is capable of being molded, and can be sterilized.

J. R. MARTIN

SURGERY OF THE HEAD AND NECK

HEAD

Von Hacker. The Plastics of Penetrating Cheek Defects Due to Gunshot Injuries. (*Plastik bei penetrierenden Wangen Defekt und nachfolgender naherliegender Kieferklemme insbesondere nach Schussverletzungen*) *Beitr. klin. Chir.* 9 6 xxviii, 89

Von Hacker's method of remedying defects of the cheek due to gunshot wounds is divided into two stages.

In the first stage an Israel flap is cut from the cheek down the neck commencing close to the defect but in such a way that a strip of skin is left between the defect and the flap. This strip is termed the bridge. The flap which hangs from the cheek, is turned over, passed under the bridge, and part of it covered over the defect. This is sutured to the edges of the defect and the former outer skin surface of the flap thus forms the interior lining of the mouth at the defect. The edges of the flap site are approximated.

The second stage of the operation takes place when the flap has healed in the defect. This consists in severing the lower edge of the bridge and with this and the unused portion of the turned over skin flap patching over the external surface of the defect and approximating edges.

The author illustrates his procedure by several diagrams clearly showing the steps of the operation. He also shows some photographs of the excellent results obtained. He points out that his method by allowing the flap to be nourished during the healing process prevents necrosis and is thus superior to other methods in use. W. A. BARNARD.

Perry R. St. J. Pons Nasal. *Am. J. Clin. Med.* 9 6, xiii, 309.

The author describes in detail the method of making a plaster cast of the nose in deformities thereof.

An attempt is then made to correct the deformity by one or more procedures. Submucous resection with straightening of the nasal bones may give the result desired. When depressed areas are present a piece of cartilage from a rib may be inserted to fill out the nasal contour. When unsightly pro-

jections are present these may be curetted off subcutaneously with a special spokeshave. An injection of paraffin must sometimes be resorted to finally. J. H. SKINNER.

Vilvandré, G. Radiography in Gunshot Wounds of the Skull. *Arch. Radiol. & Electrophys.* 9 6 xi, 306

The point which the author wishes to emphasize is that owing to the bad prognosis in lesions in which foreign body has lodged in the brain, an operation should take place on a skull which has not been previously radiographed to ascertain the presence or absence of a foreign body and its careful localization.

To trephine a skull for depressed fracture will of course give relief, but a patient with a bullet or piece of shrapnel in his brain will, with perhaps a few remote exceptions, die within six months of cerebral abscess. The only exception which might be allowed is that in which the bullet is not distorted through a previous ricochet and is in all probability aseptic. The first point can be determined by the X-ray. HOWARD E. POTTER.

Lee, J. R. Removal of Intracranial Foreign Body Under X Rays. *Bull. M. J.* 9 6 i, 447

Attempts to locate a piece of shell in the occipital bone with probe or to remove it with an electromagnet having been unsuccessful, the X-ray screen was tried. The operator was clearly able to see a probe which had been passed in along the track and the fragment which had been pulled forward by the magnet and was caught in brain tissue. Removal of the fragment was effected by means of a crocodile forceps passed along the track to a depth of four inches. Noting the relation of the fragment to the instrument during the process of removal may prove of material assistance.

L. K. ARMSTRONG.

Whitaker R. Gunshot Wounds of the Cranium. *Bull. J. Surg.* 9 6 iii, 706.

The author reviews the results of his observations on 106 cases of cranial injuries which have been re-

ceived for treatment from seven to ten days after the injury. Of this number 88 were penetrating or perforating wounds of the brain.

The operative treatment originally advocated by Sir Victor Horsley was the method of procedure adopted in these cases. It is in the main as follows:

1. The injured and septic area of the scalp must be freely excised.

2. The injured area of skull must be freely exposed by suitable incisions and turning down suitable flaps.

3. Normal dura mater must be freely exposed around the entire circumference of the wound which it penetrates by a wide removal of bone. Foreign bodies, blood and pus must be removed from the brain without breaking down protective adhesions. The whole wound must be left open from the start.

In wounds where the bullet has perforated the brain the wounds of entrance and exit must be treated alike. When the wounds of entrance and exit are close to one another the two openings are joined — a new factor that of decompression is appreciated in the treatment of these cases. It soon became apparent that these cases did better than those in which the wounds of entrance and exit were not so close together. Cerebral hernia in these cases did not become strangulated but ultimately retired inside the dura mater which in the end became slightly concave. Whitaker has made it a practice to remove those foreign bodies and fragments of bone which are obvious but he has not searched at length for them as he has found that the brain is far more able to take care of itself in this direction than is ordinarily believed.

The length of time taken for the operation is an important factor in preserving the patient's life. Speed and free decompression have been the dominant ideas in these cases. The type of infection has been an important determining factor. Streptococcal infection has been fatal in 90 per cent of cases. It is not usually associated with the formation of adhesions; the hernia grows rapidly and is not covered by a protective membrane. In the cases showing a staphylococcal infection the patient makes an amazing fight when death occurs it is due to infection of the ventricles through a narrow track. These cases show a marked protective covering for cerebral hernia.

As to the technique employed, chloroform and oxygen have been given. The local preparation of the scalp consist in washing with petrol, with methylated spirits and then with iodine. From the beginning of the operation the wound area is continuously irrigated with 1:50 carbolic. Bleeding vessels are ligated but forceps are left on for twenty-four hours. Bleeding from the dura and sinuses are dealt with by muscle grafting.

The muscle graft not only serves to control hemorrhage but it serves as a center for granulation formation. When the bony parts are removed the irrigating fluid is changed to hydrogen peroxide. All obvious foreign bodies are removed and the

wound dressed prior to this. No ever an unperforated piece of rubber is placed over the dura. The wound is dressed with a 1:50 carbolic or iodoform gauze. Morphine is given as needed. Uroline is the only other drug given to control pain. 6 hours. The first dressing is applied after 6 hours and the rest as required.

Lumbar puncture has been used in only a few cases in this series. The effect of lumbar puncture are very transitory. A permanent cannot fail to mean an added strain on a system that has already as much as it can bear.

Under good conditions a patient has every case of fracture of the skull that is operated upon within the first three or four days at the hospital when cases are rare after seven days it is probable that the patient cannot survive. The definite clinical picture is one of increasing intracranial pressure. During the intervening period the following conditions demand immediate operation: active septic process in a drained wound, evidence of cerebral irritation, compression of coma and slow pulse.

Jackson H. Cranio-pharyngeal Duct Tumors.

Jackson reports one case and refers to cases collected from the literature. The tumor arising from rests of embryonic tissue along the course of the cranio-pharyngeal duct.

These rests of buccal epithelium which may occur within the persistent canal and at the cranial extremity of this canal in the region of the infundibulum and anterior lobe of the hypophysis may give rise to cystic or solid tumor.

These hypophyseal duct tumors lie in the median line at the base of the brain bounded anteriorly by the optic chiasmus posteriorly by the pons above by the floor of the third ventricle and below by the sella. Laterally they may encroach on the cerebral peduncles and temporal lobes. The circle of Willis usually surrounds the tumor. The hypophysis itself may be found intact or be pressed against the floor of the sella. The first five cranial nerves may early undergo a pressure atrophy but the olfactory nerves usually escape. The foramen of Monro may be occluded and internal hydrocephalus may result. The optic tracts are most seriously affected and may be spread out on the tumor like a ribbon. The sella is usually normal in size or only slightly enlarged. The tumors are usually the size of a pigeon or hen's egg when discovered. The majority are cystic when solid they show areas of cystic degeneration. The author describes the histology in detail.

Of 17 cases in which the symptoms are clearly stated 12 were associated with adiposity and other symptoms of the Froelich syndrome such as genital dystrophy and loss of body hair. In 6 cases 19 had symptoms of falling vision and 15 of brain pressure. Optic atrophy was noted in 17 cases. The clinical course is varied some cases are acute

stige in three or four weeks, others have symptoms for years.

No case reported has been associated with acromegaly.

In regard to diagnosis, roentgenoscopy is usually negative because the sella is rarely enlarged. The early disturbance of vision and one or more symptoms of the Froelich syndrome, especially adiposity will suggest a tumor of the hypophyseal region. 70 per cent of these are craniopharyngeal duct tumors. The finding of cyst at operation with the microscopic demonstration of stratified epithelium of the buccal type completes the diagnosis.

If drainage of the cyst type can be maintained, the patient can live for an indefinite length of time. If the cyst continues to enlarge, blindness usually results from pressure on the optic tracts, and death follows in a few months or years from brain pressure. On the whole the outlook for this type of tumor is bad as it is practically impossible to separate the cyst wall from the surrounding brain structures.

Three operations were performed by Kanavel by the transphenoidal route, the nose being reflected upward. The anterior wall of the cyst was removed together with some blood-stained fluid. The patient is still living one and half years after the last operation, and there has been no return of symptoms to date. E. H. POOL.

Royce, C. E.: Sarcoma of the Base of the Skull. *J. Am. Med. Assn.*, 9 6, 1914, 183.

Reported cases of sarcoma of the bones of the base of the skull are not numerous. Of twenty sarcomas in this region, 60 per cent occupied the middle fossa. They rarely progress toward the brain but invade the bones and sometimes send processes into adjoining sinuses. Disturbances of the cranial nerves gradually appear due to growth about the nerve-roots. Sarcomata tend to involve one side only if bilateral they are almost always carcinoma or endothelioma. Exceptionally bilateral growths may be fibrosarcoma or very malignant sarcoma. The author quotes Cantanetti's case of sarcoma of the sphenoid and reports a case of his own. In the latter there had been complaint of headache and disturbance of vision, ophthalmic examination showing optic neuritis with exudate. Decompression revealed nothing but increased intra-cranial pressure. At necropsy an encapsulated mass 9 cm. in diameter was found intimately connected with the periosteum covering the sphenoid bone. Section showed cells of spindle-shaped type, mitotic figures not being numerous, and tumor cells everywhere separated by reticulum of connective tissue. E. K. ANDERSON.

Black, D.: Cerebellar Localization in the Light of Recent Research. *J. Lab. & Clin. Med.*, 9 6, 1, 467.

The author points out that the general theory of cerebellar localization as originally formulated by

Bolk has been to a large extent confirmed not alone by experimental studies but also by careful clinical observation. Barany's localizations in the human cerebellar cortex remain yet to be confirmed in detail but the importance of his work in thus presenting a possible means of early diagnosis of cerebellar disease cannot be overestimated. Black further points out the contrast in the phenomena of motor localization characteristic of the cerebrum with those of the cerebellum and notes the fundamental differences between cerebral and cerebellar control. The cerebellar cortex has been shown to be practically indestructible as compared with that of the cerebrum over the motor area.

He points out that muscular representation in the cerebral motor is chiefly determined by the segmental point of the respective muscles and, broadly speaking, more distal muscles are represented in the upper portion of the motor area while the most cephalic groups are represented in the lowermost areas of the precentral region. On the other hand in the cerebellum, while the grouping of the tonus extensors has been determined in part by segmental points, their arrangement within the lobules has been chiefly determined by the functional association of muscular groups.

The cortex of the cerebellum is everywhere concerned in the elaboration of fine, rhythmic, and static impulses of recurring nature distributed for the most part homolaterally. A special part only of the cerebral cortex is concerned in the elaboration of impulses of voluntary motor clonic nature distributed heterolaterally.

Destruction of the motor cortex on one side of the cerebrum gives rise to a total paralysis of spastic nature in the musculature of the opposite side of the body while destruction of the cortex on one side of the cerebellum causes no paralysis but gives rise to atonia, astasia, and ataxia of the musculature on the same side of the body. GEORGE E. BEHRER.

Amberg, E.: Conduction Anesthesia in a Case of Brain Abscess. *T. Am. Otol. Soc., Washington*, 9 6, 1917.

The patient, 37 years old, had been ill for about ten days with severe pain. He had had middle-ear suppuration on the left side for sixteen years. Various mental tests with pencil, watch, keys, etc., showed that he recognized the objects but could not name them, and a diagnosis was made of intracranial complication of a chronic middle-ear suppuration.

The patient was removed to the hospital and a radical mastoid operation was performed and masses of cholesteatomatous material removed. Pus led the way upward and backward, and a small opening of the skull above and behind the external ear canal exposed a fresh pinkish-colored pachymeningitis. The patient was not benefited by the operation, and several days later an extensive opening was made adjacent to the small upper opening, about 1.5 inches backward and about .5 to 1 inch wide, exposing also the lateral sinus. Introduction of the

brain knife through the area of pachymeningitis to a depth of 1 cm failed to reveal anything of importance. The patient did not improve.

Four days later the dura which did not pulsate was incised vertically about half an inch behind the area of pachymeningitis and a Jackson brain searcher introduced forward upward and inward liberating about six drams of pus. There was no pulsation, no colon bacilli were found.

Two days later the brain scar her was introduced backward liberating about three drams of pus. There was no brain pulsation and not much improvement.

Several days later the process was repeated, the brain-searcher being introduced deeper and more forward over one ounce of pus being liberated. The brain pulsated and the patient's condition was improved.

Three days later more pus was liberated. Pulsation was good. The brain searcher was directed to a point about 0.5 to 0.5 inch above the eyebrow in the middle of the forehead and introduced to a depth of about 1.5 to 2 inches. About one ounce of foul smelling pus with gas was evacuated. A rubber drainage tube was introduced and there was a constant discharge. Fresh dressings were applied daily, the rubber tube being reintroduced the length gradually being shortened for about five weeks when the brain wound had entirely healed.

The patient's perception and recollection seemed to improve throughout the course of treatment. When shown objects such as a nail file, collar button he could recognize them but was unable to name them readily. He could write better than he could read. He wrote rapidly but was unable to repeat the words he wrote.

NI-29-5 C. C. McClelland reports: Examination of fundus with H & C drops pupils dilated fully and equally in usual time. Left eye details of fundus easily seen. Nerve head indistinct on nasal side, more clearly defined on temporal side. Right fundus about same as left.

NI-0 Total leucocytes 9,000 polynuclear 88.4 per cent blood-culture negative

NI-3 White 14,032 polynuclear 9 per cent

NI-25 Total white 14,100 polynuclear 9 per cent

NI-26 Total white 13,240 polynuclear 5 per cent

NI-7 Total white 10,666 polynuclear 16 per cent

NI-9 Total white 11,000 polynuclear 71.3 per cent

NI-7 Total white 12,000 polynuclear 68.5 per cent

NI-3 Cells in spinal fluid 17.3 per cent mononuclears

When heard from three months later the patient stated that he felt very well but that he tired out quickly and that he sometimes had headaches and dull pain in his head when he worked too hard.

Cope, V. Z. The Pituitary Fossa and the Surgical Methods of Approaching It. *Lancet* Lond. 9/6/00

A pituitary body is present in all vertebrates but only in mammals is there a specialized protection afforded by the skeleton. In the human embryo

the fossa is formed at an early stage a recess being observable in an embryo of 25 mm. The current statement that the transpharyngeal anal lies between the pre- and post-sphenoid is incorrect. The canal traverses the anterior part of the post-sphenoid. Radiograms of the skulls of children show that there is normally great variation in size and that there is no particular age at which peculiar increase in size occurs.

The size of the pituitary body is usually 11 mm long and 11 mm wide. The sella is lined by dura mater which is continuous with the diaphragma sellae so that the gland is hemmed in by a cuboidal box three sides of which are bone and three sides fibrous. The phenoidal sinus enlarges somewhere between the seven and the fourteenth year until the whole of the pre-sphenoidal area is excavated at which point the excavation may stop but it commonly proceeds back into the basopharynx. In the former type the pituitary body causes no bulge into the sinus while in the latter phenoidal type the bulge is always present.

The fossa is surrounded by a bony rim mounted by an arterial circle (Horsley & Willis). The venous circle is formed by the internal carotid and the anterior and posterior intercavernous sinuses. A pituitary growth ascending from the fossa enters the arterial circle pushing up the optic chiasma until the optic nerves are gradually strangled between the neoplasia and the arteries.

Abnormal tissue may be laid down, enlarged, reduced and deformed. Enlarged sella may be due to adenomatous overgrowth of the anterior part of the gland to malignant neoplasia originating in the fossa, possibly to repeated physiological enlargement due to increased functional activity and more rarely to a general or local hydrocephalus, chronic circumscribed meningitis or to tumors of other parts of the brain. Very small fossae are seen in cases of hypopituitarism associated with imperfect development of the gland. The fossa may be deformed by tumors butting from within or by interpeduncular neoplasms pressing down from above. In the former the nature of the deformity would depend upon the rate of growth producing a thinning, a cup-shaped outline or bony rim or all traces of the original shape. If the dorsum sellae or anterior or posterior clinoid processes are obliterated or markedly eroded, there must be a large intracranial extension to the tumor.

The pituitary fossa has been arrived at either directly through the cranium or indirectly through the facial skeleton the following table showing the routes which may be utilized.

CRANIAL

Temporal —

Intradural (Horsley)

Extradural —

Extradural (Braun)

Frontal (Krause)

Fronto-orbital (Frazier)

Callosal puncture

FACIAL

Nasal —

Septal resection (Schloffer, Hirsch)
West, Cushing, Kanavel,
Halstead, etc.)

Nasal —

Ethmoid resection (Hirsch)
Paranasal (Chiari, Kahler)
Palatal (Koenig Freytag)
Maxillary
Suprathyroid pharyngotomy

Of these operations only four have been done in sufficiently large number of cases to merit special attention.

Horsley's temporal method is done in two stages. A temporal bone-flap is made in the first stage, and in the second, the dura is incised and the temporal lobe lifted up exposing the lateral aspect of the pituitary body. In Schloffer's method approach is gained to the nasal cavity either directly through the anterior nares or by reflecting the nose, or by sublabial incision. Varying portions of the septum and lateral walls of the nasal fossa are removed to furnish more room; the sphenoidal sinus is opened and through it the pituitary fossa is approached. Hirsch and Cushing do a most ingenious subnasal septal approach, Cushing removing the vomer part of the median plate of the ethmoid, and a strip of septum. The attachment of the septum to the sphenoid being exposed, the anterior and lower walls of the sinuses are chipped away and the floor of the exposed sella turcica removed. Hirsch removes the middle turbinates some days before the chief operation. The fronto-orbital method of Frazer is begun by forming an osteoplastic flap in the frontal region; the roof of the orbit is removed as far back as the optic foramen; the orbital contents are displaced downward and outward; the frontal lobe is elevated and the dura incised for a sufficient length to expose the contents of the sella. Other operations have rarely been performed.

The nasal route of Schloffer is fundamentally unsound, as are all of its modifications, excepting the subnasal as the sella is approached through a region teeming with organisms or harboring foci of infection in adjacent sinuses. Considerable deformity of the external nose may follow also. The same objections hold against the palatal method which traverses the septic post-nasal space and also against the Chiari-Kahler approach through the ethmoid by external incision. Though Kahler has had some success with it it is too early to say much in its favor. The temporal method has been found practicable by one operator only but with a considerable mortality.

The only justifiable method of approach through the sphenoidal sinuses is that of Cushing or Hirsch, especially that of Cushing. Of 35 operations performed by the sublabial method by the latter operator but one death occurred. With this method special skill in working in such confined space is necessary as the surgeon cannot see what relationship his inserted spoon bears to the third ventricle. On several occasions it has been necessary to insert a metal clip for radiographic orientation purposes. A preliminary sounding of the sphenoidal sinuses is wise before undertaking this operation.

Facts in favor of the fronto-orbital method are that it provides an aseptic route, allows each step to be performed by the aid of sight and does not necessitate much dislocation of the brain as with the temporal method.

The most common indication for operation is oncoming blindness and it seems certain that in nearly all these cases there must be considerable intra-cranial extension. With the fronto-orbital method these enlarged glands present an easier object for attack. Some edema of the eye occurs after operation and sometimes the eyeball may not be left quite on the same level as the opposite one. The latter drawback should be avoided by greater care at the time of operation. The frontal sinus is sometimes in the way but by previous X-ray or transillumination it can be avoided.

While it is not possible to say which of the Hirsch-Cushing fronto-orbital methods is to be preferred, the author believes that the latter is more suitable in the majority of cases.

E. K. AMESBURY.

NECK

Wason, L. F. Quinine and Urea Injections in Hyperthyroidism. *V F M J* 916, 681, 79

The author briefly reviews some of the methods of recent years that have been instituted with the idea of controlling the hyperactivity of the thyroid gland. He emphasizes the necessity of rest, with proper dietetic and hygienic supervision as the foundation for any procedure in the treatment of hyperthyroidism and urges that the other ductless glands as well as the thyroid in each patient be studied; their rôle in contributing to the symptoms ascertained and treated accordingly.

The author recommends quinine and urea injections to relieve hyperthyroidism only and not to remove the goiter; however small, recent goiters usually disappear following the treatment. Much depends upon proper selection of cases. The technique is difficult and the method is suitable for use only in a hospital by men experienced in thyroid surgery.

The author describes an original method of raising the hyperthyroid patient's threshold to stimuli, by means of preliminary injections into the thyroid gland of a few minims of a sterile salt solution, followed by injections of sterile water given at one- to three-day intervals. When no hyperthyroid reaction follows the water injections their usefulness is at an end. If these preliminary injections are omitted, acute attacks of hyperthyroidism which might result disastrously are liable to

follow. It is important that the slight pain of the injection be minimized by the use of local anesthesia. It is important that the patient does not come to dread the injections because the best results are secured through prolonged periods of treatment.

E. H. POOL.

Marsh M. C. and Von Willer P. Thyroid Tumor in the Sea Bass (*Serranus*) *J. Cancer Research* 9: 6 1935.

The authors' contribution to the pathology of enlargements of the thyroid in fish is based upon five cases of thyroid enlargement observed in *serranus* (sea bass). The authors state that although thyroid tumors have long been known to occur in fish they have not been observed until recently outside the salmonoid group and only rarely outside of domesticated fish where they are endemic and widespread.

The only case known to have occurred in fish from marine waters besides the present specimens is the case described by Cameron and Vincent. This was in a small shark of the genus *squalus* of the Pacific coast of North America.

The authors report that of the five tumors one specimen was plainly colloid goiter, one was microscopically a step in advance toward epithelial increase of large alveolar type and shrinkage of the colloid content. In another the epithelial outgrowth was predominant over the colloid, the cells having become high columnar and the growth having taken on a definite adenomatous structure. In one case marked regression was indicated.

The growth in these specimens of *serranus* is not regarded as giving pronounced evidence of malignancy. Little infiltration is exhibited throughout the growth as a whole. In this respect the growths do not approach the process as exemplified in the fresh water salmonoids or in the case of *squalus*. The bodies of the fish were not examined for metastases. The authors believe the tumors to be true neoplasms representing early stages of processes which are of essentially the same nature as the other thyroid overgrowths in fish which have been the subject of investigation.

The authors call attention to the fact that iodine acting through the water medium even in great dilution has a marked action upon thyroid hyperplasia or more advanced overgrowth in fresh water fish, reducing the heightened epithelium, restoring colloid and effecting regressive changes in general. They claim that their specimens are of additional importance from the fact that the fish were removed from the sea to an aquarium supplied with sea water and were habitually fed with marine fish, chiefly the pilchard (*Diplodus pilchardus*). They received no mammalian tissues. They acquired the growths in sea water which contains a far greater concentration of iodine than that which is effective in reducing thyroid hyperplasia in fresh water fish.

E. H. POOL.

Gaylor H. R.: Further Observations on So-called Carcinoma of the Thyroid in Fish. *J. Cancer Research* 1916 1917.

The author reviews the literature of the so-called carcinoma of the thyroid in the salmonids.

The disease was first described by Bonnet in 1883. Although this author did not recognize its nature, Scott in 1901 regarded it as cancer and Plehn in 1902 recognized it as a neoplasm of the thyroid gland. In the same year it was described by Gilruth as epithelioma affecting the branchial arches. A comprehensive histological study based on some ten specimens of fish was made by Lick in 1905. The author's contributions to this subject date from 1908 with the description of conditions existing in a hatchery in which hundreds of fish were affected. The disease has been studied also by Marine and Lenhart beginning in 1900 and they consider it to be endemic goiter. Gaylor's studies were published in monograph form in 1914 and led to the conclusions regarding the nature, distribution and significance of the disease which are summarized in this article. Gaylor emphasizes the fact that the disease is endemic in a very high percentage of all trout hatcheries in the United States. He states that the occurrence of the disease in wild fish, its production in fish cultural stations, its localization in certain troughs of water supplies, the method of its spread, its transmission to mammals, the efficacy of three well known inorganic germicides in the treatment of the disease, the destruction of the agent by boiling and the phenomena of spontaneous recovery and immunity strongly indicate that the agent causing the disease is a living organism.

Gaylor states that as there is no line of demarcation between what is called endemic goiter and what may be considered as cancer of the thyroid, endemic goiter and carcinoma of the thyroid in the salmonoid are identical.

The cases found in sea bass by Marsh and von Willer, the thyroid tumor found in *squalus* or small shark by Cameron and Vincent together with the evidence which has been collected regarding the existence of thyroid carcinoma in fish living under natural conditions, and hence unaffected by overfeeding, overcrowding etc., strengthen the conclusion that the disease is not the result of artificial propagation. The occurrence of the disease in sea fish bears rather strongly upon that theory of thyroid hyperplasia which attributes it to a deficiency of iodine in the food or environment. In fact so far as fish are concerned the similar results obtained with mercury and arsenic would seem to show conclusively that iodine acts in a manner similar to the metals, and not by supplying a deficiency of iodine in the gland.

The observation that mercury, arsenic, and iodine when introduced even in small amounts into the water containing fish with thyroid tumors bring about a marked diminution in the size of the neoplasm, develops increased significance in the light of recent experiments reported by McCarrison.

In discussing the question whether the iodine acted as a purifier of the water especially as germicide or whether its effect was to be attributed to its supposed physiological influence upon the thyroid gland, McCarrison stated that he had obtained equally favorable results in the treatment of goiter with thymol; hence he was not inclined to attribute to iodine a distinctly physiological action in the treatment of goiter.

McCarrison's experiments do not show conclusively that iodine worked by destroying an agent in the water supply for the possibility still remains that it may have exerted some germicidal effect in the individual drinking the water. It is to be regretted, therefore, that he did not entirely substitute chlorination of the water for treatment with iodine. E. H. POOL.

Littl, E. G. Scleroderma Associated with Graves Disease, and Later Myxodema, Conspicuously Benefited by Implantation of Human Thyroid into the Bone-Marrow. *Proc. Roy. Soc. Med. 9 6 12 Dermal Sect. 69*

The case is described of a lady aged 51 who in 1900 presented the symptoms of Graves disease to a mild extent. In 1908 she developed myxodema. Her pulse rate, however, still continued to be 80 and her blood indicated marked anemia. Periods of irregular fever with urticarial swellings as well as pains in the shoulder and neck bothered her so much that she had to be carried in a chair. The scleroderma became evident in 1910 affecting chiefly the fingers, forearm, face and thighs. The stiffness became so extensive that she was greatly crippled. The mental accompaniments of myxodema, dullness and lethargy were conspicuously absent.

Implantation of thyroid was made into the tibia in 1912. Following this the scleroderma was much improved. She was taking sodium thyroxine at this time. In 1913 a second implantation of thyroid tissue was made. In 1913 pyorrhea alveolaris was diagnosed. After having all her teeth removed, there followed a remarkable change in her general health and appearance an improvement which has been steadily maintained. At present the fingers have become flexible enough to permit her to play the piano. The skin of the face is supple and otherwise normal. H. G. SLOAN.

Gronnerud, P. The Technique of the Enucleation Thyroidectomy. *Illnesses of J. 9 6 2212 59*

This operation will be found practically applicable to all parenchymatous goiters, whether of the cystic, colloid, fibrous, or mixed variety but should never be attempted under the vascular or active hyperplastic enlargements. It is a method very largely eliminating the use of clamps and accompanied by minimum loss of blood, never followed by nerve complications and when even mediocre surgical

judgment is available, of extreme breadth in application.

The usual low skin incision is made. The fascia is raised slightly and cut parallel to the contained veins and the cleavage line between the revealed edges of the sternothyroid and sternohyoid muscles observed. These muscles are separated and retracted, revealing the encapsulating fascia of the gland. It will thereupon appear that the true capsule of this organ blends with the so-called Kocher fascia and is very rich in arteries and veins. When the anterior fascia, which is comparatively free from large vessels, is opened the thyroid capsule will be seen. No clamps are used in these procedures, hemorrhage so far being slight and automatically ceasing on the correct separation of the tissue layers. The true capsule is then opened laterally, and, by posterior pressure, the tumor delivered. The tumor may be eviscerated without difficulty leaving a comparatively bloodless bed which depicts the arrangement of vessels in the true capsule.

In 98 thyroidectomies in which the above technique was followed the application of clamps to the inferior thyroid artery was necessary in two cases, but being inside the capsule no injury to the nerve was possible. Necessity for clamping the superior thyroid artery did not arise. EDWARD L. CORNWELL.

Purwen, W. J. and J. W. and Eggstein, A. A. Serum Changes Following Thyroparathyroidectomy. *J. Exp. Med. 9 6 1000, 499.*

The experiments here recorded were made on dogs. Thyroparathyroidectomy was performed in fifteen animals, and the serum changes were studied. The following two experiments were typical of the relations noted.

On the first dog weighing 5 kilos complete thyroparathyroidectomy was performed June 9 5. Tetany was observed on the third day following the operation. On the fourth day the dog showed no symptoms but on the next day (June 5) there was marked tetany. The animal was found dead the following morning.

On the second dog weighing 8 kilos complete thyroparathyroidectomy was performed June 8 915. Tetany was noted on the afternoon of June 10th again on the following afternoon, and the next morning (June 11) when the animal was killed.

In the first dog there was a gradual increase in the antiferment titer until the time of death with an irregular protease curve. The maximum protease activity was noted in the animal during the time when the tetany was most apparent. The non-coagulable nitrogen of the serum increased to more than twice the original amount. The lipase remained constantly low. The proteases increased markedly. The amino-nitrogen of the serum in this animal showed no change except an initial decrease.

In the second experiment the conditions were different. The antiferment titer showed marked fluctuation the first decline appearing shortly after the operation. The protease remained low

until the last day but the non-coagulable nitrogen increased as in the previous animal the proteoses also accumulated during the period of tetany. The increase in amino-acids was similar to that observed in practically all the other animals during tetany. This was the only animal of the entire series in which a rise in the lipase titer was observed.

From their study the authors draw the following conclusions:

1. In thyroparathyroidectomized dogs the onset

set of tetany bore no constant relation to the permanent antiferment balance of the serum.

2. The serum lipase titer remained at a low level throughout.

3. A progressive increase in non-coagulable nitrogen and proteoses was observed in the serum following the removal of the glands.

4. The amino-nitrogen of the serum was usually increased at the time when tetany was most marked.

(CLARK & E. BELL)

SURGERY OF THE CHEST

CHEST WALL AND BREAST

Menzies, J. L.: Notes on a Series of Seventy-five Gunshot Wounds of the Chest. *Brit. J. Surg.* 9: 611, 1916.

The statistics of a series of 75 cases of gunshot wounds of the chest are reported by the author, and 12 of the more interesting cases are described in detail.

The most notable feature of the series is the rapid recovery where there was no destruction of the chest wall as compared to the high mortality in cases with open wounds. Where the pleural cavity communicated with the outer air the results were almost uniformly fatal.

The symptoms are pain, shock, dyspnea, and hæmoptysis and are due to damaged lung tissue and the resulting escape of blood and air into the pleural cavity. Pain is always present but is rarely severe. On the other hand shock is usually pronounced. Dyspnea is almost always present and is most severe immediately following the wound abating within twelve to twenty-four hours.

Hæmoptysis occurs in the majority of cases, seldom, however, being severe and lasting only two or three days. In the series 2 had no bleeding in 40 it came on immediately after injury and in 8 it was delayed from one to twelve hours. In all cases there was a rise of temperature.

In the base hospital dyspnea and pyrexia are the prominent symptoms depending on the presence of an effusion and whether it is sterile or septic, the amount of effusion determining the degree of dyspnea. In the series effusion took place in 70, 40 were sterile, 10 showed slight infection and 11 marked infection.

Pneumothorax was present in 14 of the cases, in 8 it communicated with the outer air. Surgical emphysema was present in 12 and required no treatment. Twenty-seven cases were discharged as cured with the missile retained but causing no symptoms.

The cases were divided into those with wounds which were healing or healed and those with wounds opening into the pleural cavity at admission. There were 6 cases in the first class and 8 in the second. Those of the first class were much more

favorable for treatment. 66 recovered and 1 died of sepsis. The majority of effusions were bacteriologically sterile.

In the second class the results marked destruction of the chest wall, all were infected (pyohæmopneumothorax) and the mortality was very high. Of 8 cases 7 died. Autopsies show that the invasion of the lung with lung abscesses preceding from the track of the bullet.

In the entire series 6 recovered and 5 died, the deaths being due to sepsis.

In the treatment rest is a paramount morphus being used as a sedative.

When the effusion is sufficient to breathe it may or may not be removed depending upon the case. If left alone recovery is prolonged.

If the effusion is infected early drainage is indicated, resection of a portion of a rib with a large drainage tube giving the best results. With a large empyema cavity the prognosis is grave.

Early rising with general and breathing exercises was found most beneficial.

(P. M. CLARK)

Newbolt, G. P.: Clinical Lecture on Cancer of the Breast. *Med. Press & C.* 316.

In the author's opinion three reasons still militate against cancer of the breast: (1) bad advice of the family physician, (2) failure of the patients to report the presence of the tumor, (3) disinclination on the part of the patients to have the radical operation done. Another factor which influences the laity to believe that the tumor is not cancer is the fact that it is not painful.

The author lays stress on the fact that the nipple need not necessarily be retracted in cancer of the breast. He thinks that where the supraclavicular glands are involved the outlook is extremely grave, and the prospect for cure quite remote. The prognosis usually depends upon the stage of the growth at which removal is undertaken as well as the age of the patient. The prognosis in young and healthy persons is bad. The best results are in women over 50. In males the outlook is extremely poor. Attention is called to the frequency with which metastasis occurs in the opposite breast, sternum, spine, and hip.

(H. G. SLOAN)

Gatewood. Tuberculosis of the Mammary Gland. *J. Amer. Med. Ass.* 9 6 xiii, 72.

The author credits Astley Cooper with having described the condition in 1829. Dugar in 88 first described the disease microscopically. Deaver collected 94 cases which were reported between 19 4 and 9 5 and Durante collected 150 cases in 9 4.

Tuberculosis of the breast has been classified into primary and secondary groups. The primary group comprising only those cases in which the disease was limited clinically to the breast and the glands of the axilla. In that class there are no post mortem has been made in which the condition was so localized. Gatewood is of the opinion that all cases of tuberculosis of the breast are but secondary manifestations of tuberculosis elsewhere.

In the majority of cases the bacillus reaches the breast through lymph channels, probably retrograde embolic process. The disease usually occurs in the female breast. No cases have been observed before puberty cases usually occurring between the ages of 3 and 50. The most frequent initial lesion is a painless lump in the breast. Any patient presenting a lump in the breast and complaining of pain in the region of the tumor on deep inspiration should be radiographed for tuberculosis of the ribs.

The progress of the disease is usually rapid. One breast is involved as a rule. The lymph-nodes are enlarged in from 60 to 70 per cent of the cases.

Fistulae, retraction of the nipple, and enlarged lymph-glands on the affected side are the most constant physical findings of the disease. The majority of the cases present tumors they may be discrete, disseminated, or become confluent. The consistency varies with the amount of liquefaction and caseation. The skin becomes adherent to the mass and assumes a dark red appearance. This is followed by a rupture, discharge of caseous material and sinus formation.

Tuberculosis of the breast must be differentiated from syphilis and actinomycosis. Potassium iodide is almost specific for both.

The treatment of tubercular mastitis is surgical. The after-care is important. The use of boric acid is of questionable value. **IMMOBILIZATION**

Robinson, S. Treatment of Chronic Non tuberculous Empyema. *Surg. Gynec. & Obst.* 9 6 xiii, 557.

Three types of cases are mentioned: (1) those with an operative drainage wound; (2) those with leakage through a *necessitatis* opening; (3) those with bronchial drainage. Several types of cavities are described and illustrated: lateral cavities, small and large, anterior cavities, posterior cavities, cavities in the upper thoracic segment, multiple cavities designated as generally fatal. A preliminary drainage operation regardless of previous openings is imperative at least six weeks previous to any operation for cavity obliteration. Operations for

obliteration should be without mortality. The Estlander-Schede, Wilms-Delorme-Fowler, and Sudek methods all possess advantages and also sources of error.

Muscle implantation may be employed in cavities of moderate size utilizing the latissimus dorsi muscle dissected from the Schede U-shaped flap. The operation is preferable to those requiring partial resection of the scapula, described by Sudek and others, the latter producing limitation of shoulder motion.

Another operation is described involving the infolding of lateral skin and muscle flaps with exposure of the entire cavity for subsequent skin grafting or suture granulations and epithelialization. Surgical success depends upon the choice of a single method or a combination of methods applied with accurate knowledge of the extent and location of the cavity and with conservatism in the number of operative stages. The non-operative treatment of chronic empyema such as vaccine therapy and antiseptic injections, produce symptomatic relief and a diminution in the discharge but the relief is more apparent than real. These treatments are frequently misapplied and generally serve unnecessarily to postpone obviously indicated surgical therapy. Bismuth and vaseline injections (Beck) possess no definite curative value in cavities primarily small or reduced to suitable dimensions by paracentesis.

Ewing, J. The Thymus and Its Tumors; Report of Three Cases of Thymoma. *Surg. Gynec. & Obst.* 9 6 xiii, 46.

The thymus reticulum is composed of modified epithelial cells, while the parenchyma cells are lymphocytes which have wandered into the stroma from without. The evidence indicating the derivation of thymus parenchyma cells from the epithelial stroma is unsatisfactory.

General pathological conditions affecting the thymus include aberrancy of thymus tissue in thyroid, simple hyperplasia in status lymphaticus, Graves disease, and simple lymphadenoma, exfoliation of reticulic cells in leukemia and infectious cysts and neoplasms. Cysts arise from persistent embryonic epithelial canals, from branchial and ventral ectoderm, from distended softened Hassall's corpuscles and from lymphangiomata.

Neoplasms include round-cell growths, commonly classified as lymphosarcoma and tumors composed of flat or cylindrical epithelium. There are rare myxosarcomata of congenital origin, but malignant tumors arising from the connective tissue probably do not occur.

The so-called round-cell tumors, properly called thymomata, are derived from the epithelial stroma cells, and may be distinguished from true lymphocytomata of lymph nodes. The cells are not round lymphocytes but polyhedral or cylindrical, or giant derivatives of the stroma cells. The same variations in structure are observed as in Hodgkin's

granuloma and reticulum-cell sarcoma of lymph nodes. The clinical course of these tumors also varies from the character of a progressive granuloma to that of a highly malignant locally aggressive neoplasm which may produce widespread extensions and metastases. A notable feature is perforation of the chest wall. The anatomical position and peculiar structure usually permits a satisfactory diagnosis. Thymic carcinoma includes those tumors composed of pavement, cubical or cylindrical epithelium, but there is no sharp dividing line between the two groups and both arise from the reticulum cells. The parallel existing between thymic granuloma and thymoma on the one hand and lymphatic Hodgkin's disease and reticulum-cell sarcoma on the other suggests that in both organs an infectious agent initiates an infectious process which often runs into a neoplasm. Most reported cases of the transformation of Hodgkin's disease into sarcoma relate to mediastinal and probably thymic tumors.

The reported cases include a rapidly progressive febrile case with very extensive invasion of the neck, chest and axilla by a tumor of diffuse structure, a perforating sternal tumor of two years' progress structurally resembling Hodgkin's granuloma, regressing under X-ray and a slowly progressive thymoma of granulomatous type limited to the mediastinum and showing polyhedral reticulum cells and Hassall's corpuscles.

TRACHEA AND LUNGS

Moore A. B. and Carman, R. D. Radiographic Diagnosis of Metastatic Pulmonary Malignancy. *Am. J. Roentgenol.* 1916 11: 116

The authors give a report based on 71 positive cases examined at the Mayo Clinic by both clinical and radiographic methods.

LOCATION OF PRIMARY FOCUS IN CASES SHOWING RADIOGRAPHIC EVIDENCE OF METASTASES IN THE LUNGS

	% Cases
Total number tabulated	71
Breast	20
Thyroid	8
Kidney	5
Soft tissues of forearm and shoulder	6
Soft tissues of leg and thigh	6
Soft tissues of neck and face	5
Uterus	2
Esophagus	2
Prostate	2
Testicle	2
Hard palate	1
Larynx	1
Sigmoid	1
Adrenal	1
Lung	1
Abdominal and pelvic masses	4
Origin not determined	4

Men	32
Women	39
Average age	45 5 years
Average time since growth was noticed	2 25 years
Histologic examination	59 cases
Carcinoma	40 cases
Sarcoma	16 cases
Hypernephroma	3 cases
Enlargement of superficial glands	35 cases
Enlargement of deep glands	8 cases
Other foci of metastasis	14 cases

Apparently no idea as to the presence of pulmonary metastasis can be gained from the extent of the primary growth. Many cases with extensive involvement showed no metastasis while in many the primary growth was small and clearly operable except for the radiologic evidence of metastasis.

Fourteen of these cases showed metastasis in organs other than the lungs or lymph nodes. The other organs most frequently involved were the liver, bones and brain.

Of the patients operated on 42 had been subjected to surgical procedure for the removal of the primary growth of these 10 showed local recurrence. The average time from the operation to the discovery of the metastasis was 15 months.

Cough was present in 32 cases. It was usually dry hacking and unproductive expectoration having been noted in but 8 cases. Only 3 gave any history of blood spitting. The so-called prune juice sputum, regarded by some observers as indicative of this condition was not observed.

Dyspnea occurred in 30 cases. It was usually progressive and, when marked, tended to be spasmodic in character quite often simulating asthma.

Pain referred to the thorax was noted in 14 instances, usually described as gnawing and not influenced by respiration.

There was both clinical and radiographic evidence of pleural effusion in 12 of the cases.

A very striking feature was the relative absence of definite physical findings.

The conclusions are:

1. Pulmonary metastatic malignancy is not an uncommon condition and may occur regardless of the seat of primary focus.

2. Pulmonary metastasis bears no relationship to the extent or duration of the primary focus.

3. The clinical picture in a majority of these cases is very indefinite neither the subjective nor the objective manifestations being characteristic.

4. Metastatic pulmonary malignancy is a definite roentgenographic entity appearing in the roentgenogram as clear-cut circumscribed areas of increased density.

5. In many instances the diagnosis can be established only by the roentgenogram. By routine roentgenographic examination of the thorax many patients suffering from malignancy will be saved from useless and unwarranted surgery.

DAVID R. BOWEN

PHARYNX AND ESOPHAGUS

Hirsch, I. S. The Roentgen Ray Study of the Esophagus. *Intern. M. J.* 9 6 xiii, 42

Hirsch's paper is comprehensive. For a contrast mixture he uses a tablespoonful of bismuth subnitrate (subnitrat) stirred for about ten minutes with a teaspoonful of m. dilage of acids. The resulting mass is viscous and by coating the walls of the esophagus outlines its lumen. The examination is essentially fluoroscopic but plates are also made. The oblique view either of noventral or ventrodorsal, is emphasized. Two periods in the act of swallowing the buccopharyngeal and the esophagogastric may be differentiated. The bolus is propelled by the pharynx into the esophagus with great force and rapidity. It is carried through the esophagus by peristalsis. Solid food is carried down solely by peristalsis, while liquids are ejected from the pharyngo-esophageal junction (int. ostium) to the cardia. The wave is deepest in the lower esophagus where it is necessary to overcome the sphincter action at the cardia.

Foreign bodies are most frequently impacted at four points opposite the cricoid cartilage above the arch of the aorta, at the crossing of the left bronchus and at the diaphragm.

Two great classes of spasm may be differentiated the primary so-called idiopathic spasm, the etiology of which is not clearly understood and the secondary spasm, the reflex of irritation inflammation or laceration. The former affects the lower end of the gullet and leads to dilatation the secondary spasm may involve any part of the lumen. Spasm is indicated by the arrest of the bismuth in a cone-shaped shadow at the constricted point. In the primary cases with dilatation there may be rapid deep peristaltic waves moving to the base with occasional regurgitation. The outline is smooth and symmetrical above the point of obstruction.

Benign or scar stenosis is usually asymmetrically situated, while the extent of the stenotic area is short. Stenosis due to corrosives is most frequently found either at the pharyngeal mouth or in the upper dorsal part of the tube.

The commonest form of stenosis is that due to carcinoma. At least 70 per cent of patients complaining of dysphagia have this disease of the gullet. As a rule these tumors involve but a part of the surface of the tube rarely do they involve its entire circumference. This account for the irregular asymmetrical filling defect. Dilatation above it is never marked. Peristalsis is absent over the invaded area and distal to it.

Syphilis of the esophagus resembles cancer roentgenologically excepting in regard to the multiplicity of the lesions.

Diverticula are of two varieties, pulsion and traction. The former are most common are situated high, near the Introitus and appear as pouch-like adjuncts to the esophageal lumen.

ALBERT MILLER.

Moore, J. The Removal of Foreign Bodies from the Esophagus and Bronchi; with a Description of Some New Instruments. *Lancet*, Lond., 9 6 Oct. 99

The author has designed a new non-slippping forceps for removing foreign bodies of any description. The blades are shaped on the principle of crab claws the upper blade being curved and having at its extremity a triangle tooth which fits between two similar ones in the lower blade. Both blades are transversely serrated giving greater security to their hold on a foreign body. They are in addition grooved down the center so as to prevent any lateral slipping. He has also devised an endoscopic cutting forceps or shears which combines both the grasping action of forceps and the cutting action of shears.

OTTO AL. ROTT

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Sampson, H. H. Clinical Notes on Penetrating Wounds of the Abdomen. *Brit. M. J.* 9 6 1, 547

The extent of the visceral injury caused by rifle bullet in the abdomen depends to a large extent on the distance the bullet has traveled before the impact. The most extensive wounds are caused when the range is less than five hundred yards.

The importance of primary hemorrhage lies in the fact that there is little tendency toward spontaneous arrest. When seen three or four hours after the receipt of the injury small arteries in the wounded bowel are still spurting vigorously. In fatal cases death is almost invariably due to primary hemorrhage. It becomes obvious, therefore

that on this account also, every effort should be made to convey the abdominal wounds with the least possible delay to a place which is equipped for operative treatment.

One case is reported in which a bullet traversed the peritoneal cavity in an area occupied by intestines without causing perforation of the viscera with which it must have come in contact.

Wounds of the small intestine are generally multiple but are usually confined to one segment of the bowel. Wounds of the colon are often complicated by injuries to other viscera. These cases show a high mortality. If however the injury is confined to the colon, the outlook is more hopeful, provided operation is performed before a widespread peritoneal infection has occurred.

Wounds of the stomach bleed freely but if un complicated respond well to operative treatment. Wounds of the liver give the best results. In simple perforations hemorrhage is slight bile drains away for a few days recovery is the rule.

The spleen is seldom injured alone. Its injury is often associated with that of the left kidney, pleura and lung.

J. H. SKILES

Fraser, J. and Bates, H. T. Penetrating Wounds of the Abdomen. *B. I. M. J.* 9, 6, 509

The authors report the operative results in penetrating wounds of the abdomen and discuss their observations in these cases.

In wounds of the stomach the degree of damage depends on the nature of the projectile and the part of the stomach injured. Shell fragments produce the most extensive destruction while bullets generally behave as in other soft tissues, i.e. small entrance wound and larger exit wound. Bullet wounds of the center of the stomach produce the least destruction; those of the pylorus quite extensive laceration while those of the greater or lesser curvatures are accompanied by widespread splitting and tearing of the tissues. Hemorrhage is not severe unless one of the larger vessels is ruptured.

Clinically this class of cases shows pain, sickness, collapse, abdominal rigidity and tenderness, the sickness being more pronounced than is usual and the collapse less marked. The pulse and respiration rates are increased, the latter proportionately more rapidly than the former. Pain is more pronounced when the pyloric or cardiac ends are involved and collapse more marked in wounds of the curvatures.

In the operative treatment the authors employ a left rectus incision, occasionally enlarging it laterally. When the situation of the wound is doubtful an incision parallel to the left costal margin is used. After rigid inspection one of three lines of treatment is instituted: (1) simple suture, (2) gastro-enterostomy or (3) pylorotomy with partial resection depending on the conditions found.

Six illustrative cases are described, 3 of which died, 2 recovered and one was unoperated. Suture was used in 3 cases, gastro-enterostomy in one, and resection in one.

Bomb fragments wounding the small intestine cause small multiple wounds with invaginated edges and a marked tendency to surrounding hemorrhage. Bullets traveling at high velocity cause small equally sized perforations at low velocity they cause considerable destruction of tissue. Wounds by shell fragments are usually quite extensive. Wounds of the free edge of the gut involve more tissue destruction than those of the fixed or mesenteric border.

Bleeding from the small intestine is usually severe especially in the jejunum and mesenteric hemorrhage is always progressive. It was also observed that the less the damage to the gut the

more likelihood there was of extensive peritoneal soiling. Massive injuries inhibit peristalsis.

Bullet wounds of the buttocks, it is noted are liable to be followed by evidences of injury to abdominal viscera.

Clinically these cases show signs of beginning peritonitis coupled with those of hemorrhage, the symptoms of bleeding coming on at first followed by those of peritonitis. The abdominal rigidity when bleeding is profuse often disappears.

The author advocates the routine incision and a complete inspection of the entire small gut before deciding upon the best method of procedure. The various methods are: (1) simple suture, (2) resection followed by lateral end-to-end anastomosis, (3) resection and temporary enterostomy.

With simple suture it was found essential that the wound be small, edges undamaged and mesentery intact. Wounds by bomb fragments are ideal for suture. The wound edges are not excised and linen thread was used.

The indications for resection and anastomosis are: numerous perforations, extensive size and degree of injuries and involvement of related mesentery. This procedure is highly favored by the authors. They also prefer the lateral anastomosis as being less likely to be followed by paresis and distention of the proximal segment.

Resection and enterostomy are only indicated as an emergency measure in rapidly developing collapse during operation.

A synopsis is given of 21 illustrative cases, 7 died, 14 recovered and 1 was unoperated. Suture was done in 5, resection in 13 and enterostomy in one.

In wounds of the colon the effects of the different projectiles are similar to those in the small gut with the exception that the septic material is much more likely to be walled off by adhesions. Peritonitis from such wounds however is intensely virulent.

Clinically the symptoms are likewise similar to those of wounds of the small intestine except in not being so widespread and with an absence of early sickness or nausea.

In the treatment if the case comes to hand later than twenty-four hours enlargement of the original wound and drainage is the best plan on the possibility that the infection is becoming localized earlier it is wisest to open the abdomen through a separate incision. The methods best adapted to this class of wounds are simple suture and simple suture with colotomy, resection not being deemed advisable. Drainage of the retrocolic space is always recommended.

A synopsis of 12 illustrative cases is given, 7 died and 5 recovered.

In wounds of the spleen the presence of free fluid in the abdomen, evidences of hemorrhage and the exit and entrance wounds diagnose the condition.

Splenectomy is usually indicated.

Two cases are reported with one death and one recovery.

Wounds of the liver, gall bladder and ducts are usually complicated by damage to the overlying lung or pleura. It is not usual to have much destruction or disruption of tissue in wounds of the liver and post-traumatic jaundice is uncommon.

The clinical symptoms may be remarkably absent, the lung symptoms frequently disguising the abdominal condition. Abdominal rigidity, increase of pulse, and temperature and pain over the liver were observed.

Cases showing progressive hemorrhage or complications of other viscera only were operated.

A synopsis is given of 14 cases all of which recovered.

In kidney wounds, extensive organic disintegration may occur with merely slight wounds. Hematuria may or may not occur in severe injury the kidney pelvis is usually blocked by a blood-clot.

Treatment consists in (1) simple drainage (2) kidney suture, and (3) nephrectomy.

Three cases are reported, all of which recovered, simple drainage being used in two and nephrectomy in one.

In wounds of the bladder it was observed that intraperitoneal wounds are usually complicated by injuries to the rectum and small bowel, and that a non-penetrating wound of the abdominal wall may cause rupture of a full bladder. Clinically the symptoms were the usual ones of bladder injury. Drainage, suprapubic, urethral, perineal, was indicated. Four cases are reported with one recovery and three deaths.

In wounds of the rectum the entrance wound is usually in the buttocks and, as a rule, fracture of the pelvis and injuries to the small bowel complicate the case. Hemorrhage is profuse, and appears from the rectum as well as internally. The treatment is that of the complications. Two cases are reported with two deaths.

The conclusions are as follows:

1. In the majority of penetrating abdominal wounds operation offers the best chance of success. Spontaneous recovery rarely occurs.

It is advisable to wait one or two hours for symptoms of shock to abate unless evidences of progressive hemorrhage are found. Warmth and 1 cc. of pituitary extract are used.

3. Three to four pints of saline administered subcutaneously during operation and closed ether anesthesia are to be recommended.

4. Careful abdominal inspection and examination before instituting treatment is advisable.

5. In early cases of extensive peritoneal soiling the abdominal cavity is to be washed out. After peritonitis has set in, drainage only should be used.

6. Speed and every possible avoidance of shock are important factors.

7. Post-operative rectal saline and subcutaneous infusions are to be recommended.

8. The prognosis depends on the degree of injury

and the time elapsing before treatment is instituted. Early operation offers the best and surest chance of ultimate success.

P. M. CHASE.

Abadie, J. The Treatment of Penetrating Wounds of the Abdomen (A propos d'un traitement des plaies pénétrantes d'abdomen). *Bull. et mém. Soc. de chir. Par.* 6 6 111 480.

The author reports on two series of observations: those treated by laparotomy and those which recovered in spite of non-interference and in which the proof of penetration had been made either by X-ray or by visible wounds.

Laparotomy was performed on 5 cases in 9 months, including cases tangential to the peritoneum, univisceral intestinal perforation, laceration of the liver, laceration and perforation of the intestines, perforation of the rectum, bladder and small intestine, all these cases recovered. The cases upon which a laparotomy was performed and the individual succumbed included multiple sectioning of the small intestine, rupture of the urethra, perforation of the colon, crushing of the cecum, perforation of the iliac fossa, and double perforation of the bladder.

It is generally admitted that wounds made by bullets are less grave than those inflicted by fragments of Howitzer shells. However, the proportion of cases wounded by one or the other means, depends upon where and how the fighting is carried on. The method of fighting in trenches closely situated explains the rarity of bullet wounds, and those occurring are extremely severe due to the short distance. The author has never seen a case of a wound of the buttock with abdominal penetration recover without actual interference; the peritonitis reveals the seriousness of small orifice (an anodic appearance). The presence of perforations or lacerations of the vesicle aggravates the prognosis considerably. One of the author's cases on whom he operated recovered, three died.

Whether or not to operate at once in shock or to postpone the operation is a question of considerable importance. Frequently the wounded have to be carried for a distance of 100 meters, and as the shock reveals two essential causes, severe hemorrhage or nervous shock, the selection of treatment is momentous. A hemorrhage that has allowed a patient to be carried 5 kilometers could be modified momentarily in its effects by injections with serum and adrenalin. The nervous shock can assuredly be lessened by tonics. The method pursued by the author consists in immediate injection with camphorated oil, either morphine, if the wounded suffers intensely, abundant injections with serum and mg. of adrenalin. If intravenous injection is indicated, it should be given liberally. The injection with serum is continued even during the operation if it is indicated by the patient's pulse. In the majority of cases the author has poured 100 to 150 cc. of ether into the abdominal cavity, notably the pelvic cavity, the anus are cleaned by means of compresses im-

hibited with warm serum in two cases he has replaced the ether by salt solution. Pelvic drainage has been practiced in all cases but one sometimes a second drain is inserted toward the lesions. For lateral and terminal anastomoses the author praises the efficiency of the coupled forceps of Temoin.

Post-operative care consists in absolute diet Fowler's solution by the drop method rectally. A maximum absorption of 4 to 5 liters a day is considered sufficient.

The author recommends the establishment of surgical stations near the front systematic arrangement in the immobilization of surgical ambulances for a small place especially for laparotomies during fighting specialization of a unit for that purpose where the number of units is sufficient if not sending a reinforcing unit with assistants and all the material necessary for efficient treatment.

The author believes that the treatment of choice for penetrating abdominal wounds in war as well as peace is laparotomy. RAOUL L. VIGORAN

Lancet T. F. The Acute Surgical Abdomen. *Med R.* 9, 6, 1918, 648.

The author's paper is based on a recent series of unselected acute abdominal cases operated on by him at the St. Laurence Hospital, New York, most of them desperately ill, such as one finds coming into an emergency service by ambulance. He makes a special plea for the early recognition and prompt operative procedure in this class of cases.

The following is a classification of this series of 30 acute abdominal lesions:

In Group A, in 19 cases, or 63.3 per cent of the total, the appendix was the offender. Of these cases 8 had had one or more previous attacks. In 6 cases the inflammatory process had not extended beyond the walls of the appendix, that is they were operated upon early. In 6 cases of appendicitis the damage had extended beyond its origin, causing a local peritonitis with limiting adhesions. In 3 cases diffuse peritonitis had resulted from delay in submitting to operative interference. Of these 19 cases of appendicitis only 6 were seen early that is before the infection had extended beyond the appendix.

In Group B, in 5 of the total cases the uterine adnexa were at fault.

In Group C, in 3 cases the biliary passages were the site of the lesion.

In Group D, there were 3 acute operative cases: a case of abscess between the layers of the mesentery of the small intestine; a subdiaphragmatic abscess of the left side, traumatic in origin; and a case of diffuse peritonitis thirty hours after perforation of a duodenal ulcer.

The leucocyte count proved valuable, especially in cases with little or no elevation of temperature, low pulse rate, and slight abdominal signs, as in many of these cases the increased total count or preponderance of polymorphonuclear cells in the

differential count was the only evidence of the seriousness of the lesion.

Abdominal muscular rigidity, pain and tenderness and a blood picture that shows a high total white cell count and a high percentage of polymorphonuclear cells in the differential count, either one constitute the essential trial for demanding operative exploration of the abdomen. The only exception would be in a case where the surgeon was sure that these signs were due to a gastric salpingo-oophoritis which should be treated conservatively at the beginning. EDWARD L. CORNELL

Crispin E. L.: Visceral Crises in Angioneurotic Edema. *St. P. J. M. J.* 1916, 11.

A large number of patients suffering from visceral crises, particularly of the erythemic, purpuric, angioneurotic group, are advised to undergo surgical operations.

The author calls attention to this group of cases and discusses the diagnostic importance of visceral crises more from the standpoint of value in negating or avoiding surgery, which does not give relief than from the standpoint of too closely differentiating interrelated medical conditions.

Severe abdominal pain, which does not conform to the true surgical types, may be confused with visceral crises for which surgery would be of no benefit.

When a history of severe abdominal pain is given which does not conform to true surgical types, careful inquiry should be made as to the presence at any time of urticaria, erythema, purpura, and swellings of angioneurotic edema types.

A history of recurrent severe abdominal pains with constancy in the nature and duration of the attacks with skin manifestation of any of the exudative erythemic forms, with or without noticeable association with the abdominal pains, should excite suspicion as to the presence of crises of angioneurotic type.

A diagnosis of visceral crises of angioneurotic type should not be made until careful examination has excluded or made independent surgical causes. In this roentgenologic examination of the gastrointestinal tract is valuable negative evidence. Syphilis and tuberculosis should be excluded.

The constancy in the recurring attacks of pain not conforming to surgical types in patients who have had skin manifestations of the exudative erythema group and whose general condition does not account for the suffering they have had to bear, will warrant a diagnosis of visceral angioneurotic edema.

Repeated or even single attacks of intestinal colic, with tumefaction, in which the patient's general condition is too good for the extent and severity of the trouble and in which history of swellings can be obtained may be of this type. To wait is good surgery. The rapid return to health is strongly suggestive of visceral angioneurosis.

Having determined the medical nature of these

gioneurotic visceral crises even in these cases of agoneurotic edema or the entire exudative erythema group, we should endeavor to work out the sources of toxemia. These may be foci of pus in the upper respiratory tract and sinuses, bacterial absorption, idiosyncrasies to heat, cold, chemicals, parasites, carbohydrates, or proteins that are the causes for anaphylaxis.

Removing the causes for anaphylaxis whether it be idiosyncrasy in one patient for ice cream—some constituent or the cold—banana in another alcohol in a third, or any anaphylactic base or source of exogenous or endogenous irritation or poison, may give the patient relief that the advised surgery would not have given him.

EDWARD L. C. SMELL.

Makins, G. H. A Study of the Symptoms and Complications of Gunshot Wounds of the Solid Abdominal Viscera. *Brit J Surg* 9 6 44, 643.

The author reports his observations on a series of gunshot wounds of the solid abdominal viscera, these observations were made in a base hospital and do not include the immediate results of the wounds.

In wounds of the liver especially those made by bullets, in many cases no evidence of liver injury is detected except that afforded by the course of the missile, provided the bullet or no large vessels are injured. Thirty-seven cases only are reported on the grounds that the liver wound was the chief element and as illustrating the varying degree of gravity which lesions of this organ may assume.

Two classes of wounds were observed (1) those of a rupture due to contusion and (2) simple perforations. The liver offering considerable resistance as it does, is frequently comminuted or ruptured.

The most common course of the missile is transverse. Of the 37 cases, 1 were transverse. Also the simple furrows often give rise to more trouble some and persistent hemorrhage than the perforating wounds.

Shell wounds are usually most extensive they frequently give rise to secondary hemorrhage, and almost invariably are seriously infected from the start. Under these circumstances it is the rule to have progressive necrosis and sloughing of a great part of the liver.

The most common coexistent injury is pleural and lung involvement. In the 37 cases, 5 showed pleural injury. Next in frequency come injuries of the stomach. Wounds of the right kidney are not rare but have a very good prognosis.

The symptoms and signs may be entirely wanting or very slight. Of the 37 cases, 7 showed no physical signs of liver injury. However bleeding into the peritoneal cavity is one of the most common results and may lead to a rapidly fatal issue at best. It is one of the most troublesome complications and is not often seen at the base hospital. If injury is on the inferior surface the blood will collect

in the lesser sac and if on the anterior surface it will eventually collect in the pelvis.

Secondary bleeding usually occurs about the tenth day and is always associated with septic infection. In the series it occurred 4 times. It is accompanied by pain, abdominal distention, rise of temperature and acceleration and loss of pulse volume.

In 1 of the 3 cases, urine was observed being deepest in serious septic infection. Deep staining of the urine is rare. It is believed to be hemolytic in origin.

The most characteristic sign is the escape of the bile from the wound. Some form of biliary fistula was present in 5 cases of the series. Persistence depends mainly on the size and degree of infection of the wound. Of the 5, 7 showed fistula opening by a view of the pleura and all recovered. In none was the object in the bile in the peritoneal cavity noted and in 1 was the gall bladder perforated.

With an open infected shell wound temporary suppuration is the rule but is of great importance. The formation of secondary abscesses however is grave matter. In the 37 cases, 4 subphrenic abscesses developed with deaths and recoveries.

The post mortem records show that of 5 deaths 60 per cent were due to sepsis and 40 per cent to secondary hemorrhage. The most prominent complication causing death was hemothorax. 7 cases died from infection from the effusion. There were 3 cases in which kidney wounds complicated the liver injury. Practically all the deaths may be attributed to sepsis as secondary hemorrhage is always due to infection.

The treatment at the base hospital is purely expectant. If the missile is easily accessible it may be removed otherwise no fresh incision is made.

In wounds of the spleen, diagnosis is rarely made on any grounds beyond the position of the external wounds and the direction of the internal track. Left hemothorax is the most prominent complication, followed by renal injury.

Spontaneous healing is to be expected with simple perforations and moderate lacerations of the spleen. Death from hemorrhage from this organ is not at all common.

Injuries to the pancreas are just as difficult to diagnose as those of the spleen and are usually found at operation or autopsy. Three cases of wounds of the pancreas are cited.

In injuries to the kidneys the simple perforations may often be regarded as negligible. Twenty-seven cases are included under this head as showing the complications most frequently associated with injuries to the kidneys. In 2 of these cases the wound of entry or exit was in the loin.

The most common complications outside of injuries of the hollow viscera are wounds of the liver, spleen, and pleura.

Among the signs and symptoms, hematuria is the most prominent, although often absent. It is rarely severe or persistent. In the series, only

showed primary hemorrhage. Likewise the degree of hemorrhage in no way was with the severity of the damage to the bladder.

Two interesting cases of kidney wounds are described.

Secondary bleeding after an injury usually about the green field. In every case the urine was infected. Hemorrhage occurs either as a persistent hemorrhage or as a perinephric hemorrhage. This latter rule is seen in the bladder and alone. Primary hemorrhage is usually accompanied by the presence of a large amount of blood in the urine. The temperature rises to 100° F.

In rupture of the kidney is usually accompanied by a large amount of blood.

Extraperitoneal hemorrhage is no common. It is believed that the extraperitoneal kidney does not secrete blood as the escape of urine externally during an injury is no abundant. Extraperitoneal hemorrhage was noted in cases of the series. This condition is more marked where the kidney is perforated.

The mortality after a case of death is secondary hemorrhage. In all cases were due to this cause.

Original trauma as he is wounded in the cases of the spine in the and hemorrhage.

In the repair of the parametrium. Operation is rare repair of primary hemorrhage. However it is a hopeless damaged should be removed.

Primary hemorrhage nephrectomy is indicated and is a difficult thing to the communication of the organ and the circulation of blood.

A large blood vessel the bladder should be removed. In primary hemorrhage suture pack in the parametrium. The need of nephrectomy is rare. P. M. CHASE.

Wells, B. H. The Care of Abdominal Surgical Cases.

The patient is seen, examined and treated. The patient is the New York Polytechnic so that the general physical as well as their personal and mental conditions is obtained. If patients are needed they are admitted to the hospital and prepared the preparation of all the organs of the body and of a mild laxative is given. The day preceding operation is followed by an enema in the evening to either the preparation of the skin.

Here purgation is avoided as being unnecessary and the patient is all as a source of great discomfort to the patient. The author strongly emphasizes his point as there are ill men who employ these measures to clean out the intestinal tract.

Usually the evening before operation the abdominal is washed and scrubbed with a tincture of green

soap and warm water. The patient is given a glass of water. The patient is given a glass of water.

When the patient is in the hospital, the patient is given a glass of water.

dry skin is put on the patient. The patient is given a glass of water.

McCrae, T. and Coplin, W. M. L. Gelatinoid Carcinoma (Morbus Gelatinosus) of the Peritoneum. *Am. J. M. S.* 9 6 cil, 475

An account is given of a case of gelatinoid carcinoma of the peritoneum in a male negro aged 41 who had been troubled with chronic ascitis for four years, and had had 57 successful tapplings. For three years the fluid showed no particular features, then gelatinous colloid material appeared and was present for a year until death occurred. During the greater part of this period the patient's condition was excellent. The liver and spleen showed enlargement to time and later became red ced in size. Shortly before death many hard round movable masses were found in the abdomen. There was intractable diarrhoea for the last few weeks of life.

At autopsy it was found impossible to find the primary seat of the disease because of the matting together of all the viscera. The diaphragm had been perforated by the growth and metastatic nodules were found in the lungs. The universality of the retrograde changes in the epithelium not commonly encountered in cancer the authors think was due to some condition which their study failed to disclose. Apparently the proliferating epithelium encountered some antagonistic influence which was constantly breaking it down. Complete early removal of the disease may be curative. Even incomplete removal of the mass may be followed by long intervals before recurrence takes place.

ILL. G. SLOW

Handley W. S. A Method of Treating General Peritonitis with Obstruction; its Application in Military Surgery. *Bru. M. J.* 9 6 4, 59

The author discusses those cases of general peritonitis in which the accepted modes of treatment have failed to avert or relieve paralytic obstruction of the bowels and cites a case successfully treated along lines laid down in his article.

In cases of general peritonitis where the picture is one of complete obstruction death is only a matter of hours. Immediately preceding this stage however is one not described in textbooks, wherein, while obstruction is usually complete the pulse is relatively good, the vomit is not offensive, and the abdomen rigid below the umbilicus but moderately soft above with slight respiratory movements. This is the last stage in which surgical interference may help.

Fortunately general peritonitis is rarely universal. The infection no matter where its source, as a rule begins in the pelvis and gradually spreads upward gravity having carried the septic material downward. Thus there is quite a period in the disease in which the upper abdomen, i.e. above the umbilicus, is comparatively free from infection.

Likewise the presence of persistent active vomiting may be considered hopeful, in that it shows that the stomach and upper intestine still retain their contractile power although reversed. Hence,

Handley believes that surgical interference in the upper abdomen before general collapse, is advisable and should be considered. This interference should involve only the stomach, jejunum and transverse colon.

Jejunostomy falls it is believed because it cuts off the supply of fluid to the mucosa of the large intestine. Handley however recommends a jejunocolostomy to the transverse colon with cecostomy and pelvic drainage. This relieves the vomiting establishes an emergency intestinal canal which supplies the body with clean food and fluid and obviates the necessity of overcoming the general infection.

This procedure the author states may be carried out quickly and easily and practically without shock.

A case is cited in which after an operation for pelvic appendicitis with beginning peritonitis the symptoms of intestinal obstruction supervened giving a characteristic picture of ascending peritonitis with total obstruction. A jejunocolostomy with a cecostomy was then done with immediate improvement and complete recovery.

In closing Handley states, I hold no brief for my conclusions and only ask that they shall be tested.

P. M. CHASE.

Saliba, J. Th. Antiseptic Action of Ether in Peritoneal Infections. *J. Am. M. Ass.* 9 6, ivii, 295

Saliba states that he has introduced ether into the abdominal cavity as a routine measure in 248 hospital cases of peritoneal infection. The injection is made with a syringe just before the last peritoneal cure is tried.

He concludes as follows:

Ether experimentally and clinically has been proved to have bactericidal action.

In peritoneal infections it is safe and beneficial antiseptic.

3. The dose of ether instillation into the peritoneal cavity is one ounce for child above four years and three ounces for adult.

4. Generally no untoward after-effects and complications follow its use.

5. Any possible toxic action of ether on the various body organs is very slight. A. LAMBERTSON.

Finochietto R. Retro-Inguinal Hernias. *Surg. Gynec. & Obst.* 9 6, xvii, 554.

Retro-inguinal hernias (Corbellini, 1906) are the right hernias of the classics, the internal hernias of Tillaux, the juxtafuniculaires of Villere.

They are called retro-inguinal because coming outside, they push before them the posterior wall of the inguinal canal the transversalis fascia. They are found in 63 per cent of hernias, coming to operation. The principal alteration of the walls is an atrophy of the conjoint tendon and Hassert's triangle.

The hernial tumor is slightly attached to the cord, but its base is fixed, owing to its continuity with the

transversalis fascia, which in this place presents its fibers of reinforcement strong but separated.

According to the predominant element in the hernial tumor, i.e., the peritoneal sac, the peritoneal fat or viscera, the hernias are classified in the order of their frequency: a) 73 per cent lipomatous; 20 per cent aplanchnic; 6 per cent. In the lipomatous variety occupying the under part of the base of the hernia there is found an ample cavity with walls formed by connective tissue, which is a prolongation of Bogros space. These three varieties of retro-inguinal hernias are independent of each other; they do not follow one another.

Simmons, C. C. The End Results in Seventy Consecutive Cases of Umbilical Hernia Operated upon at the Massachusetts General Hospital. *Boston M J U S J* 916 decr 34.

The length of time the cases were followed after operation was from one to four years. Cases with out recurrence at the end of one year were considered cured since the records showed that all previous recurrences took place within one year from operation.

The operations reported were performed by 21 different surgeons. The three main types were: (1) closure of the ring vertically with or without overlapping of the aponeurosis; (2) transverse closure of the ring without overlapping; (3) transverse closure with overlapping of the aponeurosis—the Mayo operation. The author described his technique in the last method which he has used in 14 cases without recurrence.

Simmons divides the cases into three groups: (1) children and small hernia in thin adults; 15 cases, 10 traced, all cured by various types of operation; (2) stout adults; 45 cases, one death directly attributable to the operation for hernia, a mortality of 2.4 per cent. Six cases of strangulated hernia were included in this group. Of these 45 cases the hernia recurred in 10, or 22.2 per cent. In 30 cases closed by the Mayo method 10 per cent recurred. In 14 cases closed vertically with or without overlapping 42.8 per cent recurred. Local sepsis apparently played little part in the recurrent cases of 31 clean cases, 6 recurred of 14 in which there was local sepsis, 3 recurred. Of the recurrent cases 4 were sutured with chromic gut, 2 with kangaroo tendon and 3 with non absorbable material.

The recurrent cases are described in detail and the cases in each group carefully analyzed, the following conclusions being reached:

1. Small umbilical hernia in thin adults and umbilical hernia in children may be cured by any operation which removes the sac and closes the defect in the abdominal wall.

2. Cases of umbilical hernia in stout adults are difficult to cure. The Mayo operation of transverse closure of the ring with an overlap of the aponeurosis gives the best results.

3. In adults closure of the ring by any other method than the Mayo in a general hospital is followed

by 46.4 per cent of recurrences. Recurrence if it is to take place usually does so in less than one year.

4. The suture material employed has no relation to the liability to recurrence.

5. Skin sepsis is very likely to occur but apparently has no relation to recurrence.

GASTRO-INTESTINAL TRACT

Gasbarrini, A. The Ionic Concentration of the Gastric Contents in Some Stomach Diseases. (Sulla concentrazione ioni del contenuto gastrico in alcuni malati dello stomaco). *I ter I Beitr path u ther d er hr* 33 95 33.

The author used Sorensen's lately introduced calorimetric method of estimating the ionic concentration of the gastric contents. This ionic concentration gives an index of the dissociation of hydrochloric acid, i.e., of the amount of free hydrochloric acid in the stomach.

The author submitted to this process the gastric liquids from 36 patients with various stomach diseases and from his results he is of the opinion that the calorimetric method is excellent for clinical diagnostic examinations.

The method and technique are fully described, also a detailed tabular statement is given of the 36 cases examined—gastric ulcer, dyspepsia, etc.—and the findings in each case. W. A. BRENNAN

Friedman, J. C. Time Relations of Gastric Pains, with Special Reference to Gastric Adhesions. *Am J M S* 96 cli 35.

Friedman reports a number of operated cases of gastric pain with special reference to the time of occurrence as a diagnostic help. He divides all gastric discomfort of the intragastric and perigastric regions into continuous and intermittent varieties. The continuous pains are most frequently due to carcinoma to marked pyloric obstruction, and to penetrating ulcers with peritoneal involvement. The intermittent pains are divided into immediate early and late. The immediate are found frequently in ptosis, nervous obstruction of the cardia, and various other conditions.

The early pains including those occurring fifteen to sixty minutes after eating are most often due to adhesions in any part of the stomach including ventral hernias and pericholecystitis.

Late pains include those occurring one to three hours after eating and indicate an increase in intra gastric pressure or pylorospasm of which the most frequent cause is hyperacidity. J. W. TORREX

Barbacci, O. Gastric Volvulus in Hour Glass Stomach of Congenital Malformation 366 of Rotation (Volvolo gastrico in stomaco a forma di pe. malformazione congenita—366 di rotazione). *Rf m m d* 96 xxiii 4.

Volvulus of the stomach is undoubtedly a rare affection and there are only 30 observations of it.

on record. In recent years it has been seen more frequently than in the past owing to the greater number of surgical interventions. The affection occurring in a so-called hour-glass stomach where the rotation is in only one gastric segment is still rarer. There are only a few observations of this kind. It is exceptional for the rotation to exceed 360°. Only 3 cases have previously been recorded in which the rotation reached the limit of 360°. The author now adds a fourth to these 3 cases. The clinical history of the case is wanting. The patient reached the hospital in a moribund condition and died shortly after his entrance. The particulars were gleaned from the autopsy. On opening the abdomen there was found in the left precordial region a sac the size of a child's head of semi-ovoid shape, the base being above and the apex below. It reached to the level of the iliac crest, at which point it was twisted upon its axis and evolved into another apparently smaller sac of semilunar shape, which occupied all the right hypogastric region and had a general direction from left to right. On the left of this sac were two greatly distended loops of intestine, the upper corresponding to the descending colon and the lower to the sigmoid colon which was buried in the lower pelvis. On the right side of the sac was another distended loop which corresponded to the ascending colon. The viscera generally were malformed and displaced.

The lower of the two sacs referred to has undergone a torsion on its axis. This torsion amounts to 360° so that the anterior face of the sac which is presented to view is really the visceral anterior face after complete twist. This torsion is verified by complete removal of the sac and its attachments.

From the detailed findings the anatomic diagnosis was gastric volvulus in bilocular stomach with 360° of rotational abnormal mobility of the pylorus and duodenum, congenital malformation of the gastrohepatic ligament, slight pulmonary emphysema with hypostasis and edema, degeneration of the myocardium and liver, hepatic calcosis, deficient aortic, splenic and renal arteriosclerosis, etc. Histologic examination showed no alteration whatever in the stomach walls in either sac.

The author thinks the two conditions in this case which merit special attention are the bilocular conformation of the stomach and the gastric volvulus. Bilocular stomach is not rare. It may be congenital or acquired, although many authorities deny the existence of congenital variety.

The author is so convinced that in his case the deformity was congenital and gives his reasons discussing the theories of other writers, Barnabo, Veyrassat, Bédinger, W. Stein, etc. who have devoted considerable attention to the occurrence of this congenital anomaly. Veyrassat has laid down the dictum that in order to be considered congenital the following should be fulfilled:

The biloculation should not cause any gastric disturbance during life.

It should not disappear under the influence of insufflation of the stomach.

3. It should not be accompanied by any appreciable lesion of the gastric tunica.

Biloculation is as likely to be met with in the foetus and in the infant as in the adult and the old.

In the above case the second and third conditions were fully met. The first condition could not be established owing to the lack of sufficient history of the case.

The author next takes up in detail the consideration of volvulus occurring in connection with bilocular stomach. From review of the literature of the subject he reduces such cases to only two. He gives a short résumé of these 2 cases. Only in the 3 cases reported by Hedlung, Schell and Walther, and Kocker did the rotation reach the limit of 360°, as in the above case and that of Schell and Walther was the only one in which the other concomitants agreed with those of the case now reported. The above case is therefore unique.

W. A. BREYER

Burge, W. L. and Burge, E. L. The Cause of Gastric Ulcer. *J. Am. M. A.* 1906, lvi, 908.

In accordance with the theory that gastric ulcer is caused by decreased resistance in the limited areas of the gastric wall the authors undertook this investigation to determine experimentally if possible whether or not such diminished resistance would give rise to gastric ulcer. The point to what has been known for some time that the resistance to the action of the digestive juices of limited portions of the mucosa of the stomach is decreased by cutting off the blood supply to these portions, as for example, by a clot in a small blood vessel (thrombosis) or by the ligation of the vessel and that under such conditions the area is digested by the pepsin with the formation of an ulcer. The fact that gastric ulcer occurs so frequently in anemic persons led to the advancement of the theory that the oxidative processes are decreased and that this may be the cause of the diminished resistance of the tissues.

Working upon the theory which assumes that normally a balance exists between the oxidative processes of the cells of the mucosa and the digestive action of the pepsin in the stomach, and that if this balance is destroyed, as for example by depriving a limited area of oxygen by cutting off the blood supply and thereby decreasing the oxidative processes of the area, this area should be digested by the pepsin with the production of ulcer, the authors derived numerous experiments to imitate the protective mechanism as thus set forth. From their experiments they are able to draw the following conclusions:

The decreased resistance of a circumscribed area of the stomach to the digestive action of gastric juice is due to a decrease in the oxidative processes of the cells of the area. Gastric ulcer is due to the subsequent digestion of the area by pepsin.

2. The resistance of unicellular organisms (para-

mediums) to the digestive action of the proteolytic enzymes can be increased or decreased by increasing or decreasing the intensity of the oxidative processes of the organisms the greater the intensity of the oxidative processes the greater the resistance and vice versa.

GEORGE E. BRILAY

Elliot T. R. and Henry H. Traumatic Gastric Ulcers. *Bri M J* 9 61 523

The formation of gastric ulcers following trauma to the stomach is discussed.

Surgical work with the army in France has proved conclusively the value of early operation in gunshot wounds of the abdomen. It is the consensus of opinion that any wound of the intestinal tract is less likely to be fatal if repaired immediately than when left to rest and nature although Surgeon General Sir George Mackenzie claims that it is unwise to open the abdomen in cases where only the stomach is supposed to have been wounded.

While the chief danger in intestinal wounds is from peritonitis in stomach wounds it is less to be dreaded as frequently adhesions seal the aperture and the gastric contents that do leak out are not very septic. However the real danger in this latter class is from secondary hemorrhage due to erosion of the injured tissues by the gastric juice.

Immediate hematemesis and melena are rare as the bleeding is usually intra or retroperitoneal. However these symptoms often appear during the second week and then are to be interpreted as due to an extending ulcer of the stomach or duodenum. These ulcers are the exact counterpart of the non-traumatic ones with the exception that gastric fissure is much more liable to formation in the track of the initial injury.

A detailed clinical report is given of the 4 illustrative cases 3 of which died 2 from uncontrollable hemorrhage and one from widespread septic infection. In all 4 cases the missile either penetrated the stomach or came so close as to cause a direct injury to the wall. None of the cases was operated upon and hematemesis and melena occurred in each during the second week.

In the case which recovered the stomach was probably contused and recovery from following ulcer unexpected as the rule in these cases is subsequent death.

P. M. CHASE

Verbruyck J. R. Jr. Post-operative Treatment of Peptic Ulcer and Cholecystitis. *Med Rec* 9 61 vii 74

The first step in the post-operative treatment begins at operation. Whenever possible the ulcer should be exposed kept from contamination and examined for organisms from which autogenous vaccines can be prepared and administered during convalescence.

There can be no routine treatment for ulcer after operation. The individual patient must be treated bearing in mind the possible cause of the trouble

the character and position of the ulcer found at operation and the nature of the operation itself.

In cases of excision it is necessary simply (1) to regulate the diet for from ten to fourteen days (2) to administer atropine or belladonna to prevent spastic contraction of the pylorus which would tend to produce further trouble (3) to make and administer autogenous vaccine (4) to avoid irritating purgatives (5) before the patient is discharged to make search for the original focus if it has not already been located and take steps to eliminate it and (6) to instruct patients to report at least every two months for a year with a specimen of stool while on meat-free diet for three days to be examined for occult blood.

Not only does the location of the ulcer influence the after treatment but also the conditions found at operation. A large callus ulcer of many years' duration if ever curable by rest will certainly take longer than a small non-indurated one. Perforated ulcers naturally demand certain other treatment which comes purely under the domain of the surgeon such as (in acute cases) the Murphy salt solution and the Fowler position. For some reason perforated ulcers seem to tend to heal without much difficulty after the perforation is closed.

Ordinarily results in gall bladder cases may be said to be decidedly better than those following operations for ulcer however the number of secondary operations required and the not inconsiderable number having a continuance or recurrence or trouble after drainage or even removal of the gall bladder would indicate that there is room for improvement in the treatment. The author believes that the reason for many of the poor results lies in the fact that the original factors which caused the trouble have not been influenced.

The patient should have an individual diet list based upon the condition of digestion and the weight but in all cases fat should be restricted to a greater degree than the other food products. In the obese fat reduction should be practically absolute for a time so that the patient may use up some of his own. Some control should be kept over the fat ingested for at least a year. If the bowels tend to become sluggish from the absence of fats mineral oil which lubricates without being digested may be given.

Next to fats the carbohydrates should be restricted. Judgment is required in determining how far this may be safely carried. Proteins are allowed in sufficient quantity to maintain nitrogen equilibrium. All of the vegetables that are desired may be taken also fruit provided the chemical condition of the stomach does not contraindicate its use.

The bowels should be kept open. If necessary will help with the addition of Carlsbad or Epsom salt when required.

After convalescence exercises should be prescribed. Outdoor exercises such as walking, golf, etc. especially if the patient has special local troubles which tend to irritate the stomach.

tion, and correct sluggishness of the biliary as well as the whole digestive tract.

Post-operatively 15 grains of hexamethylenamine a day should be given for a number of months unless contra-indicated by some untoward action. One five-grain tablet of sodium glycocholate or its equivalent two or three times a day should be administered for some months.

Thyroid extract, for its action on fat metabolism, should be used temporarily in the cases in which it would seem that there was deficiency of thyroid secretions with poor oxidation. Small doses should be used at first, and close attention paid to the blood-pressure and pulse. EDWARD L. CORNELL.

Mackay W. A., and Macdonald, I. Perforating Pyloric and Duodenal Ulcers. *Edin Med J* 9 6, xvi, 350.

The article briefly reports three cases of perforating pyloric and duodenal ulcers with perforation. One died and two recovered. These three cases were from a series of 250 operations for gastric and duodenal ulcers occurring in the authors' experience in southern Spain.

All the cases gave the typical history of duodenal ulcer of several years standing.

In the first case, perforation occurred in the middle of a large cedematous mass occupying the pylorus, which prevented the sutures from holding. Under these circumstances, the abdomen was thoroughly dry-swabbed and the pyloric portion of the stomach belayed to the abdominal wall. Two drains through the incision and one through the loin to the kidney pouch were used, being removed on the ninth day. Uneventful recovery followed and two months later gastro-enterostomy was done.

In the second, perforation occurred in an ulcer densely adherent to the posterior border of the liver making suture impossible. The leak was stopped by an mental tag, the abdomen dry-swabbed, a large drain put under the liver, another through the lower end of the incision and a third over the pubis into the pelvis. This patient suddenly died on the fourth day after developing a duodenal fistula.

In the last case, small perforation occurred in an old ulcer scar on the front part of the duodenum. This was closed by a single catgut suture followed by continuous suture of the serous coats, and tag of gastrohepatic omentum sutured over all. Following this a posterior gastro-enterostomy was done. One drain was then placed under the liver and a second above the pubis into the pelvis. These were removed on the third day and uneventful recovery followed.

The authors strongly recommend pelvic drainage and immediate operation. P. M. CHASE.

Morgan, E. A.: The Post-Operative Management of Pyloric Stenosis. *Am. J. Dis. Child.* 9 6 xi, 245.

The author's study is based on the personal observation of fifty children who were operated on in

the Babies Hospital of New York during the last two years. The post-operative results are dependent to no little extent on the pre-operative condition of the patient.

The maintenance of the body temperature is of paramount importance. A sudden loss of body heat has, in some instances, been the undoubted cause of collapse occurring a few hours later.

The greatest danger is in the exposure incident to the operation, and to minimize this it is advisable to encase the infant's legs and arms in non-absorbent cotton. Under the pad the operating table is placed a hot water bag which fits into the small of the back and serves the double purpose of supplying warmth and keeping the site of the operation well elevated.

The removal from the infant's stomach, by gastric lavage, of food residue and gas accumulation is the next most important pre-operative measure.

The post-operative management of the maintenance of the body temperature is as before, of the utmost importance. The infant is wrapped in a warm blanket or cotton jacket and the bed is well equipped with hot water bottles.

The first hour after the head of the bed should be lowered. After nourishment has been commenced the head if the bed may be raised and from this time on the infant is kept in a semi-erect position. This elevation assists in emptying the stomach, especially in gastro-enterostomy cases, and at the same time permits the escape of gas through the mouth.

The use of extensive hypodermic stimulation after operation is to be deprecated; only one measure, namely hypodermicoclysis of normal saline or of glucose solution, is always indicated and this may be safely used as a routine practice. Of the other stimulants, epinephrin, subcutaneously is the most satisfactory because of the rapidity of its action. Caffein and tropine, hypodermatically are sometimes valuable, and by mouth dilute whiskey or brandy. The value of blood transfusion as a stimulant is very questionable.

A post-operative rise in temperature is to be expected in nearly all cases. No antipyretic measures are needed if the reactionary temperature, except that care should be taken not to use excessive artificial heat. A pyrexia that persists for more than three days, or one that unexpectedly occurs after the first reactionary fever has subsided, should be investigated as it usually indicates some complication.

Feeding is the most important feature of the post-operative care of infants; a slight error in judgment may precipitate a gastro-intestinal upset that is very difficult to control. It is impossible to feed all children by the same set rule, but a general routine is of value and is applicable to the majority of cases. The aim should be as soon as possible after operation, to start nourishment in concentrated and readily digestible form. For this purpose there is no food that can take the place of breast milk and

very effort should be made to procure enough to tide the patient over the first week at least.

An hour after operation, providing the recovery from the anesthetic has been complete, the patient is given 10 c. m. of water and an hour later 15 c. m. of breast milk mixed with 4 c. m. of water. It may be necessary at first to use a medicine-dropper for the administration. The breast milk is repeated every three hours eight feedings a day and is alternated with the water. Both are gradually increased so that twenty-four hours after operation 16 to 24 c. m. of undiluted breast milk is being given every three hours and a similar amount of water between feedings. At the end of forty-eight hours the child is usually taking 20 to 30 c. m. and at the end of seventy-two hours 30 to 45 c. m. at a feeding. The administration of water by mouth during the first three or four days is of the greatest importance. The time required to increase the quantity of milk to meet the caloric requirements of the child has been on an average five days in small babies three days may be sufficient and in the well nourished as much as eight to ten days.

It is wise not to defer putting the baby to the breast longer than one week after operation or when the feeding from the bottle has been increased to about 60 c. m. This is usually on the sixth or seventh day. The nursing must be carefully supervised for the next week the amount taken at each time being measured by weighing the baby before and after. If the quantities obtained are too small the nursing may be supplemented by a modified milk mixture.

In well nourished children a sponge bath may be given every day until the abdominal wound is completely healed and the dressing discarded. In poorly nourished or emaciated infants an oil rub is to be preferred.

Vomiting although it is to be expected in a certain degree in a large proportion of the patients after operation is frequent and troublesome in some cases. The more common exciting causes of vomiting are

1. Distention due to accumulation of gas either in the stomach or in the intestines.

2. Defects in the operation such as faulty adjustment of the jejunum and stomach, or incomplete severance of the constricting muscle fibers of the plastic operation.

3. A too rapid increase of the feeding.

4. The occurrence of complications especially general peritonitis. Of these causes distention due to gas accumulation is by far the most frequent. If it is mainly intestinal a colon irrigation, repeated as often as necessary, is all that is required for relief. When the accumulation is in the stomach the head of the bulb should be elevated and the child frequently raised to the upright position to allow the free escape of the gas. In patients who do not respond to these measures it is well to pass a soft rubber catheter into the stomach before each feeding. Lavage may be employed if the vomiting is persist-

ent but its use in the first two or three days after the operation of gastro-enterostomy entails not a little risk.

Repeated fecal evacuations are usually not seen during the first twenty-four hours. At the end of this period therefore it is well to give a teaspoonful of castor oil to stimulate peristalsis and remove mucus and gas. The first few stools are usually loose and green in color (raw or turpentine like) if there has been any bleeding into the terminal ileum. Normal breast milk stools are not seen as a rule until the fourth day after operation. A too rapid increase in food especially in children who have been vomiting for several weeks prior to operation is very apt to produce loose frequent stools. The measures usually employed for the relief of acute intestinal disturbances are applicable to this condition.

The dressing at operation should consist of a narrow fold of sterile gauze which just covers the incision and is held in place by a adhesive strapping. There is seldom any indication to disturb it for the next four or five days. A binder should not be used. The advantage in using a small dressing is that the least hemorrhage can be readily detected and controlled. The stitches may be removed on the sixth to the eleventh day depending on the condition of the wound and after that a protective pad of gauze is all that is required.

Of the 36 infants discharged in good condition 4 died from a variety of causes none of which were directly associated with the operation. The deaths occurred two weeks after discharge in two instances and two months after discharge in the others. Two children were lost sight of and of the remainder 10 were followed for one or two years after discharge 13 for six months to one year and 17 for less than six months. EWARD L. C. RYAN

Bradford W. H. Chronic Gastric and Duodenal Ulcer. J. M. 15:1, 26, 1, 3.

The results obtained from surgical treatment of patients suffering from chronic gastric and duodenal ulcer have been among the most satisfactory in all the author's surgical experience. The mortality has been exceedingly low. A man with acute perforation of a chronic gastric ulcer died one week after operation. With this exception no deaths have followed surgical treatment.

Among his successful cases the following may be briefly mentioned.

A male aged 30 was operated on eight years ago for a large palpable mass diagnosed as gastric cancer and is now perfectly well.

A male aged 55 had been suffering from gastric ulcer for seven years. In May 1914 he had the pyloric half of his stomach removed and he gained 55 pounds since operation.

A male aged 40 at 60 had been suffering from chronic stomach trouble for thirty years. He was emaciated and anemic. He was operated on for duodenal ulcer in November 1914. After operation his

Improvement was wonderful and he had no further need of medicine.

EDWARD L. CORNELL.

Mills, R. W. Observations on Duodenal Ulcer with Special Reference to Its X-Ray Diagnosis. *Internat. M. J.* 9 6 xliii 68.

The stomach in uncomplicated duodenal ulcer is generally considered to be characteristically hypertonic. Hypertonic stomachs are characteristic of those of asthenic habitus; consequently either the stomach in duodenal ulcer becomes abnormally tonic, or duodenal ulcer occurs in those who naturally have hypertonic stomachs. Mills' thesis in investigation will suggest that both are true. Should certain complicating factors exist, the gastric hypertonus of duodenal ulcer is lost to a degree commensurate with that of the complicating factor. Such factors are: duodenal stenosis, result of ulcer, and general conditions causing atony, such as general debility from hemorrhage and the like.

In uncomplicated duodenal ulcer there is a well-known increased initial motility, early and free pyloric outflow. With stenosis motility is tardied and there may be a six-hour retention. Cap deformity is by far the most valuable and constant diagnostic indication of duodenal ulcer. Callous ulcer situated in the first part of the duodenum is impossible without characteristic and persistent anomaly as to the firmness of the cap, and is at times added to by spasm. A perfect cap means a callous ulcer. Deformity may also occur as the result of adhesions to duodenal ulcer. The contention that small ulcers can exist without cap deformity is in dire need of illumination through illustrated specific case reports. Certain peculiarities of gastric peristalsis occur in uncomplicated duodenal ulcer which were not anticipated before the advent of the X-ray. We have heretofore known of but one clinical condition resulting in visceral hyperperistalsis, namely stenosis.

In uncomplicated duodenal ulcer gastric hyperperistalsis occurs immediately or shortly after the ingestion of the contrast meal, or only without stenosis distal to it, but with a decrease in the resistance normally offered by the tonus of the pyloric sphincter. Mills thinks that all indications are unfavorable to the idea that the pain of duodenal ulcer is due to hypertonicity in either at night or cap the so-called dequate stimulus of visceral pain, but that it is due rather to the nerve-endings in the ulcer-floor becoming actually and abnormally sensitive to excess of hydrochloric acid.

ALBERT MILLER.

Woolsey, G. The Surgical Treatment of Gastric and Duodenal Ulcers. *Med. Rev.* 9 6 lxxviii, 59.

Woolsey advises a thorough trial of medical treatment for gastric and duodenal ulcers, and states that acute ulcers will almost always yield to only cases of perforation requiring surgical treatment. The symptoms due to chronic ulcer will in time subside

with rest without treatment. But relapse is the rule and there is some question whether medical treatment gives permanent cure.

After two or more relapses have occurred surgery should be resorted to. Gastro-enterostomy is the operation of choice. It affects both the drainage and the biliary system of the stomach; the acidity is diminished by the presence of a small quantity of bile and pancreatic secretion; the pylorospasm is relieved and the stomach empties itself without irritant food (the ulcer by the passage of food). Healing occurs in 8 per cent of cases (Paton). Symptoms will persist if due to adhesions or malignant degeneration. Gastro-enterostomy is of certain preventive value if perforation, hemorrhage, but it diminishes the probability of their occurrence. On account of the anatomical structure of the duodenal ulcer of the anterior duodenal wall can be overlooked and search should also be made for the existence of an equivalent ulcer on the posterior wall which is more durable and of the gastric type (cases where the pylorus is stenosed give the best results).

The various methods of operation are: (1) Von Eiselsberg's, the most radical in which the stomach is divided proximal to the ulcer and both ends sutured; (2) Wilms', in which the band of fecal half an inch wide is fastened tightly round the stomach proximal to the ulcer; and (3) the method of infolding the pyloric end by ture.

Simple duodenal ulcer almost never undergoes malignant degeneration; gastro-enterostomy with or without pyloroplasty gives excellent results. It is different in callous gastric ulcers, which, or infrequently become malignant. It is sometimes impossible to differentiate between an indurated ulcer and carcinoma. A radical removal of the chronic ulcer is best in such cases.

The two complications of gastro-enterostomy, venous thrombosis and peptic jejunal ulcer usually of the stomach are avoided by proper technique. The latter uses fine chromic gut for both suture layers.

The more radical operations for gastric ulcer are excision, pyloric resection, and mesogastriectomy. Excision is not a satisfactory operation. Resection is more radical but gives better results.

Ulcers of the pyloric region of the stomach, the Billroth method is the operation of choice. It should be followed by gastro-enterostomy or the Pyloroplasty modification in which the proximal end of the stomach is sutured directly to the jejunum. The chief technical difficulties are due to adhesions, especially in case of penetrating ulcer. When the ulcer is farther from the pylorus, usually on the lesser curvature the mesogastriectomy or resection in continuity is the method of choice. The mortality of resection is greater than that of gastro-enterostomy but the operation is well borne and the mortality not high. In all cases of gastric or duodenal ulcer the patient should be put on a special diet for some time after operation.

The so-called hour-glass stomach which results

from a cicatricial contraction of a gastric ulcer is treated on the same principle as callous ulcers.

The two complications of gastric and duodenal ulcers are hæmorrhage and perforation. Sudden acute hæmorrhage is usually due to acute ulcer and is best treated medically. In recurring hæmorrhages with threatened severe anaemia operation should be done before the anaemia progresses. In cases of dangerous hæmorrhages during transfusion of blood is of great value. In acute perforation early diagnosis and immediate operation are most essential.

Subacute and chronic perforations result in perigastric and subphrenic abscesses, which demand accurate diagnosis to indicate the operation suitable to the case. L. R. GOLDSWORTHY.

Haines, W. D. Some Features in the Management of Surgical Disorders of Digestion. *Lancet*, 1911, 1, 35.

The newer pathology has shown that the organs of an infection occurring in the buccal cavity, the tonsils or elsewhere may be transmitted by the lymph or blood stream to remote parts of the body, thus to form new foci when arrested in the terminal vessels of such organs as the gall bladder, stomach, duodenum, brain or kidney. According to these newer concepts digestive disorders, gastric ulcer, cholecystitis and appendicitis are to be regarded as terminal infections. Gastric and duodenal ulcer must be regarded not as a disease but as the end result of a disease. To successfully cope with the symptoms the original source of infection must be removed. Pus must not remain unchallenged anywhere in the system.

The author is convinced that 10 per cent of digestive disorders may be cured by removal of some extragastric pathological condition, the source of the disorder being an overloaded colon, infection of the pancreas, gall bladder, gums, sinuses or tonsils.

The mortality following perforation of an ulcer increases by leaps and bounds after the first few hours and immediate operation is imperative. The thick indurated mass associated with chronic pyloric ulcer should be removed, but these patients are in such poor condition from prolonged starvation that they are poor surgical risks and the better practice is to do a two-stage operation, a primary gastrojejunostomy and a secondary resection after recovery from starvation. Occasionally one finds that the mass at the pylorus has entirely disappeared. In this case the second operation terminates as an exploration.

Hyperæmæmia is a symptom difficult to relieve. Calcium chloride and horse serum may tide the patient over until an interval operation may be done. The discrepancy between the size of the ulcer and the amount of blood lost may be great. Perigastric adhesions are prone to undergo contraction with the production of obstructive disturbances in the stomach. When firm it is better to provide a pleurostomy for the stomach in preference

to making extensive laceration with subsequent production of new adhesions. In the vast majority of instances separation of adhesions is but temporary and permanent benefit may not be expected.

The author's experience with cancer of the stomach has been discouraging but unfortunately only means by which life may be prolonged. It has been said that gastrojejunostomy and resection of the subsequent development of carcinoma, but several cases are mentioned in which the perforation of a clinically benign ulcer is followed by cancer within the following 12 months.

One third of all cancer of the stomach is located in the stomach and the vast majority originate in the margin of an unhealed ulcer. He who recognizes this and deals with the ulcer for malignancy has begun to diminish the sum total of human life. J. K. AUSTIN.

Childert, H. Intestinal Adhesions. *Chirurgia*, 1910, 5.

From the viewpoint of the author's experience would seem to include the frequency to be:

1 Former attacks of inflammation in some intra-abdominal organ.

2 Injudicious manipulation, negligent attention in necessary handling of the intestines and other intraperitoneal organs during previous operation.

3 Traumatism through external or internal hernia of the abdomen including the too frequent reduction of hernia; the improper application of truss pressure and the injection treatment of hernia.

4 The use of drainage after operation, either capillary or tubular.

5 Imperfect wound healing with resulting ventral hernia.

6 Idiosyncrasy—some patients seemingly predisposed to the formation of adhesions even upon the most gentle manipulation.

The prevention of adhesions following operations upon abdominal organs depends upon the following factors:

1 Gentleness of manipulation in all necessary handling of tissues.

2 The avoidance of unnecessary exploration by more careful case taking and more accurate drainage.

3 The free exposure of the abdomen sufficiently large incisions and especially by posture to minimize the necessity of blind and blunt separation of adhesions.

4 The use of moist rather than dry packs, except when their retention may be indicated for protective.

5 The avoidance of drainage where possible.

6 The covering of all denuded surfaces.

7 The use of normal salt solution poured into the peritoneal cavity after completion of operation.

8. The early establishment of and continuance of peristalsis.

9. The assumption of a posture favoring the prevention of contact with sutures or ligated parts.

10. The frequent change in position of the patient.

The suture of the peritoneal wound with edges.

11. The covering of all denuded areas not amenable to suture with omental grafts.

12. The use of sterile omental oil rather than the normal salt solution where denudations cannot be properly covered.

Edward L. CORRELL

Fraser J. Enteric Intussusception. *Edinb M J* 9 6 xvi, 275

Two cases are briefly reported in which intussusception occurred above the ileocecal valve, complete recovery following operation.

In both the symptoms were greatly similar showing early colic-like abdominal pain, slight nausea, increasing constipation, rising temperature and pulse-rate, with abdominal distention and rigidity. In either was the presence of blood per rectum noticed and general prostration occurred early. The age of the first was three and one half years, that of the second ten years.

In the first case the intussusception was found about ten inches above the ileocecal valve. This then was invaginated into the large bowel, the ileocecal valve remaining at its apex. In the second case, the intussusception involved about twenty inches of ileum, extending within twelve inches of the ileocecal valve.

In both cases resection of the involved ileum was performed followed by end-to-end anastomosis. In the first case recovery was complicated by acute parotitis and later by a condition resembling polymyelitis; recovery however occurred. In the second, an uneventful recovery took place.

The author emphasizes the age, the gradual onset and the absence of blood per rectum. The latter is almost diagnostic of enteric intussusception.

P. M. CHASE

Johnson, J. E. Conclusions in the Study of Intestinal Stasis. *South M J* 9 6 ix 342.

The author traces his experience with cases of intestinal stasis, beginning with the stage where the appendix alone was removed to what he terms the "blackest page of disappointment" in this endeavor, the mechanical correction of the various ptoses and kinks discovered in this condition. Finally comes the physiologic stage which offers most hope for the proper understanding of this condition.

There are three sphincters: the gastro-intestinal tract, the pylorus, the ileocecal valve and the anal sphincter. The function of the pylorus is to hold food in the stomach proper length of time—4-5 hours—for its preparation for intestinal digestion. If held longer by obstruction or spasm of the pylorus it becomes putrefied and the intestine consequently

absorbs bad food. The caecum is the cesspool of the intestinal tract. If the ileocecal valve be incompetent there is regurgitation and the patient literally feeds on his own excreta.

The author points out the effect of irritation on one of the sphincters in its relation to spasms of the sphincter higher up. The most common example is pylorospasm due to chronic appendicitis. This condition will cause a delay toxemia, the points of diagnosis of which are repeated soreness in the right side preceded by toxic headaches without colic. In advanced cases of this type there is a thickened terminal ileum and a distorted infected colon. Right-sided colectomy is the only remedy of value in such cases.

The toxemia of ileocecal regurgitation is quite different from the toxemia of delay. The former is the cause of visceroparalysis (through toxic paralysis of the planchic nerves) and the formation of inflammatory membranes due to bacterial invasion of the walls of the intestine. The cure for ileocecal regurgitation is a plastic operation described by the author in a previous paper for the re-establishment of the function of the ileocecal valve. E. FRANKLIN

Hubeny M. J. Roentgen Examination of the Appendix. *Ill M J* 9 6 xix, op.

Roentgen examination has eliminated some of the possible errors in the diagnosis of chronic appendicitis. Hubeny gives some of the confirmatory data which with the clinical findings warrant this diagnosis.

The fluoroscopic examination is the most satisfactory and visualization of the appendix is preferably made by opaque meal.

It is necessary that the appendiceal lumen be patent, otherwise the appendix may not be demonstrable.

Some observers think that every appendix which permits the entrance of an opaque meal is pathological; however if the appendix empties itself at the same time as the caecum it must not be so considered.

Adhesions are considered as pathological evidence of previous inflammations. These may be fluoroscopically recognized particularly if extensive, contractions of the structure of the lumen and other results of a diseased condition can also be demonstrated. Much information may be derived from the size and other conditions of the visualized appendix.

Since it is well known that aside from gastric ulcer chronic appendicitis is the most frequent cause of spasmodic bow glass action of the stomach, this as well as other effects on remote organs, may be looked for. H. LEE E. POTTER.

Morris, R. T. Fibroid Degeneration of the Appendix. *J M Soc N J* 9 6 viii 20

Among four well-defined types of appendicitis, fibroid degeneration appears to furnish the commonest lesion. It is an irritative lesion, not infectious. Individuals of the asthenic group presenting a

number of stigmata of decline appear to have fibroid degeneration of the appendix more frequently than do other individuals of normal development. Patients with enteroptosis and with the features of arrested development belonging to visceroptosis are prone to include symptoms of fibroid degeneration of the appendix along with their other symptoms.

The signs which belong to fibroid degeneration of the appendix, the irritative lesion, the commonest form of appendix trouble are:

1. Transitory pain and discomfort in the appendiceal region, not sufficiently severe to send the patient to bed, and extending over many years.
2. Hypersensitiveness of the right group of lumbar ganglia, determined by making deep pressure upon the abdominal wall about an inch and a half to the right of the navel and a little below that point not accompanied by similar sensitiveness of the left group of lumbar ganglia.
3. Habitual distention of the ascending colon with gas.
4. Various gastro-enteric disturbances partly due to irritative influences from the appendix and partly due to other features of neuroathenic habit or arrested development such as sagging colon, loose kidney and complications previously alluded to.

EDWARD L. CORWELL.

Dubose F. G. Neglected Appendicitis: Its High Mortality, a Diagnostic and Therapeutic Responsibility. *S. A. M. J.* 1916, 11, 332.

The unduly high death rate from appendicitis, given in reports of insurance companies as compared to the exceedingly low mortality from early operation in acute appendicitis makes it incumbent upon the physician to enlighten the laity upon the possible seriousness of what appears to be a bellyache.

Under the title pathology, the author accepts and quotes freely from the report of Stanton. All cases represent merely different stages or degrees of inflammation. The second day is considered the most serious and Dubose says: "If it is going to occur at all, gross perforation of the appendix itself with or without gangrene usually takes place before the end of the second day." Attention is called to the conclusion in Stanton reached denying the existence of catarrhal appendicitis as a pathological entity and admitting that bacteriological perforation occurs during the first few hours of the attack whether or not gross perforation of gangrene is present. Movvhan and Deaver are freely quoted as pointing to the direct connection between perforation and spreading peritonitis and pergaetion.

Under the heading symptomatology, after describing the usual well-known symptoms and signs, the author states that the differential diagnosis lies not between a late appendicitis and acute indigestion but between appendicitis and some other condition demanding surgical interference. It is only the neglected cases which demand careful judgment as to when is the best time to operate.

In coming to a decision the surgeon must always bear in mind that what has been done before he has been called and what can be done post-operatively have as much bearing on the ultimate outcome of the case as the operation itself. If a late operation is unavoidable the author advises that the stomach be emptied and kept empty, that the large bowel be cleansed with enemata and be prepared for the use of proctocolysis, that morphine in sufficient quantities be given to relieve pain, lessen peristalsis, diminish shock, retard absorption, limit tissue waste and to favor the formation of protective peritoneal adhesions, that the patient be put in Fowler's position and that proctocolysis of 15 per cent glucose and 1 per cent sodium bicarbonate and 0.5 per cent sodium chloral be given. If operative delay be unavoidable the author gives in full his reasons for never administering a purgative for withholding all nourishment by mouth and for the administration of morphine.

In case more than forty-eight hours have elapsed between the onset and the time when the surgeon is called, immediate operation is imperative. (1) If all unfavorable symptoms become exacerbated in spite of the starvation rest treatment. (2) If there be sudden relief of pain with subjective betterment but with a quickened pulse rate indicating rupture of the appendix or of an abscess or of thrombosis. (3) If a circumscribed swelling appears in the right abdomen (evidence of localization of inflammatory process by adhesions). (4) If the previously high leucocyte count fall suddenly or gradually declines with a steady increase in the polymorphonuclears. (5) When more than one week has elapsed since the onset.

Operation should be deferred from the third to the seventh day after onset long enough to give the starvation rest treatment a chance and should be deferred as long as the patient shows improvement under this treatment in the presence of a blood count which shows a high polymorphonuclear count without a corresponding leucocytosis which is indicative of intense infection or of a patient with low resistance so overwhelmed that a fatal outcome is to be expected under any treatment. The benefits derived from delay are the recovery of the sympathetic nervous system from shock, the blood is given time to form antibodies and the peritoneum is allowed to form limiting adhesions. The dangers in postponing operation are further saturation of the system with toxins, especially in the presence of a gangrenous or obstructed gut, bacterial invasion of the blood stream, lymphatic infection with resultant empyema, subphrenic abscess, multiple abscesses of the liver or cholecystitis, progressive suppurative peritonitis.

Of the factors influencing the outcome, rational pre-operative treatment is the most important in favorably influencing the result of operation. The anesthetic of choice is nitrous oxide-oxygen alone or combined with inhalation. The operation should be well planned. The author describes an

incision which he has proved to be very satisfactory. The skin is incised transversely through McBurney's point the aponeurosis and muscles are divided in the usual way and the peritoneum opened. If more room is required, the fused psoeura to the outer border of the rectus is cut and extended downward, thus permitting a triangular flap to be raised and as extensive an exploration as may be desired. Every pus pocket is opened and drained. The appendix is removed in every case where at all feasible, and thrombosed or gangrenous mesentery is likewise excised. Sheets of rubber tissue gauze, jelly covered with rubber tissue are used for drains. The author believes that too late the errors of appendicectomy result largely in mortality or conserving them due to lack of understanding of the pathology underlying the picture.

At the close of the operation hypodermolysis is given supplemented by proctoclysis. The patient is placed in Fowler's position, and morphine in sufficient quantities to relieve pain is administered hypodermatically. Stomach lavage should be used every four to six hours, and where duodenal intubation is regurgitated, the stomach contents retained by lavage are re-introduced in the proctoclysis. Essence of pepton, one teaspoonful to a quart of water is administered per rectum to relieve gas. Pilocarpin is used for dilatation after the third day, when it is first permissible to stimulate peristalsis. Milk and molasses, equal parts are the safest ingredients for an efficient purgative enemata. The routine use of strychnine, caffeine, puerari, nitroglycerine, and atropine is condemned. Morphine, atropine and pilocarpin have shown indications and are valuable when properly used. Glucose and soda administered intravenously make an ideal heart muscle stimulant besides affording nutriment and acting as acids to the elimination of toxins. The post-operative care is equally as important as the operation. I. I. McC

Andries, J. H. The Choice of Time for Operating in Acute Appendicitis and Gall Bladder Disease. *J. M. Ch. St. M. Soc.* 96 8

In acute appendicitis early operation is the best and oftentimes the only chance of cure. If the patient is not seen until the third day or later it is best to postpone operative treatment until the disease is circumscribed and localized. The danger to the life of the patient is greatest if operation is performed on the third or fourth day. After the fifth day there is no longer any danger if it is treated simply as an abscess. If pneumonia complicates acute appendicitis the outlook is poor and the condition had best be treated non-surgically until the pneumonia subsides.

Appendicitis during pregnancy is also a very grave condition, the more favorable cases being those that are operated upon during the first few hours of the attack. In every case of appendicitis in the female the physician should satisfy himself as to the

possibility of pregnancy as such a complication is always hazardous to the patient's life.

In gall-bladder disease early peritonitis is contraindicated only by the presence of some condition in another organ which would constitute a hazard to the patient's life. Early operation is not accompanied by danger provided the patient is then in good condition. Delay means courting advanced pathology and complications. Should tests of the gall-bladder be present operation is contraindicated if the temperature is above 102 except in those cases of greatly distended gall-bladder where rupture is imminent. Here all that is necessary is incision and drainage removal of the stones by any method until these circumstances become dangerous.

Thus it is seen that in both affections the choice of time for operation runs parallel, an early operation being necessary to avoid progressive pathology to lessen the difficulty and seriousness of surgical treatment and to minimize the danger to the patient's life. E. K. ARMISTEAD.

Wiener, J. Appendectomy Under Local Anesthesia. *J. Am. M. Ass.* 96 175 78

The technique which the author employs is as follows:

Half an hour before the operation the patient receives a quarter of a grain of morphine hypodermatically. A 1 per cent solution of novocaine is used to an ounce of which is added 20 drops of 1000 solution of epinephrine. As much as 240 minims of this solution can be safely used for an adult child would correspond to about 5 grains of novocaine. As a matter of fact the author has never found it necessary to use anything like that amount to do painless appendectomy.

The muscle-splitting McBurney incision is used in most cases cut as well as horizontal. This incision is particularly adapted to the peritonotomy under local anesthesia. The skin near the tensor superficialis is not very sensitive but by far the greatest advantage of an incision in this location is the fact that it comes directly out on the caecum. Rarely is it necessary to pack against the small intestines (although this can readily be done without causing pain) and there is thus less handling of the intestines. The novocaine is first injected into the skin along the line of the proposed incision. In doing this the author insists to bleach the skin with the injected solution. Then the novocaine is injected under the skin along the same line.

After a wait of three minutes the skin and subcutaneous tissues are painlessly incised down to the aponeurosis of the external oblique. A sharp scalpel is used for dividing all layers, as scissors, being blunter than a knife, are more apt to cause pain. Next novocaine is injected under the external oblique aponeurosis and after two minutes that is divided. The solution is next injected into the internal oblique muscle, parallel to the fibers of the muscle.

After another wait of a few minutes the internal oblique is cut parallel to its fibers. A little novocaine is then injected under the peritoneum and an interval of fully three minutes is allowed to elapse before dividing it. If done in this way there will be no pain up to this point. All manipulations should be as gentle as possible. It is rarely necessary to apply artery forceps in opening the abdomen through this incision which is an additional advantage as the crushing of the blood vessel with forceps may cause some pain unless the novocaine is injected around the vessel. If necessary a packing can be introduced to keep the small intestines out of the way although it is rarely necessary with this incision.

As soon as the caecum with the appendix is exposed some novocaine is injected into the mesentericolum. If this is not done the patient will complain of cramplike abdominal pain referred to the navel or put of the stomach. By anesthetizing the mesentericolum this pain is obviated. After a wait of three minutes the appendix can be pulled out of the abdomen the mesentery ligated and divided and the appendix removed with almost no pain. It is not necessary to inject novocaine into the base of the appendix before ligating and removing it. If the mesentericolum is properly anesthetized there will be no pain during the removal of the appendix. It is perfectly feasible to draw the right tube and ovary into the wound and do any operation on them that may be indicated.

The abdomen is closed layer by layer in the usual manner and if the technique has been correct the closure of the wound will be entirely painless.

EDWARD L. CORNELL.

Landman A. A. Anorectal Fistula. *A. J. M. J.* 9: 1189

The author treats anorectal fistula from the standpoint the anatomy of the pelvis and ischio-rectal fossa and maintains that the condition in practically every case is preceded by a suppurative focus which in turn originates in the bowel or any viscus between the pelvic and the retroperitoneal fascia or out on the skin surface. It is followed by a well recognized physical law and should originally be looked for in the situation where gravity and diminished resistance of the tissues militate in favor of its production. Hence internal opening of fistula is met with at the junction of the two sphincters while external opening when the bowel ruptures through any portion of the ischio-rectal space has been found in the upper perineum in the post-rotational angle of the fistula.

Abscess of the pelvic or anopercineal region results in fistula primarily because of failure to drain promptly thoroughly and efficiently or because of careless or unskillful after-treatment or both favored by natural conditions in this region which interfere with rest and cleanliness so necessary in wound repair in other situations.

It is evident from the above that the successful

operative treatment of fistula depends in a general way upon the production of favorable surgical conditions followed by suitable after-care.

Saphir J. F. Ischio-rectal Abscess from a Fish Bone. *A. J. M. J.* 9: 1194

A man aged 34 swallowed a fish bone and three days later developed boils and tenderness. He was operated upon in two weeks of ischio-rectal abscess but the fish bone was not removed. The fistulous tract returned in six weeks. At the second operation the bone was removed by the author.

The points of interest that stand out in the case and treatment of ischio-rectal abscess are as follows:

- 1 The necessity for early diagnosis.
- 2 The necessity for more frequent rectal examinations on the part of the family physician.
- 3 The necessity for complete and thorough laying open of the canal and prolonging the affected area for branch canals, pockets and foreign bodies.
- 4 The necessity for trimming out the edges of the wound to prevent bridging and to hasten healing.
- 5 The necessity for keeping the wound clean and properly drained to prevent infection.
- 6 The sphincter can be cut without causing incontinence if cut at right angles to the muscular fibers.
- 7 The ability to get along with out locking up the bowels for a week without the use of opiates and without the use of the barbarous rubber hose.

I. A. C. HILL.

Hoeve H. J. Complete Removal of the Intestinum Rectum and Colon Peritonum for Carcinoma. *A. J. M. J.* 9: 1195

The author briefly discusses the subject of carcinoma of the rectum and colon and reports a case of complete removal of these structures. He emphasizes the necessity of a thorough rectal examination in all cases showing low bowel symptoms.

The theory of Lark and Bliss that an early infectious disease due to a parasite belonging to the chytidia class a vegetable organism on the border land of the vegetable and animal kingdom is considered by Hoeve to be the most probable.

In a colon with the junction of the left colon and the sigmoid the author originally indicates the abdominal route in the removal of the rectum and sigmoid as giving better exposure and cleaner removal of all the glands and surrounding tissue usually in the abdominal cavity. In either the left iliac region or through the left rectus muscle. Contraindications for operations are metastases into the liver and involvement of the seminal vesicles, the prostate or the base of the bladder, the parietum and the ovaries in the female and parietal and omental of the upper hemorrhoidal and inferior sigmoidal arteries.

The case reported is that of a middle-aged 46-year-old man of a cruciate shape, pale, anemic, malnourished, loss of weight, weakness, general debility. On examination the tumor of

the rectum was found, extending upward from the prostate for about five inches. The mass was hard and bled easily. No enlarged glands were palpated.

Median abdominal section was performed, but no liver metastases and no glandular involvement were found, the growth being entirely extraperitoneal. The bowel was severed well above the mass, sterilized by phenol and alcohol, and closed by purse-string sutures. The rectum was freed by blunt dissection and the perirectal tissue completely removed. The rectum was then cut at the internal sphincter which was touched with phenol and alcohol. The cavity was drained through the anus by a large rubber tube. Small tube was inserted through an opening posterolateral to the anus and few strips of iodoform gauze inserted, after which the abdomen was closed.

On the third day bacillus coli infection developed which was checked by irrigation through the anal tube, but the patient died on the eighth day. No post-mortem was obtained.

The pathological diagnosis was adenocarcinoma of the rectum. P. M. CHASE

Morley, A. S. The Treatment of Hemorrhoids by Injection. *Lancet*, Lond. 9 6 10, 0 7

The obvious advantages of the treatment are (1) that the patient need not be confined to bed for more than 24 hours, at most (2) that there is no need for general or local anesthesia since the treatment is practically painless, if properly performed (3) that it can be made quite inexpensive so much so that it may be brought within the reach of even poor patients who certainly could not face the expense of an operation in a hospital (4) that it is perfectly safe procedure in such patients as the very aged, pregnant women, and others, who for some reason cannot take an anesthetic safely (5) that there is no after-pain and (6) that it is invariably harmless.

The treatment is not suited to cases of strangulated or irreducible hemorrhoids (1) cases in which there are other complicating conditions, such as old-standing fissures, fistulae, ulcers.

The treatment consists of the injection into each internal pile of a few drops of carbolic acid and glycerine. The following solution is employed:

Acid carbolic	gr. xlviii
Glycerine	dr. ii
Aquæ destillat	dr. ii

The amount which should be injected into each pile varies from 2 to 6 minims of this solution. Inject all the piles at one sitting whenever it is possible to do so. It is easiest and best in every way to perform the injection through a large speculum. The one most suitable is Kelly's sphincteroscope. The other useful appliance is a suitable syringe.

Before making the injection, the piles may be sponged over with a little weak biniodide of mercury 0.1% lycol solution, which should be mopped up

at once with a dry swab to prevent risk of absorption. It is a good plan also to touch each pile at the spot where it is proposed to inject it with a drop of pure carbolic.

The patient should be instructed to keep quiet, in bed if possible for the first 2 to 24 hours and to wash the piles at once with cold water should they prolapse and then to grease them well with vaseline or some simple ointment and gently press them back. Where the piles are large, as many as four or five injections at weekly intervals may be required but, as a rule, two or three are sufficient.

EDWARD L. CORNWELL

Edwards, F. W. The Treatment of Hemorrhoids by Injection. *Lancet*, Lond. 9 6 10, 8 9.

The author refers to the fact that Van Buren was one of the first to advise the treatment of hemorrhoids by injection. He has tried out the method in some hundred cases and seems well satisfied with the results. Except in two cases there was no pain. One injection sufficed to cure some, but the majority required two or three. It failed in one or two cases, which later required excision and ligation. He uses 30 per cent carbolic acid in equal parts of glycerine and water. Having protruded the piles, the patient is placed in the knee-elbow position and an injection of from 3 to 6 minims of the carbolic solution is made into the center of each pile. In some of the large piles he injects 5 minims in two places. The piles are then well smeared with vaseline and replaced as soon as possible, for the injection always causes the hemorrhoids to swell. Bowel movements are prevented for forty-eight hours, and should prolapse occur in the meantime, immediate replacement is necessary.

He emphasizes the importance of protruding the piles before attempting the injection and gives as his reason the following: (1) It is much easier and one is more certain of getting into the center of each pile. (2) If the piles are injected through a speculum a special long syringe is necessary whereas an ordinary hypodermic syringe suffices when the piles are protruded. (3) Piles which cannot be protruded should be left alone. They are to be cured by palliative means such as local applications, coemata, etc. (4) As to diet, regulation of the bowels, etc. (5) An assistant is almost necessary if a speculum is used, and should any bleeding occur on the withdrawal of the needle, is indispensable. He does not believe that this is as likely to take place as when the piles are protruded but it might occur when a extra pair of hands would be useful.

Cases fitted for injection are those of uncomplicated internal hemorrhoids which can be protruded, then returned and kept within the bowel, so that comparatively few cases are fitted for the injection treatment. For instance he cites cases in a day's experience in his clinic in which were complicated by other lesions 4 with fissure, 4 with external piles with an anal ulcer and 1 with a thrombosed internal pile. After the injection a few hours

in bed are advisable, after which the patient can walk about and attend to his usual occupation.

The great advantage Edwards sees in the injection treatment are (1) no confinement to bed excepting for a few hours when possible (2) no anaesthesia needed therefore there is no post-anaesthetic vomiting (3) no pain (4) no enforced absence from business (5) no risk from the little operation itself and no risk of stricture or infection following and (6) immediate and steadily increasing betterment.

As regards operative treatment he is a strong advocate of the ligature periton and cædemus the Whitehead operation. Dr. A. C. BAXTER.

Burrows W. F. and Burrows, E. C. A New Hæmorrhoidal Operation: The Snare and Bullet

J. L. M. I. I. 18

The hæmorrhoidal operation described is simple rapid and free from danger suitable for the use of local anaesthesia and has been used in a series of 60 cases.

The instruments required are a hypodermic syringe and local anaesthetic half a dozen artery forceps two pairs of scissors— one pair for cutting the wire, four or five strands of strong pliable wire— both ends of each strand threaded through a perforated lead bullet and a bullet hammer and crusher. The operation resembles most the ligature method but is cleaner more thorough and more quickly carried out than the latter. The pile can be cut away clear to the snare than the ligature and the snare and bullet finally lie at a higher level than does the ligature which the fingers must get into the anal canal to tie a procedure that is difficult.

The tissue to be removed are thoroughly anaesthetized with the local anaesthetic fluid and an incision is made below and to either side of the extra-intestinal hæmorrhoid extending into the rectum and dividing the deeper tissues in a somewhat the form of a V. A pair of forceps previously applied to the tissues to be removed is used to exert gentle traction on the parts exposing more of the rectal mucosa proper. A second pair of forceps is placed in the rectal mucosa and again traction is made in the mass and the lateral incisions are extended in order to the degree desired. About the last pair of forceps a transverse incision is made in the mucous membrane a point of some importance since it is the slit that the wire will sink and prevent slipping. A wire loop threaded through the perforated bullet and its free ends held in a clamp is then slipped over the handles of the forceps at the hæmorrhoid and then placed in position with the forceps. While the wire loop is kept taut the bullet is grasped by the bullet holder and crushed and forced down on the mucosa to either the skin or mucous side of the pedicle (preferably the latter) thus tightening the snare. The bullet forceps are released with pressure and the lead bullet made to collapse on and hold the taut wire where they pass through it securing the snare in proper

position. The excess of the lead bullet and the wires are secured by the bullet holder.

When extensive prolapse is accompanied by hæmorrhoids somewhat changed in position the same manner is used. A curved needle passes through the rectal mucosa in the hæmorrhoidal area. On half an inch of the thread is threaded through a perforated bullet which encircles the pile. The same bullet is then used so that the wire is secured and the hæmorrhoids present are removed in the same manner. Three in all will usually clear the rectum.

Most of these patients are cured but if any are not cured the operation is complicated by the fact that the hæmorrhoids remain in the rectum from the fact that the wire is not inserted.

It is not necessary to insert plugs which are used to close the wound and pain on removal of the wire is usually relieved. The operation is completed in five or ten minutes. The snare and bullet may be used on the same day but usually the interval is between the two.

E. B. L. C. ALL

Bell F. M. Bloodless Operation for Hæmorrhoids and Prolapsus Ani

The following procedure is indicated in any case in which the hæmorrhoids are indicated. After dilatation of the anus is effected at the junction of the internal and external perineal line and the rectum is exposed, a uon is made the stricture is made a triangular shape. Each side of the triangle is successively clamped the turrel is then moved to the clamp marking the stricture. The latter is placed at the apex of the triangle using silk with a Hagdon needle at both ends and the needle is as a cobbler's stitch. The triangle is then where it is used. The stricture is then cut with a pair of forceps and the free edge of the triangle is then treated with traction sutures removed. The operation has the advantage of being bloodless and less liable to complications. E. F. ARMSTRONG.

LIVER, PANCREAS AND SPLEEN

Deaver J. B. Operation for Removing the Gall Bladder

The type of operation which is recommended is described as follows. With the abdomen opened the gall bladder and right flexure of the large intestine are freed. In case there are adhesions the removal is thoroughly well off. The edge of the liver and the fundus of the gall bladder are grasped with the right hand and the

piece of moist gauze, and are pulled downward, outward and then upward, making the cystic duct and the free border of the gastropyloric omentum taut. A small incision is made through the upper part of the border of this omentum and the duct exposed. It may well be clamped at its junction with the gall bladder and cut across distal to the clamp with the canter. The common duct can readily be explored by passing a probe through the stump of the cystic duct into the duodenum. Before the probe is removed the duct is palpated between the fingers and thumb of the free hand, so that no stone is overlooked. The cystic artery lying above and to the inner side of the cystic duct is next clamped and cut. If it is not necessary to drain the common duct the stump of the cystic is ligated and next the cystic artery.

The gall bladder is freed from below upward. This is done step by step following closely with continuous suture of catgut which passes through the liver tissue forming the sides and floor of the gall-bladder bed. In this way the operation is a bloodless one and the author regards it as superior to packing with gauze or to placing a cigarette drain in the cavity left behind. The divided layers of the gastropyloric omentum are sutured, not covering in the stump of the cystic duct. A small rubber tube is placed just beyond the free border of the gastropyloric omentum and is left for four or five days. Should the stump of the cystic duct leak bile, this it may be left in place. (1920)

O'Brien, F. W. The Present Status of Gall-Stone Diagnosis by the Roentgen Ray. *Boston M & S J* 96 dec 300.

O'Brien reviews the literature, paying particular attention to the works of George and Cofe. In his own work O'Brien uses fast finely grained, intensifying screen in all gall bladder work. The advantage of employing screens is that of time as well as intensification. It is fundamental in this work that the patient should not breathe during the exposure. Stout individuals may find it difficult to hold the breath even for a second, hence the reason for speed. The screen, too, will catch more surely the markings of the so-called soft gall-stones. It is again of special value in the robust and corpulent where long exposure on an unreeled plate would give rise to so much secondary radiation that the gall-stone shadows would actually be lost to the eye.

The position of the tube will depend upon the position and size of the patient but usually it is in plane parallel to that of the patient's body. A small diaphragm and small cone are very important factors in the successful search for gall-stones.

One objection to the diaphragm and small cone is the liability to overlook stones in horizontally placed gall-bladder so that it is well not to confine the search for stones to the commonly accepted location for them. They may be found anywhere

in the lower or upper right quadrant and even to the left of the median line.

The importance of using a satisfactory developer need not be mentioned. More than that one may with advantage overdevelop certain plates while giving others their normal developing time. Plates that are too dense to be read may be reduced in that way gall-stones had we may be detected in the process of reduction that would not be likely to be found in any other way.

The plates should be read only when thoroughly dry. Direct illumination by the ribberm sky is often particularly helpful.

That experience is a tremendous asset to successful diagnosis is attested by the number of roentgenologists who under the impetus of the recent advances in gall-stone diagnosis, have gone back over their old plates of the gastro-intestinal tract and gall bladder region in which they have reported no evidence of gall-bladder calculi only to find on re-examination very definite evidence. (1920) R. BOWEN

Petersen, W., Jobling, J. W., and Eggstein, A. A. Serum Changes and the Cause of Death in Experimental Pancreatitis; Studies on Ferment Action. *J. L. P. Med.* 96 xiii 491.

Identical study of the ferment balance of the serum during various pathological conditions. The authors had occasion to observe the serum changes in a series of eighteen dogs in which an acute experimental pancreatitis had been produced.

From the series of experiments the authors believe they are justified in assuming that death was caused by the sudden flooding of the blood stream with the higher split products formed at the expense of the pancreatic tissue of which the protease in essence was a index. Except in the experiment in which they used trypsin for injection there was no increase in serum protease at any time, as would have been expected if the intoxication had been true trypsin shock, or was there much change in serum lipase (esterase) the condition in this respect resembling closely the results observed following the injection of split products.

From this study the following summary is given: The serum changes observed during acute experimental pancreatitis indicate that the shock and death are due to an intoxication from protein split products and not to an intoxication from pure tryptic ferment.

2. When the pancreatitis is produced by the injection of an antiproteolytic substance (sodium oleate) the degree of intoxication bears no relation to the degree of tissue destruction.

3. The increase in serum antiferment apparently favors the recovery. (1920) E. BELL

Levy, I. H., and Kantor, J. L. The Incidence of Visceroptosis. *Boston M & S J* 96 dec 534.

Visceroptosis, in the sense that the organs assume a lower level in the abdomen than we are in the

habit of calling normal is in the joints the authors in a large majority of congenital conditions or a reversion to the primitive type of development. Their conclusions are based on a study of 1600 patients having a ligamentous disturbance as to the hip joint referred to a routine roentgen examination. All the cases in which the ligamentous abnormality was more than one inch below the line between the iliac crests are included in the posterior classification. On this basis of the classification the percentage was 64.4 per cent had congenital. The condition was slightly more frequent in men than in women and in individuals under forty years than over that age in both

males and females. It occurred more often in single than in married women, and was associated with ptosis of the other viscera, the chest and abdomen in varying degrees in many of the cases.

Improper garments, occurrence of pregnancy or any other incidental causes play no part or at most only a very minor one in the production of the condition. The authors hold that it is intimately related to the structure of the body and probably arises from some congenital predisposition. Ptosis in itself is not a disease. Mild degrees of it may be under certain circumstances cause symptoms, whereas marked types need not necessarily impair the functions of the affected organs. A. HARTMAN.

SURGERY OF THE EXTREMITIES

DISEASES OF THE BONES, JOINTS, MUSCLES, TENDONS, CONDITIONS COMMONLY FOUND IN THE EXTREMITIES

Henderson M. S.: Loose Bodies in the Knee-Joint. *Am. J. Orth. Surg.* Rochester 1906.

The author classifies loose bodies in the knee joint as follows:

1. Fibrous loose bodies intrinsic in origin.
2. Bodies composed of organized connective tissue of bone and cartilage intrinsic in origin.
3. Loose foreign bodies extrinsic in origin.

He recommends that in the operation the most rigid asepsis be observed and usually a general anesthetic is necessary. The incision may be laterally on either side or the patella may be split. The condylar incision is better for the removal of the meniscus. If the body is in the posterior part of the joint the incision described by Brackley and Osgood is the best. If the body eludes the surgeon a second attempt at a lateral incision is better than a too prolonged scarring.

The author's conclusions are as follows:

Fibrous loose bodies are due to some disease condition of the joint and do not cause mechanical derangements.

Organized connective tissue loose bodies produce mechanical derangement.

Loose bodies may have as their primary cause some condition such as osteoarthritis or Charcot's disease, but the secondary cause is direct or indirect trauma.

Orthopedic treatment alone is a group more or less distinct from the rest. The bodies seem to be produced by very slight indirect trauma.

Trauma direct or indirect is essential to the production of a loose body.

Surgery offers the only permanent relief and the general condition of the patient being satisfactory the bodies should be removed.

PHILIP LEWIS.

Young J. K.: A Case of Arrested Development of the Carpus and Tarsus. *J. J. K. S.* 1916.

The author was unable to find a recorded case of bilateral club-foot and club hand due to arrested development or from congenital absence of bony structures.

He reports a case of a ten year-old girl with the condition in which he thinks the arrest of development as probably caused by some acute infection general in character but its exact nature unknown. PHILIP LEWIS.

FRACTURES AND DISLOCATIONS

Skilern P. G. Jr.: The Diagnosis of Fracture by Physical Examination Versus Skiagraphy. *Intern. M. J.* 1916.

By obtaining a careful history of the mechanism of the injury and by a brief and gentle physical examination with the elicitation of true guarding, tenderness, the diagnosis of fracture can be established in the great majority of cases without the aid of a skiagram.

The chief value of a skiagram consists in checking the extent of the deformity. A skiagram must be considered merely as one of the many signs of fracture.

It is more difficult to diagnose contusion and sprain than to diagnose fracture. Such diagnoses are often but cloaks to cover hasty and incomplete physical examinations and should presuppose negative results following the exhaustion of every means at command to prove the presence of fracture. F. D. DICKSON.

Ellenby G. F.: The Fracture Problem. *North. M. J.* 1916.

The author in this general paper calls attention to the seriousness of every fracture. He lays stress upon proper alignment and its relation to function. Between the open and closed methods

of treatment he thinks there is a happy medium. H advises the open treatment in fractures of both bones of the leg, the arm with irreducible overriding fracture of the femur with overriding fracture of the patella and most fractures of the olecranon. If there is no infection, operation is indicated at once. Massage and manipulation should be begun at once in the closed, and after few days in the open, operative treatment. In compound fractures he operates at once. In ununited fractures the bone-graft is recommended.

E. B. MURKIN

Rosenzweig, S. B. The Causes of Prolonged Disability from Fractures. *V F M J* 9 6, 401, 440

Rosenzweig urges that as much care be given to the prevention of prolonged disability after fractures as is given to the various operative procedures used in their reduction.

The causes of prolonged disability may be general or local. The general causes are less frequent. Among the most important are cachexias, as in tuberculosis and malignancy and the severe anemias, circulatory disturbances, as in cardiorrenal or hepatic diseases, nervous disorders, as in tabes, paresis, or myelitis. Old age is also important.

The local causes are divided into three groups: (1) amount of bone injury and damage to soft parts, (2) the sequelae of poor reduction, malunion, delayed fibrous union and non-union, and excess of callus and its results, (3) the result of insufficient or improper care such as pressure ulcers, muscular atrophy, ischemic contracture and adhesions within the joints and tendon sheaths.

LLOYD T. BROWN

Henderson M. S. The Transplantation of Bone in Ununited Fractures of the Shaft of the Humerus. *A m. Surg. Phila* 9 6 441, 464.

Henderson reports 10 cases of ununited fracture of the shaft of the humerus operated upon at the Mayo Clinic, with the following results. In 4 cases union was obtained at the first operation, in 3 a second was necessary, in 3 no data could be obtained as to the final results, and in one no union is known to have occurred. In 7 cases there was primary musculospiral paralysis produced at the time fracture occurred. In one no attempt to trace the nerve was made. In the other the severed ends were encased in fascial tube made from the fascia lata, the operation being too recent to state the result. One case developed the same kind of paralysis at the time of operation from too vigorous retraction, but at the end of one year full function was restored.

H arrives at the following conclusions:

1. The transplant must be as large as is practical (6 inches by one half inch or larger). It must extend well past the thinned decalcified ends into the hard healthy bone beyond.

2. The inlay is the method of choice.

3. Adequate post-operative fixation is necessary. A split plaster-of-Paris spica prepared a few days before operation can be fastened on with adhesive strips immediately after the operation is completed thus eliminating the difficulty of applying the spica and the danger of disturbing the graft thereby. Two or three weeks later when the wound has healed and the stitches have been removed, a new cast can be applied carefully with the patient sitting up.

4. By removing the bone-graft from the internal, flat surface of the tibia the strong crest of the bone is left to perform its important weight bearing function. The patient may be allowed to walk in from 1 to 4 days and by this time the blood-clot filling in the bony defect has become sufficiently organized so that no hemorrhages will occur when the leg is used.

5. A properly applied spica cast may be comfortably worn for 3 months when in all probability union will be complete.

R. S. BROWNE

Hawley G. W. A New Method of Fracture Fixation. *Intern M J* 9 6 441, 7

Hawley describes a method of clamping oblique or transverse fractures by means of wire in such a way that the wire may be withdrawn from the wound whenever desired without disturbing the fixation or making a fresh incision.

The instrument consists of a long slender bar a loop of heavy woven bronze or ordinary picture wire attached to a sliding clock and thumb-screw. The wire loop is designed to encircle the bone and engage the end of the bar to form a false knot. By turning the thumb-screw in one direction the loop can be tightened, and by turning in the other direction the loop is released and withdrawn. For application the fracture is exposed in the usual way and the apparatus applied after reduction of the fragments the wound is then closed leaving the bar protruding and dressings and a plaster cast are applied. The clamp may be left on as long as desired and withdrawn by loosening the loop and allowing it to slip off the end of the bar.

From experience in 7 cases the author concludes that the instrument has its field of usefulness in fractures where there is much tendency to displacement. A few cases have become infected, but only in a mild degree, and healing was without incident.

F. D. DICKSON

Simmonds, B. S. A Method of Treating Gunshot Fractures by an External Fixation Apparatus. *Brit J M* 9 6 448

The author describes an apparatus for holding in position the fragments in compound fractures. By means of an aseptic operation he inserts into the bones at a distance from the seat of the fracture screws which are long enough to project well beyond the skin and to immobilize the fragments by

means of a rigid plate fixed to the screws by nuts the entire operation being done without interfering with the original wound.

The advantages of the method are (1) the apparatus is simple and inexpensive (2) the operation is simple and easily performed (3) the original wound is not interfered with and healthy tissues are not extensively opened.

LLOYD T. BROWN

SURGERY OF THE BONES JOINTS ETC

Cotton I. and Mann G. A Further Study of Bone Repair. *S. Ark J. Med.* 9 6 15

The authors give a report of studies in bone repair from experiments done within the last two and a half years. The literature since 1913 is reviewed and grouped into two schools: one in which claims are made that periosteum makes bone and the other in which claims are made that periosteum plays no rôle in new bone formation. The conclusion from the study is that the periosteum is a means of protection against infection, a source of added blood supply, a limiting membrane and its presence favors an earlier repair of defects, but the healing in its absence is bony nevertheless.

The authors found that free transplants of periosteum in the anterior chamber of a cat's eye did not live and produce bone. Free periosteum wrapped around the carotid artery showed no growth of bone. Resections of the tibia subperiosteally leaving the closed periosteal tube behind gave no regeneration of the tibia from the periosteal sheath. The authors give a summary of the literature up to date in regard to callus formation. In 19 fracture experiments where the tibiae in the same animal were broken simultaneously, one leg having the periosteum removed first and one having the periosteum remaining intact showed repair in both cases. In the bone from which the periosteum had been removed the callus formation seemed to be greater than in the other, but not so far advanced in its development up to 30 days after the experiment started. A series of experiments where a tibia was trephined from the bone subperiosteally and the periosteum sutured back into place again in contrast to a case where the same operation was done but the periosteum was removed, showed that new bone was formed in each instance similarly, namely, that it seemed to spring from the medullary part of the bone working toward the surface, only in the case where the periosteum was not removed the repair was much greater in extent. In regard to the use of small free bone transplants uncovered by periosteum the authors state that sooner or later these perish.

In regard to intramedullary transplants the authors think that although osteogenesis on the part of the recipient bone is stimulated, yet the ultimate fate of the transplant is death. Protocols of the experiments with the appropriate bibliography are given in the original article.

Campbell W. C. General Heliotherapy in the Treatment of Bone and Joint Affections. *Am. J. Orth. S.* 9 6 15

The author used the sun treatment in 8 cases in 8 of which sufficient time had not elapsed to obtain results. Of 4 with histologic improvement was rapid in 3, but for various reasons exposures could not be continued. Of the remaining 4 in which treatment was satisfactorily given, 1 was tubercular, 4 osteomyelitis, 2 pneumocele, 1 arthritis, 1 peri-arthritis following direct infection of the knee joint, 1 arthritis deformans, 1 decubitus.

He concludes:

1. That there is rapid expulsion of sequestra.
2. That there is marked and early beneficial effect in severe septic conditions.
3. That there is rapid resolution of the tubercular process resulting in bony ankylosis in every case.
4. That there is much difficulty in having the exposures regularly given in well-regulated general hospitals.

5. That close attention should be given to orthopedic measures for the prevention of the deformity as in any previous treatment by using removable apparatus and extension.

6. That a decided advantage has been made not only in the treatment of surgical tuberculosis but in certain other affections of bones and joints.

THOMAS L. LIND

Roberts P. W. The Influence of the Os Calcis on the Production and Correction of Valgus Deformities of the Foot. *Am. J. Orth. S.* Washington 9 6 15

In this paper attention is called to the importance of the os calcis as a basic factor in the cause of valgus deformities of the foot and as a medium through which weak foot and moderate paralytic valgus can be controlled. The observations are based upon the principle that a body with an arc for its base can support a superimposed weight without tilting only when the thrust of that weight is received over the center of balance. It is shown that the under bearing surface of the os calcis is on cross-section of the bone at its point of contact with a plane surface an arc and is therefore subject to the law just cited. It is further demonstrated that because of the firm ligamentous union of the os calcis to the rest of the foot any rotation of the heel bone must alter the strain on the longitudinal arch raising it if the superior surface of the os calcis is rotated outward and depressing it if rotated inward. Therefore by means of a plate designed for the purpose weak foot and moderate paralytic valgus may be controlled without any prosthesis whatever under the arch. The same principle is applied in the surgical treatment of acquired varus.

Lord J. P. Arthroplasty of the Interphalangeal Joints. *Am. J. Orth. S.* 9 6

The author used free fat and fascia from the fascia lata to relieve some cases of stiffening and

some with congenitally contracted and pathologically dislocated fingers. He usually employed 400 novocaine locally and a tourniquet. It is necessary to control bleeding thoroughly before transplants are placed and the wound closed.

While his results were somewhat disappointing in the interphalangeal joints of the fingers the majority of the joints were greatly improved, some to the extent that the patients were satisfied because the fingers became usable whereas before they were almost useless.

Free full motion was obtained in none of the cases. Some joints, with a chronic arthritis, lingering and somewhat painful before operation, became painless afterward.

PHILIP LEWIS

Tarnowsky G. d. The Heterogenous Bone-Peg: Its Possibilities and Limitations. Surg. G. & O. Abst. 9 6 222, 6

In view of the present well generalized belief that all bony transplants are ultimately absorbed, the author was led to try sterile intramedullary pegs derived from the long bones of cattle. Sufficient time has not yet elapsed to permit of a positive statement regarding the exact interval which must elapse between the implantation and final absorption of the peg, but serial skiagraphs of operated cases show the bone to be slowly absorbing. Clinically the results have, in the main, been good. The callus while tending to be excessive has been firm and primary union has been obtained in all but one case.

The distinct advantages of the soup-bone pegs are (1) they are easily obtainable (2) they can be sawed or chiseled into any length or thickness (3) they are easily sterilized (4) they do not become brittle even after repeated boiling. The pegs are especially indicated in transverse or slightly oblique fractures as well as in fractures of the neck of the humerus or femur. They are less satisfactory in markedly oblique fractures or fractures with considerable splintering of the shaft.

Soule, R. E. The Use of the Autogenous Bone-Graft Pin in the Treatment of Painful Flat Foot Paralytic Valgus, etc. T. Am. Orth. Ass. Washington, 9 6, 31

In his paper read before the American Orthopedic Association in Washington in May 1916 Soule gives his observations from experience gathered in his investigations of painful foot disability over an extended period in orthopedic practice and emphasizes the fact that in acquired deformities of the foot the astragalus is seldom if ever displaced laterally. From his findings he has applied a new method of treatment to correct deformity and relieve painful disability which is applicable to a very large percentage of the conditions. He cites 33 cases operated on giving numerous illustrations of his cases before and after treatment, including painful pronated flat foot paralytic valgus fracture displacement of the tarsus, and osteo-arthritis where

he has applied arthrodesis of the astragaloscaphoid joint and autogenous bone-graft pinning of these bones with extremely satisfactory results.

The indications for this method of operating in flat-foot are

1 Where the methods have failed to restore the foot to full function, painlessness, and normal contour after reasonable trials and a relapse toward the original deformity takes place

2 Where bony prominences of the tarsus preclude the use of the rigid flat foot plate and where pronation of the foot is predominating part of the deformity found in cases of relaxed pronated weak feet

3 In cases of pronation of the foot with depression of the longitudinal arch as result of fracture of the scaphoid or astragalus or displacement of the scaphoid

4 In cases of pronation and valgus of the foot following a flat paralytic valgus with anterior and posterior talar muscles in similar position to the scaphoid

5 In cases of osteo-arthritis of the foot where the predominance of pain is associated with the mid tarsal joint with or without valgus pronation.

The technique of the ortho operation is as follows. With the foot in a leg prepared for operation preferably by the iodine method and a tourniquet applied above the knee an incision two and a half to three inches long is made on the dorsum of the foot along the inner border of the tendon of the anterior talar muscle from the bend of the instep. At the distal end of this incision it is curved inward and downward to expose the inner prominence of the scaphoid through which the bone-pin is to be inserted.

Through this incision the dorsum of the foot the entire width of the astragaloscaphoid articulation is exposed.

The articular connecting ligaments of the entire width of the anterior area of the joint are dissected away and the forefoot is freed downward to expose freely the articular surfaces.

With the author's double curved gouge made to fit the ovoid of the head of the astragalus the corresponding concavity of the scaphoid the entire articular cartilage is easily removed from both surfaces, preserving the ovoid of the head of the astragalus and the corresponding concavity of the scaphoid thus assuring greater area for bony contact and accuracy of relation of the two bones in position.

With the forefoot freed into a normal position and held by an assistant securely in proper adduction a hole three sixteenth to one-fourth inch in diameter is made with the motor drill through the inner extremity of the scaphoid from before backward obliquely outward and upward into the head of the astragalus to sufficient depth, one and one-half to two inches, to securely lock the scaphoid to the astragalus. The drill is disengaged from the motor and left in position in the drilled hole. A strip

of cortical bone is next removed from the crest of the tibia sufficiently thick to form the dowel peg of the same size as the drill used. This can be done with a chisel but preferably with the single or twin motor saw. When shaped in the dowel shaper it is ready to be substituted for the drill which has been left in position in the hole drilled through the scaphoid into the astragalus. The loof is introduced into the bed immediately the drill withdrawn the foot being held firmly and steadily in its correct position by an assistant during the withdrawal of the drill and the introduction of the loof pin which is driven home by a tap of the mallet. The excess length of the pin is cut off with forceps or the motor saw flush with the bone surface.

The skin wound in the leg and foot are closed with suitable suture material. Drainage dressings are applied and plaster of Paris cast put on from the toes to the knee with the foot at a right angle.

Convalescence is uneventful. The patient is up out of bed in a chair with foot and leg in a horizontal position in three or four days. At the end of two weeks he can be up on crutches for intervals during the day at a single foot is operated. At the end of six weeks the cast is removed and massage, active exercise and weight bearing is begun. At the end of eight weeks in the author's experience full weight bearing can be all well.

The advantages of the operation are

1 The period of treatment is greatly shortened.

There is no possibility of a relapse to the former condition and position.

3 A strong, painless, stable foot is the result.

4 There is no diminution of the necessary function of the foot.

5 There is no need of relief from the torture and annoyance of wearing flat foot arch supports or other external supporting braces or specially constructed shoes.

6 The operation is applicable to cases much younger than could heretofore be treated by any other technique procedure.

The technique is simple definite and accurate.

Level D Transplantation of Tissue Level 1

The author believes that the autoplasmic graft is the most successful of the skin transplants. He believes that in bone-grafting the ideal graft is one containing enough compact bone to lend support and fixation when required and not sufficient to cause cellular death hence he prefers the anteromedial surface of the tibia for grafting purposes that the compact bone of a graft is gradually absorbed to be replaced by the periosteum and the endosteum that bone-grafts placed in cavities following curettage of giant-cell sarcoma or fibrous osteitis do not live because of the bleeding into the cavity thereby preventing vascularization that bone transplanted into infected areas lives and reacts to the infection like normal bone and that the inlay graft gives

better results than the intramedullary splint in ununited fractures.

He describes in detail the technique of amputation as performed by M. Arthur upon nine patients. In this case the extremities of the forearm were torn and resected and transplanted strips of tibia which had previously covered a laceration of the tibia.

He believes that the use of the autoplasmic graft or of a replacement of the tibia by a prosthesis upon the early fixation of the fragments is a better method.

Levi and Kirk believe that the use of the autoplasmic graft is fully justified in the treatment of the tibia which is badly injured and that the use of the autoplasmic graft cannot be cured.

Watson C. G. Amputations at Base Hospitals in France

The author explains the reasons for the use of the autoplasmic graft in the method of Amputation and the present war. The method of amputation in all amputations are

1 To keep the patient comfortable and after the operation.

2 To permit an operation which is the spread of the infective gangrene and the epidemic.

3 To save as much limb as possible. The disadvantages of the flap method are

1 There will be less chance of a patient losing his life at the time of amputation, saving the patient's life because there will be less chance of checking infection.

2 There will be more chance of the patient losing his life at the time of amputation.

3 For the amputation to succeed it will have to be performed as high as or higher in the limb than the second stage of a primary flap amputation.

4 Healing by first intention cannot be expected (The cases must be seen to appreciate this).

5 The risk of secondary hemorrhage is a very grave danger in these cases is greatly increased. Since the routine adoption of the flap method the author states that not a single case has been lost from secondary hemorrhage following amputation in the hospital he is connected with. The only death in their hospital from secondary hemorrhage after amputation, during the last six months occurred in a case operated on near the front by the flap method. Secondary hemorrhage occurred during transport and again after admission to the hospital.

6 The need for reamputation for epistaxis or hemorrhage may be expected at a time when the patient is unable to stand further operation and often when there is not enough limb available for an amputation.

The advantages of the autoplasmic method are

1 Rapidity with minimum shock.

2 A plain open surface for dressing which is

favorable to the subsequent control of sepsis and which prevents pocketing.

3 Great diminution in the risk of secondary hemorrhage.

4 The operation provides the best mechanical relief of gas tension by dividing all the tissues at right angles to the muscle planes.

5 It allows a temporary amputation to be performed close to the site of the injury so that a permanent amputation can be performed later (when sepsis is under control) a little above the injured area.

6 In cases associated with fracture the proximal end of the bone can be and should be left intact (that is not sawed through) and projecting beyond the plane of muscle-section thus minimizing the risks of osteomyelitis and also providing a useful medium for the application of pressure by means of dressing in case of hemorrhage (a practical point of great value) for moving and fixing the limb and (3) for the application of extension to the skin.

The fluke circular method may be modified, according to circumstances by single flap cut from the damaged area and turned back, thus saving

few inches of bone in the final result although this flap is liable to slough owing to anaerobic or streptococcal infection.

The author lays stress on the after treatment of the flapless amputation. At the secondary operation it is important not to open up muscle planes because of the danger of flare-ups. The muscles attached to the bone should be carefully separated from the periosteum by snipping with scissors until the amount of bone required to be removed has been bared. If the bone is divided without lacerating the granulation tissue the operation can be done without any local or general caction. The periosteum should not be stripped back from the bone otherwise new bone will be thrown out in the muscles.

During the interval between the first and second operation the limb should be kept stretched by means of an extension. The second operation can and should be performed before any serious cicatricial contraction has occurred. In several instances a completely healed and comfortable stump has been secured within a month of the original amputation.

LLOYD T. BROWN

Kelly, M. F. The Flapless Amputation. *Br J Surg* 9 6 111, 676.

The author strongly advocates the flapless method of amputation: (1) gaseous gangrene (2) compound comminuted fracture and (3) multiple wounds.

The author summarizes the advantages of the method as follows: (1) it saves life (2) as the length of limb (3) lessens the risk of secondary hemorrhage (4) arrests the spread of infection whereas in flap amputation sepsis often recurs in the flap and spreads up from there.

The amputation is done as follows. The skin and deep fascia are divided usually by a circular incision.

After retraction has occurred the muscles are divided at the level of the retracted skin—not too quickly to allow retraction of the layers then the bone is sawed off flush with the muscles the vessels are secured and nerves properly shortened. Retraction is easily overcome by extension once the face of the wound is clean.

The method enables the amputation to be done close up to the involved area and would seem a rational procedure under conditions which exist at the front.

F. D. DICKSON.

Bryan, C. W. G. The After Treatment of Amputation Stumps. *Brit Med J* 9 6 1, 480.

The author describes an apparatus for making traction on the skin and soft parts after amputation of either the flap or the flapless variety. It consists of longitudinal strips of two inch adhesive strapping applied to the amputation stump from the joint above to about an inch from the edges of the wound and then prolonged about twelve inches beyond the edge of the stump. These strips are attached to an aluminum ring eighteen inches in diameter. This ring is attached by three pieces of cord tied to it at equal distances from one another the cords passing through pulleys hooked to a Balkan splint to which an extra crossbar of wood has been bolted. The free ends of the cord are tied together and the weights are hooked on. For a thigh amputation a weight of about eight pounds is used, while for the arm about five pounds suffices.

LEON T. BROWN.

ORTHOPEDICS IN GENERAL

R. Harris, P. W. Paralytic Feet. *Br J Med J* 9 6, 111, 820.

The operation proposed applies to practically all forms of paralytic feet where there is instability of the ankle. It is neither so radical as complete astraglectomy nor so certain as arthrodesis. The mechanical problem presented in cases of instability of the ankle following paralysis is the restriction of anteroposterior motion at the tibioastragalar joint and lateral motion between the os calcis and astragalus. Control of either of these joints without control of the other will yield imperfect results therefore it is necessary that both be included in any plan to stabilize the foot. If movement of the ankle joint is obliterated, there will still be enough anteroposterior motion between the os calcis and the astragalus and between the head of the astragalus and the scaphoid to maintain a considerable degree of elasticity in the foot. Hence the operation under consideration aims to efface the astragalocalcaneal joint and to drop the external malleolus down sufficiently to overlap the os calcis, thus blocking lateral motion between this bone and the astragalus. Through a fishhook incision, such as is commonly used for astraglectomy the astragalus is exposed and dislocated from the mortise formed by the lower end of the tibia and

Jones, R. Positions of Election for Ankylosis Following Gunshot Injuries of Joints. *Brit M J* 9 6 1, 609

The author discusses the position of election for the various joints as follows:

In the shoulder joint the arm should be abducted at about 5°. The elbow should be slightly in front of the coronal plane of the body so that when it is in a right angle and the forearm supinated the palm of the hand is toward the face.

As to the elbow joint the majority of men are better off with the arm at 90°. In cases in which both elbows are involved, one should be fixed at 80° and the other at 100°.

In the forearm if the movement of pronation and supination are lost the radius should be fixed midway between pronation and supination.

All injuries of the wrist joint should be treated with the wrist dorsiflexed.

In the hip-joint ankylosis should be encouraged in a position of very slight abduction with thigh extended and very slight outward rotation.

The knee should be fixed in an extended position. In injuries of the ankle the foot should be kept at a right angle with the leg, so that the sole impinges on the ground in a lightly arched rather than a valgus position.

In answer to the question: What should be done with a flail joint? Jones says: Secure by operation an ankylosis in the most useful position.

The only exception is the hip-joint where by means of simple mechanism a very useful limb may be obtained in spite of the joint being flail.

PHILIP LEWIS

SURGERY OF THE SPINAL COLUMN AND CORD

Hassin, G. B., Johnstone, K. L., and Carr, A. M. Bullet Lesion of Cauda Equina. *J Am M Ass* 9 6 1, 111, 100

The patient, a man of 28, complained of pain in the left lower extremity. The pain would jump from the left buttock to the left popliteal region, whence it would reach the left little toe and spread over the foot and the other toes. It would stop for about five or ten minutes and then begin again. He could not sleep nights; could not rest in the daytime, and could not do his work (that of a watchman) but he was able to walk.

The pain originated six years previously after he had been shot in the back. One attempt to remove the bullet, four hours after he was shot, was entirely unsuccessful. Following the shooting, the patient immediately became paralyzed in both lower extremities. The paralysis was combined with anesthesia and loss of sphincter control. A month later cystitis developed which persisted for two years. He could not move around for two years and had to be carried all this time in a rocker. The symptoms plainly indicated involvement of some of the motor and sensory roots of the cauda equina that supply the lower limbs with motion and sensation.

A curved incision was made from the first lumbar to the first sacral spinous process. The spinous processes of the second, third, and fourth lumbar vertebrae were exposed and removed. The laminae of the same vertebrae were removed and the dura exposed. The dura was split and dissected free from adhesions to the cauda. The bullet was found at the level of the third lumbar vertebra, surrounded by two solid scars. It was carefully dissected with blunt dissectors and removed. The slightest possible injury to the surrounding tissues was carefully avoided.

The operation was followed by numbness in the

gluteal buttocks, about the anus, and by retention of urine for about six days. Four weeks after the operation the wound cleaned up and for about seven weeks there still was severe pain in the legs, which, however, was gradually disappearing and the patient was getting nearer his feet. Ten months after the operation the pain disappeared entirely; the gait became practically normal, the calf muscles increased in volume one inch, the pain sensation was found to be normal—but only the right leg—while in other cases the sensibility showed the same disturbances as before the operation. No changes were found in the reflexes, or in the muscle power. The improvement was so marked that the patient insisted on leaving the hospital and fitting to resume work.

LEONARD L. CORNWELL

Kleinberg, S. Congenital Anterior Curvature of the Spine. *J Am M Ass* 123 9 6, 1, 30

The author describes a case of true congenital lordosis of the spine or associated with any other deformity.

The case is described in some detail as to X-ray and laboratory findings. His conclusions are that this was an instance of congenital lordosis in which he believes heredity played a part and despite the marked lordosis there was no abnormality.

C. C. CHITTENDEN

Armour, D. Gunshot Wounds of the Spine. Their Surgical Aspect. *Lancet* Lond 9 6 1, 110, 770.

The author divides gunshot wounds of the spine into two classes: (1) those in which there is interference with the function of the spinal cord; (2) those in which there is more or less interference with the function of the spinal cord with or without obvious injury to the vertebral column.

Injury to the vertebral column may be followed later by effects of inflammatory products adhesions narrowing of the spinal canal intra or extradural clot etc.

Immediate injury to the cord may be caused by (1) the missile passing through part or the whole of the cord (2) fractured bone causing compression contusion laceration, or complete division (3) concussion.

The author has found the X ray to have only confirmatory value in localizing bone injury and foreign body position.

The points of importance arising regarding operative intervention are (1) Will any benefit to the patient result from the operation? (2) Will his life be endangered by the operation? (3) Will he be made worse by operation?

The author then discusses indications for operation and urges interference under proper surgical skill and asepsis in all cases in which complete section has not taken place, providing the patient is in a fair general condition. He says: "It is unfair to the patient and unfair to surgery to wait on and on till hope gives place to despair and then call in a surgeon as a last resort to perform the impossible."

Operation is therefore indicated (1) to relieve pressure from depressed or displaced fragments of bone (2) to relieve pressure from blood-clot or from extensive hemorrhage, either extra or intradural (3) to relieve pressure and prevent further destruction from oedema by enlarging the constricted bony canal (4) to remove the danger of pressure from exudate and inflammatory thickening.

H. W. MEYERDING

Collier, J. Gunshot Wounds and Injuries of the Spinal Cord. *Lancet* Lond. 9.6.17

Eighteen months service has given the author an excellent opportunity to study gunshot wounds and injuries to the spinal cord. The nature of lesions caused by high velocity bullets shrapnel fragments of shell casing and by the concussion of high explosives without any external wound are

1. Direct lesions—missile through cord
2. Indirect lesions (a) those due to an in-driving of bone etc. into the spinal canal (b) Impact lesions where the missile strikes against the bony wall of the spinal canal (c) concussion lesions from the shock of high explosives
3. Secondary lesions: perithecral and intrathecal hemorrhage medullary hemorrhage and thrombosis menigitis oedema (may come late and cause in certain symptoms)
4. Remote lesions which may be found anywhere in the spinal cord and chiefly near the surface spot of necrosis sieve like rarefaction punctiform hemorrhages oedema swelling of axons. These result from passage of a missile through the cord or from concussion suddenly raising pressure.

Case history illustrating the above lesions are cited. Especially interesting are those resulting

from concussion and to shell bursting near the patient without external wound yet producing severe local transverse lesions of the cord.

Root lesions are produced by projectiles directly or indirectly the latter from subperiosteal hemorrhage perithecral swelling or pachymeningeal hemorrhage.

Intrathecal hemorrhage is discussed and the difficulty of explaining the physical signs unless this condition is borne in mind is shown by case history.

A case is cited of total necrosis of the distal segment of the spinal cord at autopsy in a case without sign of hemorrhage or septic process three months after injury which had produced a total transverse lesion at the third dorsal segment.

The author discusses reflex actions contra tures disturbances of sensibility and the distinction between root lesions and central lesions and prognostic indications.

H. W. MEYERDING

Hull, A. J.: Treatment of Gunshot Wounds of the Spine. *Bull. M. J.* 9.6.17

To be successful spinal operations must be performed at an early stage before any vital changes have occurred in the cord. By delaying operative interference cases lose their chance of recovery either by the sepsis spreading or by pressure on the nerve tissue causing these vital changes to take place.

It would appear justifiable to operate upon spinal injuries when the X ray localisation shows a foreign body present in an accessible position and especially when there is evidence of some remaining conductivity of the cord as here the removal of pressure may be followed by great improvement. Pain in some spinal lesions is so intense that an operation is justifiable whatever the lesion of the cord.

Three lines of treatment are indicated: (1) prevention of sepsis, (2) removal of gross pressure upon the spine and (3) the prevention of complications which threaten life.

R. B. CORRIE

Sayre, R. H. The Occurrence of Late Rickets. *The New York Times* Wash. 9.6.17

Rickets occurring in adolescents and adults is less uncommon than has been supposed. Its occurrence abroad has been much more frequently noticed than in this country. Apparently rickets in the adolescent is frequently of the recrudescence variety and in a number of the author's cases the patients have been subjected to various operations for the relief of the deformity earlier in life but no effort having been made to eliminate the underlying cause of the softening of the bones the deformities had recurred or else deformities of an equally disabling character had taken their place requiring further operative intervention.

In one case a girl 10 years of age who had had four previous operations before coming under observation the femora were so soft that the osteo-

t me ent through at the first blow when a supra-condylloid operation was done but six months later after the patient had been fed upon phosphorus and cod-liver oil, the edge of the chisel was broken off while an operation was being performed upon the shaft of the femur to correct twist there and a second instrument was used to complete the operation.

In the case of a boy 6 years of age, marked knock-knee had developed in the space of three months, and reasoning that if the bones were sufficiently soft to create so marked a deformity in so short a time, pressure could correct the position, the legs were put in plaster-of-Paris bandages, which were subsequently sawed through at the point of deformity and wedged straight, a perfect result being secured without the necessity of breaking the bones. This boy was placed on phosphorus and cod-liver oil, and remained straight. These cases emphasize the necessity of attending to the underlying cause

producing the softness of the bones as well as merely correcting the deformity.

Shackleton W. L. Some of the Surgical Aspects of Painful Back. *J Am. M. Ass.* 9 6 1911, 600.

Shackleton describes an anatomic variation of the transverse process of the fifth lumbar vertebra the lumbar rib and he cites three unmistakable cases, two of which when operated upon were entirely relieved. The condition arises in middle adult life after years of hard labor but may also follow fracture, or some infection. The backache seems to be due to impingement of the process on the ilium sometimes thus separating the sacro-iliac joint, or to impingement on the nerve itself. The fifth lumbar nerve seems to be the branch most commonly affected, causing most marked motor symptoms in the peroneal nerve. In the two cases reported, the prolonged processes were removed and instant relief occurred.

R. G. P. CHARD.

SURGERY OF THE NERVOUS SYSTEM

Bucholtz, C. H. Partial Resection of the 31st Nerve in Spastic Paralysis. *T. Am. Orth. Ass.* Washington, 9 6 May.

In spastic paralysis the restoration of the function of the paralyzed limbs demands long continued re-education and exercise treatment. A greatly defective balance and actual contracture may make rational exercise difficult if not impossible and may require surgical interference.

Until recently operations on the tendons and muscles were practically the only operative procedures in use in these cases but within the last two years operations on the nervous system directly have been done in various ways. Among these operations may be mentioned the following:

1. Resection of the posterior roots of the spinal cord (Foerster's operation).

2. Operations to cause temporary paralysis by the injection of alcohol into the nerve trunks (Allison's method).

3. Partial resection of the motor nerves (frequently called Stöfel's operation).

Although the last-mentioned method has at times been used it was through Stöfel's anatomical studies and clinical work that the method has been so thoroughly developed. Stöfel has shown that in the cross-section of the nerve trunk the arrangement of the single bundles is practically the same in every person, so that anyone familiar with the anatomy of the cross-section will find without difficulty at a given place that bundle for which he is looking.

Stöfel's operation consists in a partial resection of the motor supply of the spastic muscles either

after the motor branches have left the main trunk, or within the main trunk itself. The latter method is used only when the former is rendered difficult or impossible by the anatomical conditions.

Stöfel's operation is in the author's opinion indicated in all cases of rather localized spasm with markedly defective balance which is not showing any improvement and no response to treatment.

The contra-indications are as follows:

1. The progressive character of the disease causing the spasticity.

2. Permanent contracture in which case the contractures should be eliminated first and partial resection of the motor supply may be done later after a sufficiently long interval. If a markedly defective balance persists after exercise treatment.

3. Marked prevalence of the paretic element.

4. Mental deficiency or youth of the patient which prevents careful after-treatment by exercise.

Just as for the resection of the posterior roots it has been made an axiom by Foerster himself that developmental and educational exercise treatment is the most important part of the whole treatment, which is only to be made possible or easier by the operation, so too before doing Stöfel's operation one must be sure that an opportunity will be afforded to give the patient a sufficiently long careful after-treatment.

The technique of the operation is briefly described for partial resection of the motor supply of the triceps cruris and the pronator muscles of the forearm. A modification of Stöfel's operation by the author consisting in transplanting some of the motor supply of the triceps into the peroneal nerve is briefly described.

Hardouin P: Two Complete Nerve Sections Treated by Suture with Functional Restoration in the Domain of the Injured Nerve. (Note sur deux observations de section nerveuse complète traitée par la suture avec récupération fonctionnelle dans le domaine d'un nerf lésé) *Bull et mém. Soc. d'Anat. P.* 9 6 xlii, 6 2

The two cases reported by the author were selected from a series of 36 cases of complete nerve sections which were operated upon. These were the only cases which the author has been able to follow.

The first case was a resection and suture of the internal popliteal sciatic on the right. The op-

eration was done in January 1915 four months after the injury and voluntary motility was effective four months later.

In the second case there was a complete section of the radial nerve which was sutured in February 1915. Voluntary movements in this case were not noticeable till ten months later.

In the first case the injury had not caused a total anatomic section of the nerve but the presence of a voluminous neuroma necessitated resection.

In both cases there was complete restoration of the electric functions of the nerves.

W. A. BRYAN

MISCELLANEOUS

CLINICAL ENTITIES — TUMORS ULCERS ABSCESSSES ETC

Lambert R. A. Tissue Cultures in the Investigation of Cancer. *J. Cancer Research* 19 6 1 169.

A review is given of the results which have been obtained with tissue cultures in studies upon cancer and related subjects. The technique is described and emphasis is laid on the fact that the temperature of the culture medium and the tissue does not have to be rigidly controlled while the cultures are being made; moreover some time can elapse between the taking of the tissue specimen from the body and its immersion in the plasma medium in which it is to grow. There has been very little trouble from bacterial contamination, probably because of the fact that serum has a bactericidal property of itself. The principle in general consists in placing small pieces of tissue 0.5 to 2 mm. in diameter in plasma derived from the blood of the same animal making the whole a hanging drop preparation and sealing it with vaseline.

Sarcoma and connective tissue cells are wont to wander out singly or in chains, while epithelial cells normal or neoplastic, tend to spread in sheets or groups. The cancer-cell, especially the sarcoma cell, tends to show a greater motility as compared with the corresponding normal element. Sarcoma cells may often be seen traveling through the medium at a rate equal to that of a polymorphonuclear leucocyte. This fact probably throws light on the mechanism of the invasive growth and spread of cancer in the body. The author calculates that a cancer-cell by means of this locomotion might in four weeks make its way to the axillary fossa. Continued propagation of normal cells especially those of connective tissue is as a rule much easier than in cases of tumor-cells. Many carcinomata and sarcomata are very difficult to propagate even in primary cultures, while others quickly die when transferred early into fresh plasma. On the other hand connective tissue becomes much more active in subcultures. Tumor-cells are much more susceptible

to heat than it kills them much more quickly than it does active tissue cells.

The author quotes Lambert and Hanes who found that rat sarcomata cells will grow quite as well in the plasma of an immune rat as in the plasma of a normal rat without immunity. This observation affords further evidence that cancer immunity is not to be attributed to circulated antibodies of a cytotoxic nature. They are further able to show that an animal of foreign species particularly a rabbit may give plasma satisfactory for the growth of tissue elements derived from an alien species. The plasma of an animal that has been immunized to either the tissue or the blood of another is unsuitable as a medium of growth for the cells of the animal which supplies the immunizing substance. In other words it is distinctly toxic for these cells. The author emphasizes the fact that variations in growth of preparations occur from the factor of the depth of the hanging drop and the density of the fibrin meshwork. These two factors influence the extent to which the active motile cells wander out. The author cites an instance where an extract of human tumor appeared to inhibit rather than to stimulate the growth of normal human cells.

He has been disappointed in stimulating tissue cultures by using Scharlack R. and Sudan III. He thinks however that in spite of the fact that possibly with the exception of increased temperature there has been little found that will stimulate tissue growth, this is a most important and interesting field of investigation in regard to the cancer problem.

H. G. SLOAN

Collins, G. N.: The Effects of Cancer Tissue and of Normal Epithelium on the Vitality of Protozoa; Didinium Nasutum. *J. Cancer Research* 9 6 1 205.

In experimental study the author used didinium nasutum which lives on protozoa and will not eat bacteria, so that he was able to control the factor of predation to a certain extent in the food given them to live on. The carcinomata he used were

derived from tumors inoculated into mice, at varying intervals, so that when needed they were of the same age and approximately of the same size. The tumor was fed to the didinium in definite stated amounts in addition to their normal food supply of paramecia. Two series of controls were run. All the didinium were derived from the same stock. The treatment was given in three periods of five days each, from Monday to Friday inclusive. The living indicators of the didinium were observed for varying periods after such treatment and compared with the normal controls, attention being especially paid to their rate of multiplication and their death. Identical experiments were conducted, only that normal epithelium from the mouse abdomen was substituted for the cancer tissue in feeding. The dosage of food was accurately gauged. All tissue fed was finely minced and given fresh.

b) The conclusions drawn from the cancer feeding were: (1) cancer tissue contains something which produces a depressant effect on didinium; (2) it also produces something which produces a stimulating effect. In weak doses the stimulating factor of cancer tissue is apparently more noticeable than the depressing effect, or lethal. Larger doses than usual were fatal through all the organisms. In feeding normal epithelium the authors found there was no depressant lethal factor in it but that it caused a stimulation of the organisms. The double dose with cancer feeding gave a mortality of 4 per cent or more than twice that of the control, 3 per cent, while the double dose with epithelium gave a mortality of 6.6 per cent against 10.6 per cent of the control. With four times as much tissue material in the double dose series as in the half dose, the death-rate with normal epithelium was not raised even to that of the normal controls; hence the lethal factor cannot be due to an exhaustion from the excess of the stimulating factor.

The authors then propose a theory for the origin of cancer, namely, that cancerous changes may originate in cells from the predominance of the stimulating factor. This, he thinks, may be caused by the autolysis of cells which are being constantly destroyed at the seat of any chronic irritation. He quotes Bullock and Rohdenburg, working in his laboratory who showed that in rats that had the posterior lobes of their pancreas closely ligated and allowed to remain and autolyse still the adjacent parts of the pancreas showed greatly increased mitosis.

H. G. SLOAN

Ball, E. T. and Hendri A. T. Renal Tumors in the Rabbit. *J. Cancer Research* 9: 61-57

Ball and Hendri believe that new-growths of any kind are very rare in rabbits. Although the rabbit is very extensively used for laboratory purposes, reports of only 35 tumors were found. Of the recorded tumors 24 were terine and 3 were tumors of the kidney. The authors note neoplasms occurred in adult male rabbits both having been found on the same afternoon, and although they

state that they have autopsied over 400 rabbits during the last three years, no other tumors have been seen. It was impossible to ascertain the ages of the rabbits or whether or not they were both from the same litter since animals obtained from different persons had been put in the cage together. In the first case a physical tumor 4 cm. in diameter was found about the center of the outer border of the left kidney. Apparently it was of cortical origin since it did not invade the medulla. It was sharply marked off from the renal tissue fairly firm, and whitish gray in color. A thin prolongation of renal capsule covered the tumor. No metastases were found. The second case was very similar to the first though apparently in a much later stage of development. There were a few small areas that closely resembled the structure of the first tumor but almost everywhere the cellular masses characteristic of the first tumor had differentiated into solid cords and tubules.

These rabbit tumors thus correspond closely with those neoplasms of the human kidney commonly described as adenocarcinoma. The simplest interpretation of their origin is to regard them as having developed from portions of the met nephrogenous tissue which became enclosed in the kidney during its early development but failed to form connections with the collecting tubules. Since a striated muscle was present they are not comparable, the authors state to the mixed tumors of the kidney which occur so frequently in children, and which are best explained as derived from portions of the primitive segments.

GEORGE E. BRIMLEY

Tyzer E. E. Tumor Immunity. *J. Cancer Research* 9: 61-5.

In a consideration of tumor immunity it appeared to the author desirable to discuss resistance to spontaneous tumors and to implanted tumor separately. Although results obtained with experimentally implanted tumors have contributed to the biology of tumors, these results cannot be applied directly to spontaneous tumors and this is especially true with respect to immunity. It has long been recognized that immunity to implanted tumor gives no assurance against the subsequent development of spontaneous tumors.

The results of the experimental investigation of tumors, as well as of clinical and pathological observations, appear to favor the following conception of the nature of tumors and their relationship to the other tissues.

The interreactions of the normal tissues are mutually beneficial so that their relationship is one of symbiosis.

The anomalies and benign growths, while not distinctly harmful are usually of no benefit to the individual; the relationship is one of commensalism.

The malignant tumors are in many respects parasitic in nature, especially since they develop at the expense of the other tissues of the body. They are so adapted for growth, once they have become estab-

lished that they seldom arouse any effective resistance on the part of the body. There is some evidence, however, of a local reaction of tissues unfavorable to the growth of many different types of tumors.

Immunity to transplanted tumor is based on foreignness or incompatibility of tumor and host. This holds true whether the tumor or the animal is taken as the constant factor with which to test the other. Although the degree of foreignness is not sufficient for the production of markedly cytotoxic or cytolytic sera as when different species are employed it appears probable that an immune body is formed which in the presence of the antigen—or living tumor—excites an inflammatory reaction in the tissue around the tumor so that the latter is isolated and eventually destroyed.

Both susceptibility and non susceptibility or the ability to acquire immunity are inherited not as a single unit factor but apparently as a complex of Mendelian factors. Non-susceptibility and susceptibility are apparently based on factor differences or in other words on unlikeness or foreignness. Non susceptibility may thus depend with one tumor on a difference with respect to new factors and with another tumor on a difference with respect to many factors. In the comparison of a stock of Japanese waltzing and several stocks of common mice the non-susceptibility of the latter to a carcinoma J. W. A. is based on a difference with respect to a large number—probably twelve to fourteen—of independently inherited factors.

Susceptibility is in this material a dominant character since it is manifested when its factors are present in a single representation as in the F₁ hybrid. The presence of a single representation of the factors of non susceptibility in the F₁ hybrid apparently stimulates the growth of the tumor for its rate of growth is more rapid than in the Japanese walking mouse in which the factors of susceptibility are doubly represented.

There are marked differences in the behavior of various tumors on transplantation in given classes of mice. Even tumors arising in homogeneous races show such differences and thus may be attributed to the acquisition of new characteristics by the soma which are manifested in the development of the tumor. The tumor since it breeds true with respect to these characteristics in the course of asexual propagation may be regarded as a modification of the somatic tissue which may be termed somatic mutation.

Simon reports a case which ten days after recovery from soft chancre showed ulceration of the glans and a left inguinal adenitis. After about twenty

days treatment by puncture etc with little effect. filiform (thread) drainage of the bubo was instituted. Immediate improvement was observed and in eight days the skin had a normal appearance.

The author has tens to report this case in which he thinks the method of plumb training transformed a long and weary disease into a light ailment because he thinks that the procedure is of distinct therapeutic value in the treatment of tuberculous disease.

W. A. BLESS, N.

Sequeira J H Dermatology and Molluscum
Fibrosus with Congenital Verruca Cordis
and Kyphosis P a k s M d
D x s [el S t 94

The case is reported of a man age 21 who resembled a boy of 15 presenting a remarkable pendulous growth on the left side of the face although the skin of his face and his jaw had grown many times more redundant and shiny than over his cheek. Illustration shows the improvement in the patient's appearance after a remarkably successful cosmetic operation. He is now

Quillian G W Acidosis in Surgery 1 5 8
Phila. 9 6 1 1 1 385

The author having observed that the progress of the gangrene of a diabetic leg varied with the presence or absence of haematuria in the urine, he undertook a consideration of the influence of acidosis in a series of cases. The report is based on a study of 138 consecutive major peritonsillectomies. Except in a few emergency cases in which high glucose and soda assays was given as a precaution, a normal short time before the operation the following preliminary routine was followed:

Soda bicarbonate 53s in one half glass ater T
f d. one half hour before meals was given for two
days preceding operation

Soda bicarbonate and glucose 22.5 g with water q. s. ad 300 ml was given as a retention enema, 1 l. i. d. for two days preceding operation. Liquid diet and large quantities of water were given for 48 hours preceding operation but no buttermilk or egg albumens for 24 hours preceding operation.

Castor oil 358 was given the morning preceding the day of operation. Soap suds en mata were used the night preceding and the morning of the operation.

Strontium bromide gr xxx was given the night preceding operation to insure a good night's rest. Morphia gr 1/8 with scopolamine gr 1/100 was given one hour preceding gas and eth. anesthetic.

After operation the patient was again given soda bicarbonate 5ss in one half glass of water one half hour after meals for several days. Water and liquid diet were given as soon as nausea ceased and continued until a light diet was given on the fourth day. An eliminant was given on the third day after the operation.

There was no mortality in the entire series and only five cases of appreciable shock. This has led

the author to believe that acidosis has a dominating influence in surgery and that by careful pre- and post-operative treatment it may be largely eliminated. From this series, he believes that post-operative nausea is greatly diminished by the preliminary use of soda bicarbonate. GATEWOOD

SERA, VACCINES, AND FERMENTS

Sellards, A. W., and Minor, G. R. The Antagonistic Action of Negative Sera upon the Wassermann Reaction. *J. Med. Research*, 9 6 xxxi 3

At the time when the Wassermann reaction was first inaugurated it was assumed that its mechanism was completely understood, i. e. that it conformed precisely to the Bordet-Gengou phenomenon of complement fixation. With the demonstration that specific antigen was not only unnecessary but that it was inferior to some of the non-specific antigens, it became evident, once that complement fixation as applied to the diagnosis of syphilis cannot be explained on the basis of the phenomena of Bordet and Gengou. Not only is the reaction non-specific but it is now well established that the Wassermann reaction may sometimes occur in certain conditions other than syphilis.

Investigation as to whether normal sera are truly negative, in the sense that they would antagonize a positive serum forms the basis of this paper. These findings are considered in regard to their practical bearing upon the Wassermann reaction and upon the method of complement fixation in general.

A simple method was adopted in order to test the effect of negative sera upon a positive syphilitic serum. A small amount of negative serum was mixed with the minimal amount of positive serum that would cause complete fixation. A Wassermann reaction was done on this mixture in the usual routine way after it had been incubated for a short time. From their findings the authors draw the following conclusions:

1. Sera which give a negative reaction with the Wassermann test possess definite inhibitory properties toward positive syphilitic sera except in certain special cases.

2. The extent of this inhibitory action in negative sera varies widely in different diseases but it is usually comparatively weak. It is easily demonstrable even though it is present only in slight degree.

3. Human sera present three distinct phases in their behavior toward the complement fixation of the Wassermann reaction: (1) negative (2) positive and (3) inert action.

These results are explained most readily on the basis of a balanced mechanism. The inhibitory action of negative sera cannot be accounted for solely on the basis of its content in natural sheep antioceptor. GEORGE E. BRILL

Smith N. R. The Serotoxin of Jobling. *J. Lab. & Clin. Med.* 9 6, 4, 524.

The production of a serotoxin by treating homologous and heterologous sera with chloroform and

ether as reported by Jobling has found wide acceptance among workers in the field of anaphylatoxins and is incorporated in the literature of the subject alongside the earlier pioneer work of Richet, Bordet, Friedberger, Nathan, and others. Jobling maintains that the ferment action of the serum is held in abeyance normally by an unsaturated lipoidal antitryptic substance the removal of which by lipid solvents permits the lysis of serum proteins, thereby forming poisons which in all probability deal with the antigen-protein split product. Some work was under way in his laboratory in which splitting of germ substance by sera was the desired end.

In the light of Jobling's work it seemed to the author reasonable to assume that the splitting action of the sera could be greatly increased and accelerated by shaking with the sera with chloroform before incubation with the germ substance. Therefore rabbit serum was shaken with one-tenth its volume of chloroform four or five times, then centrifuged at 8000 R. P. M. for ten minutes and the supernatant serum carefully pipetted off from a precipitate that upon centrifugation was interposed between the chloroform at the bottom and the serum above. As a matter of routine controls were made by testing the chloroform serum on guinea pigs before incubation with the germ substance. As high as 0.5 ccm. of the normal untreated serum had been injected without effect, but since the M. L. D. of serum and germ substance after incubation was known by trial to be 3 ccm. or less, the control injection of the normal serum was usually limited to 3 ccm. But upon the injection of the chloroformed serum in 3 ccm. quantities as a control, that is, without incubation with germ substance, the pigs died instantly. Reduction of the dose to one cubic centimeter still produced death in most cases, and always a marked prostration.

The character of the deaths, together with the autopsy findings, clearly indicated typical anaphylaxis and pointed strongly to the residual chloroform in the serum as the toxic agent.

Smith concludes that the intravenous injection of high dilutions of chloroform may cause sudden death in guinea pigs and that when blood serum has been shaken with chloroform the complete removal of the chloroform is difficult. The toxicity of the serum falls with the completeness of the removal of the chloroform. Death in guinea pigs caused by the intravenous injection of serum which has been shaken with chloroform is often at least, he states, not typical of anaphylactic shock. Serum when shaken without chloroform may cause typical anaphylactic shock with death and typical autopsy findings. GEORGE E. BRILL

Haktoen, L. Vaccin Treatment. *J. Am. Med. Ass.* 9 6 lvi, 59

The general results so far from the routine use of commercial vaccines polyvalent and mixed, have no value as evidence for or against curative usefulness.

ness of vaccine treatment and hence no value either with respect to the soundness of the theory on which vaccine treatment primarily has been developed.

In subacute and chronic localized infections the results appear to indicate that specific vaccines properly and skillfully used have value quite likely because they increase the production of specific antibodies as demanded by the theory but probably also because they stimulate leucocytic and other activities.

In typhoid fever and possibly also in other infectious diseases the intravenous injection of specific vaccines and also of other substances may induce crisis and prompt recovery. The mechanism of this action is not fully understood but as it involves something more than or different from specific stimulation of the production of antibodies it cannot be interpreted in terms of the current conception of the action of vaccines. We are entering therefore upon a new and interesting development in the study and treatment of infectious diseases.

EDWARD L. CORNELL.

BLOOD

Della Valle, L.: Suppurative Hematoma of the Iliac Fossa (Ilioma suppurativa della fossa iliaca). *Riforma* 1906 11 99.

The author says that while almost every variety of hematoma has been the object of very close study and detailed description deep hematomata of the iliac fossa do not get the amount of attention which their importance demands particularly on account of their complications in suppurations. His article is therefore devoted to a detailed description of the pathologic anatomy, symptoms, diagnosis and treatment of this condition.

His study is based on clinical data obtained in hospital cases observed and operated upon by him within the past few years.

In the treatment of these suppurative hematomata it must be noted that the pus forms a vast subperitoneal focus which is limited in front by the fascia iliaca and beneath by the crural arcade. To open this therefore the incision must be horizontal and above the arcade in a point indicated by the fluctuation while avoiding the epigastric artery. The skin subcutaneous fascia, the aponeurosis of the oblique muscle, the transverse and the fascia transversalis must be cut through before the pus focus is reached. A hematoma of large dimensions may more conveniently be evacuated by a lumbar incision.

W. A. BRENNAN.

Kleiner, I. S.: The Disappearance of Dextrose from the Blood After Intravenous Injection. *J. Exp. Med.* 1906 10 15.

The chief purpose of the author's present work was to study the disappearance of sugar from the blood under various conditions. In order to obtain a basis of comparison a series of experiments

was first carried out in which dextrose was injected into normal animals. These experiments brought up the question as to whether the passage of sugar from the blood into the tissues was a vital process and led to a series of experiments in which dextrose was injected into dead animals. These experiments yielded the following results:

1. As has been found by other investigators when a large amount of dextrose is injected intravenously into a normal dog it disappears from the circulating blood in about 60 minutes after the end of the injection. Varying amount — an average of 60 per cent — are excreted in the urine.

Even in nephrectomized animals the same quantity will leave the circulation in the same length of time as in normal animals.

2. This phenomenon seems to be at least to a great extent independent of vital processes since dextrose after intravenous injection into dead animals is found to leave the blood rapidly.

3. The phenomenon is independent of the important abdominal organs for it also occurs in animals (living or dead) in which the aorta and inferior vena cava have been ligated near the diaphragm thus abolishing most of the circulation posterior to the diaphragm.

4. The fact that a considerable amount of the sugar passes from the circulation into the surrounding tissues was established by finding an increase in the carbohydrates of the muscle tissue. This was done in the case of the living anterior animals and in the whole of anterior dead animals. In most of these experiments there was also evidence of the formation of polysaccharides in the muscle tissue.

GEORGE E. BRLEY.

Willmoth, A. D.: Some of the Uses and Abuses of Normal Saline Solution. *Am. J. Surg.* 1906 11 147.

The author reviews the history of transfusion with its many difficulties and uncertainties dating as far back as 1492 when Pope Innocent VIII was given intravenous transfusion of blood the donors being three boys. This effort was like many subsequently unsuccessful and not until the middle of the seventeenth century did transfusion become a recognized surgical procedure. In 1666 Lower wrote the first detailed account of transfusion followed soon afterward by Denys of France with three successful cases. It being little more than a curious experiment after several unsuccessful efforts it was abandoned until the nineteenth century.

An attempt was made to overcome unfavorable results by using something that would supply the volume of blood yet be easier to obtain and safer to administer from a surgical viewpoint and would subject the patient to no danger of disease existing in the donor. Milk and other albuminous fluids were tried and soon abandoned.

Isolated cases occurred earlier but Schwartz in 1881 gave the first methodical description of saline

infusion, this being the first reliable information concerning the use of fluid to take the place of blood. Since more has been learned of the various constituents of the blood, their inorganic salts such as potassium and calcium, were added to the sodium chloride solution, Ringer and Locke's solutions, whose specific gravity should be 1.009 being most often used.

The fact that sodium chloride is found in liberal quantities in most of our food possibly accounts for its indiscriminate use in surgery. It is changed by lactic acid into sodium lactate thereby setting free hydrochloric acid. It is commonly believed that the kidney glomeruli have no limitations for excreting water and the chlorides.

The question of the use of salt solution has not been elaborately studied. Its uses are (1) to replenish the circulation, (2) to refill the blood vessels, thereby permitting the mechanical act of the circulation to proceed (3) in shock with adrenalin 1:1000 to 1:2000 to stimulate the heart and blood vessels, so that the blood accumulated in the large vessels is again placed in circulation, (4) to stimulate the action of the kidney and (5) its use in sepsis.

Salt solution may be used in the following ways: (1) intravenously especially after amputation and before tying the vessels, (2) intra-arterially (3) by hypodermoclysis, (4) by proctoclysis, (5) by leaving a quantity in the abdomen after celiotomy. It should be used at a temperature of 100° to 102° F. This temperature is perfectly safe, since gelatin coagulates at 58° F and serum albumin at 66° F and experimentally 65° F has been well borne by the dog. The heat acts as a stimulant to both heart and blood vessels, a point to be remembered by the obstetrician.

For the relief of shock it should be used in small quantities by the intravenous method at a temperature of 100° F frequently repeated, rather than one or more large injections, thereby avoiding overwhelming the heart. The conditions to be met are in striking contrast to those resulting from hemorrhage where death results from absolute loss of blood, not enough remaining in the vessels to sustain vital functions even though it could be kept in active circulation and death results from mechanical interference not enough blood remaining in the vessels to enable the heart and elastic arteries to transmit the force of the heart contractions to distant portions of the body. As consequence the blood fails to complete the circuit and all centers suffer from anemia carried to the point of death. Experiments have shown this would not occur, even though one-half or two-thirds of the total volume of blood be lost provided the circulation be maintained by supplying fluid in place of blood.

In the preparation and use of saline in any case, much depends upon the strength and composition of the solution also the technique of its administration. Too little salt causes the corpuscles to swell and lose their hemoglobin, or completely destroys

them too much causes them to shrink. To insure correctness tablets should be used or stock solution kept that has been prepared by actual weight. This solution should be prepared by sterilizing by fractional methods.

In private homes water from the teakettle is sterile enough for practical purposes to this add a heaping tea spoonful of salt and four drachms of glucose to the quart, this being accurate enough save for intra-arterial and intravenous use. As much as 500 ccm. can be easily introduced under each mammary gland or into the cellular tissue at a favorable point such as between the shoulders or over the abdomen. In the intravenous method difficulty is experienced in trying to locate partially collapsed vessels in using too sharp needle thereby piercing the opposite wall of the vessel, and by too rapid introduction. Not more than one ounce per minute should be used.

Abuses Under no circumstances should saline be used in apoplexy arteriosclerosis pulmonary edema, dilated right heart threatened sudden death or collapse from chloroform ether narcosis, the last two requiring more rapid measures. It should not be used in anemia. Not more than fifty grains of salt should be used to each one hundred pounds of body weight. If elimination be insufficiently rapid some degree of dropsy and edema must occur and is usually in the form of edema of the legs especially is this likely to occur in nephritic patients. C. C. Myers.

Krida A. The Indication for Blood Transfusion. 1924, J. U. I. 9, 6

The author describes some of the functions and properties of the blood. The indications for transfusion according to their pathologic physiology are classified as follows:

1. Conditions in which there is a deficiency in the quantity of the circulating fluid.

2. Conditions in which there is a deficiency of the respiratory elements sufficient in degree to impair the integrity of vital organs.

3. Conditions which are accompanied by disorders in the process of coagulation—increased susceptibility to hemorrhage.

4. Conditions in which the body has been invaded by infection and its products.

If concluded that blood transfusion is indicated in the following conditions:

Massive hemorrhage

Marked secondary anemia, either as a palliative measure or as a pre-operative measure.

3. Essential anemias.

4. Blood dyscrasias, if fresh human serum injections thrombin is ineffective.

5. Chronic localized infections if demonstrable etiology not amenable to other treatment. Immunized blood should of course be used in these cases.

No blood transfusion should be undertaken with

out first making agglutination or hæmolysis tests of the patient's and donor's blood.

LUCIAN H. LANDRY

Minot, G. R.: Methods of Testing Donors for Transfusion of Blood. *B. & M. S. J.* 916 131-66

The author reaches the following conclusions after a full discussion of the subject:

A donor for transfusion of blood should not only be healthy but should belong to the same iso-agglutination group as the recipient.

Simple and quick methods for testing this have been described. What these tests show *in vitro* can be taken as reliable evidence as to what may happen *in vivo* so far as agglutination and hæmolysis are concerned.

Even when donor and patient belong to the same iso-agglutination group there may occur however after transfusion, reactions of unknown nature which are probably of not so severe or serious a nature as hæmolysis.

Agglutination often does not occur *in vivo* and if it does it does not always cause a severe reaction because of the following three factors: (1) interference with agglutination by an excess of non agglutinable cells; (2) absorption of the agglutinin by the agglutinable cells; (3) the degree of concentration of the agglutinin.

Hæmolysis does not always occur *in vivo* when donor and recipient belong to different iso-agglutination groups because only about 20 per cent of sera that are agglutinative are hæmolytic. Hæmolysis however never occurs without being preceded by or associated with agglutination.

If hæmolysis is present in the plasma of the donor or recipient or both hæmolysis may not occur or may cause but a slight reaction *in vivo* because of the following factors and their quantitative relation to each other: (1) concentration of the hæmolytic concentration of the anti-hæmolytic and a certain degree of absorption of the hæmolytic by the hæmolyzable cells. In discussing these factors it is pointed out that in certain instances the knowledge of the strength of the anti-hæmolytic might be of value.

LUCIAN H. LANDRY

Singleton, A. O.: A Reliable Method of Blood Transfusion. *S. & M. J.* 916 1439

Singleton reports a method of transfusion successfully used in ten cases.

His apparatus consists of a graduated glass container with the bottom drawn out into two cannula-like processes for connection with the veins and with the top connected by a rubber tube with a pair of pressure bottles.

The container is sterilized, dried and coated with paraffin and connected with the veins of the donor and the recipient respectively following the usual technique except that the veins are flushed out with citrate solution prior to the insertion of the cannula.

About 30 cm. of a 1 per cent sodium citrate solution is poured into the container a tourniquet is tightened around the donor's arm and the clamp is removed from the vein. The pressure bottle is immediately lowered by an assistant producing a negative pressure in the container and the blood rushes in. The amount obtained depends upon the rapidity with which the lower the smaller is the amount obtained from the donor. At 200 cm. can be obtained at a time. Having secured this amount in the container the pressure bottle is immediately raised and the blood is forced into the recipient's vein of the donor's arm pressed between the thumb and finger and the lamp removed from the recipient's arm. At 200 cm. should be left in the container and the process repeated. It is essential to keep the blood moving.

Although this method is not complete it can be relied upon to transfuse any quantity of blood desired with perfect safety to the patient and the author holds that it gives a procedure that is more uniform and more easily controlled than that obtained by the use of a syringe.

Of the 10 cases transfused were 4 pellagra, 2 for pernicious anemia, 1 for purpural sepsis, 1 for pernicious malaria, and 1 for hæmorrhage. The three cases of hæmorrhage showed rapid improvement and were cured. The case of pernicious malaria showed marked improvement but the other cases died. In one of the cases of pernicious anemia an unrelated person was the donor in a second transfusion. On the second day following this transfusion the patient developed a temperature of 101 which persisted for several days and he suffered some slight hæmorrhage from the nose.

The author emphasizes the importance of making Wassermann, hæmolytic and agglutination tests with the blood of the donor previous to the transfusion, but regards the blood of an immediate relative as perfectly compatible in the greater percentage of cases.

J. W. T. RENE.

Peterson, E. W.: Results from Blood Transfusion in the Treatment of Severe Post hæmorrhagic Anæmia and the Hæmorrhagic Diseases. *J. & M. S. J.* 916 1439

Peterson studied the results of blood transfusion in severe hæmorrhagic anæmia and the hæmorrhagic diseases. His conclusions based on the literature and a series of nine cases reported in detail are as follows:

Transfusion of blood in muscular injections of whole blood and intravenous and subcutaneous injections of homologous serum are the most efficient measures and are of value in the order named in the treatment of hæmorrhage and the hæmorrhagic diseases.

In severe cases of acute post hæmorrhagic anæmia, blood transfusion is the best and at times the only efficient means of resuscitating a dying patient. In chronic post hæmorrhagic anæmia provided the cause of the bleeding is removed or

remedied no other measures will compare in efficiency with transfused blood in producing hematopoietic stimulation.

In pathologic hemorrhage, transfusion of blood has on numerous occasions proved effective after the failure of all other measures. It should be resorted to then, in those cases which do not respond promptly to the simpler methods of treatment.

A. EMMERTON.

Barnes, F. R.; and Stocum, M. A. Direct Blood Transfusion with the Kimpton Brown Tubes. *Am. J. M. Sc.* 9 6 cl, 727

Of the 9 cases reported by the authors 8 suffered from hemorrhage and were practically moribund when transfused the other suffered from sepsis. One of the cases of hemorrhage was complicated by peritonitis and another by a large carcinomatous mass at the head of the pancreas.

The only difficulty experienced in the use of the Kimpton-Brown tubes was in keeping the stoppers in when pressure was applied to force the blood into the recipient's vein. This difficulty was avoided after the first transfusions by pressing the palm of the gloved hand firmly against the top of the tube while it was being emptied, the stoppers being discarded altogether. With this technique the tubes proved entirely satisfactory.

Six of the patients showed immediate and marked improvement in the general condition and as indicated by the increase in the hemoglobin estimation and in the red-cell count after the transfusion. The patients who died were those suffering from sepsis and one suffering from carcinoma.

The authors were impressed by the value and simplicity of the Kimpton Brown method of transfusion. They emphasize the value of transfusion in all cases suffering from grave anemia, particularly that due to hemorrhage but consider it futile in cases of sepsis.

They found it best to have the donor and recipient so far apart that neither would in any way disturb the other nor interfere with work upon the other.

BLOOD AND LYMPH VESSELS

Morton, C. A. An Unusual Form of Gunshot Arteriovenous Aneurism in Which the Sac was Situated on the Side Opposite to the Vein. *Lancet* Lond. 9 6 cl, 557

In the ordinary form of arteriovenous aneurism the aneurismal sac lies between the artery and vein and the communication between the artery and vein is through the sac. In the case which is now recorded there was a communication between the artery and vein, due to the passage of a piece of projectile through them, and on the side of the artery opposite to the communication, where the portion of projectile had passed out of the artery was an aneurismal sac. Where the portion of projectile had penetrated the vein—i.e., in the side of the vein

farthest from the artery—was what may be called a venous aneurism i.e. a cavity in the tissue containing old blood-clot, communicating with the vein. The piece of metal evidently passed through the vein and artery from below upward.

This is a very rare type of arteriovenous aneurism, there being only one similar case in the series of 50 gunshot aneurisms reported in the *British Journal of Surgery* of October 9 5 J. H. SKILLER.

Fuller E. B. Notes on a Case of Aneurism of the Dorsalis Pedis Artery. *Se African M. Rec.* 9 6, 21 35

A male, aged 50 complained of a painful swelling on the back of his left foot, which had appeared a month previous and gradually increased in size. He denied any history of injury to the foot.

On the back of the left foot just below the annular ligament in the line of the dorsalis pedis artery was pulsating swelling about the size of a small hen's egg. The skin over the swelling was glazed and reddened and there was considerable tenderness and pain. The appearance of the swelling apart from the evident pulsation gave the impression of an abscess about to burst. Pressure on the artery above stopped the pulsation in the tumor. The swelling was diagnosed as an aneurism and it was decided to excise it.

The artery was ligated above and below and the sac, which contained considerable amount of blood-clot was excised. The aneurism was a curious mixture of the fusiform and sacular. At the upper part the artery seemed to have gradually dilated into a fusiform channel and then suddenly a sac was formed in its course doubtless from the more complete rupture or stretching of the coats of the vessel.

The patient made an uninterrupted recovery the wound healing by first intention. It may be mentioned that the patient's arteries were atheromatous and he had a double aortic murmur.

EDWARD L. CORNELL.

Neuhof S. Diagnosis, Symptomatology and Therapy of Dilatation Aneurisms of the Descending Thoracic Aorta. *Am. J. M. Sc.* 9 6, cl, 7 5.

The author recognizes dilatation aneurisms of the descending thoracic aorta as a distinct clinical entity presenting characteristic symptoms, and reports a number of illustrative cases.

The most constant sign is an impact area to the left of the sternum at its middle third. By placing the eye on a level with the chest a distinct heaving area, distinguishable from that of the apex and occupying the lower left sternal intercostal spaces, can often be detected. A sense of impact is also received when the bell of the stethoscope is placed over this area. This impact sensation may be well detected by snugly fitting two or three fingers in the left middle interspaces near the sternum. Occasionally a systolic thrill is palpable. In some

instances it is possible to detect a difference between the time of the apex impact and that in the left middle interspaces near the sternum. This is best done by placing one finger over the apex and another over the left sternal border. These signs are made more evident by having the patient hold his breath.

There is usually a rough systolic murmur over the dilated aortic area, the second sound has a liquid rather than an accentuated tone and is prolonged so as to occupy the entire diastole or is followed by a diastolic murmur of varying intensity. Pain when present is substernal, or may be referred to different parts of the chest, neck, jaws, or head, and is most apt to occur after exercise. These signs are usually associated with some evidence of cardiac decompensation which may not however be a marked clinical feature.

The impact to the left of the sternum and the characteristic murmurs suggest the condition, but it is absolutely essential to have roentgenograms or a fluoroscopic examination to clinch the diagnosis. The condition is a leucic manifestation and in all cases antisyphilitic medication is indicated.

J. W. TURNER.

Bernheim B. M. Choice of Operation in the Cure of Aneurisms of the Extremity. *J. Amer. Med. Assn.* 1916, vol. 3, 16.

As so many surgeons are poorly prepared to successfully cope with aneurisms, Bernheim offers several suggestions to assist in making a proper choice of procedure in aneurisms of the extremity.

The test devised by Moskowitz is recommended. This consists of rendering the leg bloodless by an elastic bandage applied to the upper pole of the aneurism; the blood stream is then shut off in the parent vessel by a pad in Hunter's canal. When aneurism is still the elastic bandage is quickly removed and the returning hyperemic wave carefully noted. Should the blush quickly spread throughout the leg compensatory circulation is assured and the parent artery may be occluded. Should the leg remain pallid, collateral circulation is absent or slight and occlusion contra indicated.

Again normal pulsation of the arteries of the foot show an absence of compensatory circulation while a lack of pulse practically assures sufficient collateral blood supply.

A case in point is given in which an aneurism of known syphilitic origin and of rapid growth was found in the popliteal space. There was pulsation of the arteries in the foot and the Moskowitz test negative. Therefore after removal of the aneurismic sac the gap was bridged by a venous transplant from the saphenous vein care being taken to reverse the vein so that the valves faced the foot. Immediate resumption of the blood stream occurred, the arteries of the foot pulsed normally and the troublesome symptoms of edema and numbness entirely disappeared within a short time.

P. M. CRANE.

Makins, G. The Importance of Auscultation in the Diagnosis of the Vascular Injuries Accompanying Gunshot Wounds. *La. & Lo. J.* 1916, vol. 8.

The author reports his experience in dealing with injuries of the blood vessels during the war.

He lays stress on the fact that in any case of swelling of the limbs in connection with gunshot wounds the stethoscope affords a ready means of establishing a diagnosis if there is an aneurism present. The point at which the bruit is loudest and highest pitched will show where the lesion is situated. Aneurisms involving either the arteries, or the arteries and veins show in addition to the local bruit at their site also a transmitted bruit in the region of the heart.

The author has not met with any instances in which a pure arterial murmur in connection with the wounded vessels of the arm was audible in the heart, but he has noticed it in a carotid aneurism and has frequently seen it in connection with the femoral vessels. These transmitted bruits show a temporary persistence. The heart at first is markedly affected, enlarged and with an increased rate after a few weeks it is able to compensate at which time the bruit disappears unless closely associated with the heart. He thinks that the cardiac disturbance is probably to be explained by the sudden alteration in the force required for the maintenance of general circulation under the altered conditions.

H. G. SLOAN.

Elsberg, C. A. The Surgical Significance and Operative Treatment of Enlarged and Varicose Veins of the Spinal Cord. *Am. J. Med. Sc.* 1916, vol. 64.

Among vascular lesions of the spinal cord such as aneurism, angioma or enlargement or tortuosity of the superficial veins although relatively common have received little attention in the literature. When the posterior spinal veins are compressed by an extradural neoplasm the veins for some distance below (on or both of the two main trunks) appear engorged and sometimes more tortuous than normal. The appearance on exposure of the cord is quite different from the pinkish hyperemic look of the distended arteries and veins in intradural inflammatory processes.

The operator should recognize the significance of these enlarged and tortuous veins. A local enlargement or varicosity may take place causing local spinal symptoms relatable by operation. Cases have been reported of varices or hemorrhoids of the spinal pia, the symptoms of which are usually those of a transverse lesion.

In several of the author's six cases the enlarged vein accompanied one of the spinal roots to the dural opening. The abnormalities were of various kinds the enlarged veins usually pressing upon spinal roots. These were in the dorsal region in five lumbosacral in one. The condition was always unilateral, proving it not to be due to the operation.

itself. In one case a tuberculoma of the cord was present. One case examined microscopically showed hyaline degeneration of the vessel walls. The author's technique in operative treatment consists in the removal of as large a part as possible of the enlarged vein by raising and ligating with fine silk in an aneurismal needle. As the veins are very fragile great care is necessary.

The results were improvement or relief in all but two cases which had spastic paraplegia following standing. The author is uncertain as to whether the venous condition is a cause or effect of spinal-cord disease, and thinks the operative result may be due to the decompression by laminectomy.

HORACE BINNEY

POISONS

Tullidge E. K. Tetanus; Surgical Complication in the Present War. *Y. I. M. J.* 9 6 cli, 02.

Tetanus is a very common complication in the present war. There is usually a mixed infection present. The anaerobic nature of the organism is especially suited to the ragged and deep character of the majority of the wounds. The filthy condition of the soldiers, especially their contamination with ground which has been fertilized by ages, predisposes them to inoculation with the tetanus bacillus whenever a wound is sustained.

The usually prodromal symptoms are stiffness and pain in the muscles, especially those of the head and neck. These steadily increase in severity until convulsions ensue.

The use of antitoxin is highly recommended as a curative measure. Enormous doses are used by the author, from 10,000 to 60,000 units being given. The local treatment of the wound is important and the liberal use of tincture of iodine seems to be beneficial.

J. H. SKILES

MacConkey A. T., and Zilke, S. S. Iodine in Tetanus. *Brit. M. J.* 9 6 i, 41.

It is a well-established fact that iodine when mixed with tetanus toxin possesses the power of rendering the latter non-toxic. The longer the period of contact between the iodine and the toxin before injection the less toxic the latter becomes. A mixture of equal parts of iodine and tetanus toxin also possesses the power to produce immunity to subsequent injections of the toxin.

These facts suggested the thought that iodine might be of value in curing tetanus, and series of experiments was carried out with that in view. The conclusions reached are that iodine when injected subcutaneously has no effect upon tetanus toxin which has also been injected subcutaneously in different place. The course of tetanus can not be favorably influenced by injections of iodine alone nor does the latter seem to have any effect in enhancing the power of antitetanic serum. Iodine can only be of use when applied to the infected focus, so that it comes into direct contact with the toxin before absorption.

E. K. ARMSTRONG

Robertson H. E. The Prophylactic Use of Tetanus Antitoxin. *Am. J. M. Sc.* 9 6 cli, 668.

Robertson in reviewing the prophylactic use of tetanus antitoxin, explains its failure in some cases by pointing out the rapid formation and absorption of tetanus toxin, associated with the extreme rapidity with which it is bound to the nerve-cells, when it cannot be neutralized. The absorption of the antitoxin into the blood is relatively slow allowing time for the more rapidly formed toxin to gain such headway as to produce fatal results.

Another reason for the failure in some cases is the short duration of immunity conferred by the prophylactic dose, usually fifteen to twenty days. When for one reason or another the formation of the toxin is delayed or not absorbed (delayed tetanus) the period of protection has passed and the disease develops. Lethal surgical interference in wounds of patients that have remained free from the symptoms for many days or weeks active symptoms of tetanus will suddenly follow a reopening of the wound as an impetus. Consequently when such interference is contemplated, a second injection of antitoxin should be administered.

Other of his conclusions are that the most ideal and perfect protection against tetanus is the production of active immunity produced before infection has occurred. This admittedly is not practical, but deserves further consideration and research.

In a large majority of cases the subcutaneous injection of twenty units immediately after the injury will prevent with certainty the occurrence of tetanus. The delay of a few hours in making the injection may mean the loss of life.

Local applications of fluid antitoxin in wounds are efficacious but unnecessarily wasteful and not always practical.

In cases where injections cannot readily be made, especially in war time, the immediate application to the wound of dried antitoxin tampons moistened by clean fluid may be used as a temporary substitute until fluid antitoxin can be injected.

D. L. DESPARD

Everidge, J. Mental Symptoms Complicating Case of Acute Tetanus During Treatment by Carbolic Injections. *Brit. M. J.* 9 6 i, 413.

Eleven days after having received severe injury to the lower extremities, the patient developed tetanus, which rapidly grew worse. Antitetanic serum was given together with 100 cc. of 30 carbolic acid solution subcutaneously every four hours. For a week the spasms were so severe that the patient was given large doses of morphine, chloral, and bromides. At the end of this time the spasms became less marked but the mental condition showed a great change, a condition resembling delirium tremens developing. This lasted five days, during which time restraint was necessary. Incontinence of urine and feces was present also. Chloral and bromides had no effect but paraldo-

byde had a quieting effect. A relapse occurred within a month after the development of the tetanus before the patient's mental state once more approximated the normal.

The author wonders what the connection is between the carbolic acid injections and the condition. One c. m. of the 1:10 solution was given every four hours over a period of about 12 days.

E. K. ANDRUSOV

Dean H. R. and Mout T. B. Bacteria of Gangrenous Wounds. *J. R. I. M. M. C. P.* 916 April 349

The authors give an interesting account of a prolonged study of the bacteria in gangrenous wounds at the Third Northern General Hospital which has brought out points of great interest to the bacteriologists and surgeons as shown in the following summary:

1. The series comprises 18 cases of gangrenous wounds of which only three were fatal. Included in this total are 4 cases of tetanus, 1 of which was fatal and 4 cases of gas gangrene, 2 of which were fatal. Among the 18 cases bacillus edematis maligni was found in 5 and bacillus aerogenes capsulatus in 13.

2. Bacillus aerogenes capsulatus and bacillus edematis maligni are apparently possessed of powerful enzymes. The former is peculiarly able to attack carbohydrates, the latter proteins. Dorset's egg medium is an admirable medium for both microorganisms.

3. The shape, size, staining reactions and capacity for spore formation of these bacilli are profoundly influenced by the nature of the culture medium.

4. On Dorset's egg medium the majority of the bacilli are typical in shape, uniform in size and gram positive. On media which contain a carbohydrate from which the bacilli can form acid, growth is at first rapid and vigorous but after a few days the bacilli become atypical in appearance, vary greatly in size, and the majority are gram negative.

5. Bacillus aerogenes capsulatus forms spores on Dorset's egg medium and inspissated serum but not on media in which an acid reaction is produced. Bacillus edematis maligni forms spores less readily in acid media.

6. The presence of bacillus aerogenes capsulatus and bacillus edematis maligni is not necessarily associated with the development of gas in the tissues.

7. Bacillus edematis maligni and bacillus aerogenes capsulatus are essentially saprophytic. They have little or no power to multiply in living tissue. In dead tissue they grow rapidly and produce poisonous substances by which the adjacent living tissue is destroyed and rendered a suitable medium for the further multiplication of these bacilli.

8. The bacillus tetani was not found in ulcers made from the discharge in any one of the 18 cases in this series in which it was present.

9. The recognition of bacillus tetani by purely

microscopical methods is complicated by the fact that slender gram positive rods bearing an atypical terminal spore may be occasionally found in pure cultures of bacillus edematis maligni and bacillus aerogenes capsulatus. Moreover, pure cultures of tetanus bacilli especially cultures on egg medium often contain many atypical forms.

10. If broth is inoculated with material from the wound in a case of tetanus and incubated under anaerobic conditions the presence of bacillus tetani can often be satisfactorily demonstrated by animal inoculation. Such a broth culture should be examined at intervals and two or three weeks may elapse before bacillus tetani can be demonstrated.

11. The presence of bacillus tetani was demonstrated in the discharge from the wounds of two patients who did not develop signs of tetanus. Both had received injections of antitetanic serum.

12. The discovery of bacillus tetani in the wounds of a patient who had not developed tetanus would obviously be an indication for one or more prophylactic injections of antitetanic serum. But the practical utility of such a procedure is limited by the difficulty and delay which attend the bacteriological recognition of this bacillus. No bacillus tetani belongs to the same group as bacillus edematis maligni, bacillus aerogenes capsulatus and bacillus edematis maligni. All three have practically a minimum of growth and the conditions favorable to their growth within a wound are probably identical. The demonstration of either bacillus edematis maligni or bacillus aerogenes capsulatus is a relatively simple matter and does not involve much delay. The discovery of either of these bacilli might with advantage be followed by a prophylactic injection of antitetanic serum.

13. A prophylactic injection of antitetanic serum should be given before any considerable operation is performed on a patient with a gangrenous wound.

SURGICAL THERAPEUTICS

Rowlands R. P. Time in Surgery. *B. M. J.* 6 1430

The author makes an appeal for the conservation of time in connection with surgery.

Often a great deal of time is lost in delay and diagnosis or operation is delayed beyond the safety point. A wait and see policy often changes the course of the case. A series of typical cases of appendicitis are reported to illustrate the point.

Avoidance of waste of time in operations is extremely important. This can be accomplished (1) by making all possible preparatory arrangements beforehand in the way of preparation of the patient, instruments, threading sutures, upon which it is before the anaesthesia begins. (2) by improving and simplifying the technique of the operation in every possible way. (3) by not neglecting full attention upon the operation. J. H. SMITH

SURGICAL ANATOMY

Horraz, G. Studies on the Pineal Gland. *Arch. Int. Med.* 9 6 xvi, 607.

Attention is directed to the fact that the clinical aspects of pineal tumors have been abundantly discussed since 1909 when Frankl-Hochwart suggested the possibility of a pathognomonic syndrome. Marburg especially has developed the subject emphasizing the association of adiposity which he regards as an indication of overfunctioning of the gland. The salient factors have been gleaned from reports of about 70 cases of tumors of the gland. Of this number only 2 occurred before the age of puberty and these, therefore, represent the source of evidence of that special train of symptoms, which have come to be associated with pineal disorders, namely premature development in the realm of both primary and secondary sexual characters. In several of these cases moreover principally in the earlier reported ones, the case records are insufficient or wanting and in the others no reference is made to the sex organs, although certain metabolic symptoms are noted. Of these, dispothymia, drowsiness, and polyuria are the most frequent suggesting at once an implication of the pituitary body. The imperfect records preclude any possibility of settling this question at present. Regarding the other cases, of which there are but 10 all but one occurred in young boys between the ages of 10 and 15 years. The exception is Marburg's case, a girl 9 years old.

The author reports three cases from the surgical service of the Peter Bent Brigham Hospital, all of which showed precocious adolescence and growth. A study of the diseases to which the pineal body is subject has been confined almost exclusively to the different varieties of tumors which have been found to arise either from the gland itself or from those structures which lie in its immediate neighborhood and therefore involve the pineal secondarily. Very rarely conditions other than tumor have been mentioned in connection with pineal pathology but these play an inconspicuous and perhaps doubtful part in this chapter of the study of the gland.

From the author's study he gathered the impression that from what is known of the physiology of the normal gland, as well as from the results of Fox and his own experimental observations, that sexual ripening occurs when the pineal ceases to be functionally alive or when it is removed and on this basis he inclines to the belief that the tumor in most of these clinical cases is associated with an inhibition of the normal products of pineal secretion. If this were really the case, however, one would suppose that glandular feeding would postpone adolescence, but from the observations of Dana and McCord the reverse seems to occur. The author's own studies in this direction with the feeding of young guinea pigs and rats were not conclusive and it is a matter which deserves further study. Briefly the author gives the following summary of his work.

1. Extirpation of the pineal in young chickens and lower animals tends to hasten normal maturity.

2. Tumors of the pineal gland in children, occurring before the age of puberty usually give rise to a syndrome characterized by precocious adolescence.

3. Feeding the gland substance to young animals is said to have the same effect as extirpation, but the observations are somewhat inconclusive.

A report of three cases of supposed pineal tumor, one of which was confirmed by necropsy is offered as a further contribution to the study of this gland.

GEORGE E. BRILEY

Vecchi, A. Critical Observations and Experimental Researches on the Regeneration and Neoformation of Lymph-Glands (Osservazioni critiche necroscopiche sulla rigenerazione e la neoformazione delle linfoghiandole). *Chirurgia Milano*, 9 6, V, 90.

The author's experiments were carried out on dogs and rabbits. The basis for the subsequent conclusions were dependent upon the following problems: Could totally enucleated lymph-gland regenerate? Could partially resected lymph-gland regenerate? Could there exist independent of any damaging operation, a neoformation of lymph-glands, and could their number be increased in a given region? The conclusions are as follows:

1. After the enucleation of a lymph-gland there is no regeneration but the formation of a new lymph-gland of substitution.

2. After the partial resection of a lymph-gland cure is obtained with the formation of cicatricial tissue without regeneration of the part excised.

3. In particularly marked conditions it is possible to obtain neoformation of lymph-glands, which increases the number of lymph-glands of a given region, either by proliferation of the pre-existing gland, or by the transformation of the adipose tissue (according to Bayer) or by the development of embryonal germs.

RUDOLF L. VON W.

Hoskins, R. G. The Present Status of the Adrenal Problem. *J. Lab. & Clin. Med.* 9 6 4, 52.

The author reviews the literature during the past ten years and summarizes the work that has been done on this subject. He comes to the conclusion that the fundamental question remains yet to be answered, Why does the removal of the adrenal glands cause death? He believes that the trend of the evidence now available suggests that muscular metabolism is at fault. If that be true the solution like that of many another of the most puzzling medical problems, rests in the hands of the biological chemist.

GEORGE E. BRILEY

Stewart, G. N., Rogoff, J. M., and Gibson, F. S. The Liberation of Epinephrin from the Adrenal Glands by Stimulation of the Splanchnic Nerve and by Massage, Studied by Means of the Denervated Eye Reaction. *J. Pharmacol. & Exp. Therap.* 9 6 iii, 305.

The observations of a number of investigators have indicated that during electrical stimulation of

the splanchnic nerves epinephrin passes into the circulation by the adrenal veins. These observations may be divided into two groups: (1) those in which blood has been collected from the adrenal veins of one animal and tested for epinephrin by its action on the blood pressure when injected into the veins of another animal; (2) observations in which the liberation of epinephrin has been deduced from changes in the blood-pressure or other reactions in one and the same animal.

It is shown in the present study (on cats and dogs) that the response of the denervated eye to stimulation of the peripheral end of the splanchnic nerves is due solely to the passage of a substance in the blood stream from the adrenals to the eyeball. For —

1. When the venous path is blocked the response fails but appears on releasing the block and at the same interval of time as when the vessels are free. The active substance must therefore have accumulated during the period of stimulation of the nerves behind the block.

2. When the heart is stopped by stimulation of the peripheral end of the vagus stimulation of the splanchnics produces no effect on the eye. But on allowing the heart to beat again the eye response occurs at approximately the same time from the moment of re-establishment of the circulation as the time interval between stimulation of the splanchnics and the response with the circulation is going on normally. During the stoppage of the circulation by complete cardiac inhibition accordingly stimulation of the splanchnics must have caused liberation of the active substance at the same point from which it starts when the splanchnics are stimulated without cardiac inhibition.

3. When the circulation is slowed without being stopped as by producing partial inhibition of the heart through the vagus or by hemorrhage the interval between the beginning of stimulation of the splanchnics and the appearance of the eye response is correspondingly increased.

4. It is possible to find a strength and duration of stimulation of the splanchnics with which no eye response will be obtained when the ipsilateral or both carotids are clamped but which will give a response with the vessels free. With longer or stronger stimulation a response is obtained on one side even with the carotids clamped. The amount of the response and its retardation can be varied when appropriate doses of adrenalin are injected into the femoral vein with the carotids clamped.

5. When adrenalin is injected into the left renal vein, the central end of the femoral vein, in a minimum amount to produce an eye response approximately equal to that produced by a given stimulation of the splanchnics the interval of time between the response follows is sensibly the same as that following stimulation of the splanchnics. When the carotids are clamped and the splanchnics stimulated a response may be obtained in the

eye while the clamp is still on or only after its removal or both during the application and after removal of the clamp. There is some variability in this regard in different experiments. There is also a somewhat greater variability in the time interval at which the response appears than in observations in which the splanchnics are stimulated with the vessels free or with the veins clamped. The interpretation of these differences is discussed.

Circulation time measurements show that there is always more than sufficient time for a substance to have been carried in the blood from the adrenals to the eye before the appearance of the eye reactions.

8. The latent period of liberation of epinephrin from the adrenals in stimulation of the splanchnics is short since the time interval after which the eye response occurs is sensibly the same whether it is evoked by splanchnic stimulation or by the injection at the level of the adrenal of a quantity of adrenalin sufficient to elicit a response similar in character and amount.

9. The minimum period of stimulation of the splanchnics needed to liberate sufficient epinephrin to elicit a response in the denervated eye is very brief (a fraction of a second). With a current of given intensity the amount of the response increases up to a certain point with the duration of the stimulation.

10. Massage of one or both adrenals cause definite eye response in an animal in which stimulation of the splanchnics has been causing it and at the same interval of time. When after repeated excitations of a splanchnic nerve the reaction of the eye ceases to be obtained it can still in general be elicited by massage of the corresponding adrenal. But this reaction is soon exhausted.

11. Good eye reactions have been obtained by stimulation of the splanchnics in cats in which attempts were made before the experiment to exhaust the epinephrin store of the adrenals for example by brightening or by administration of morphine. It did not seem that it was easier to exhaust the capacity of the splanchnic nerves for eliciting these reactions in such animals than in animals which were guarded as much as possible against preliminary exhaustion of the epinephrin store by psychological disturbances.

(L. A. E. BEILBY)

Brown, E. D. Observation on the Effect of Epinephrin on the Medullary Centers. *J. Physiol.* 1905, 5.

Brown calls attention to the fact that the slowing of the heart beat is markedly observed when epinephrin is introduced into the circulation in almost uniformly high but not at a very low concentration. The vagus center which is influenced by the rise in blood pressure is rather insensitive to this effect. The question whether epinephrin has a direct action upon the heart is still unsettled and there but little experimental information regarding the

literature which would suggest that the drug might produce a direct stimulation.

The present investigation was undertaken with the hope that some additional facts might be discovered which would aid in solving the problem. The experiments here reported were performed on 23 dogs and a titration of the results obtained on 14 dogs where epinephrin had been introduced showed that in 9 of these there was a slowing of the heart while in 5 it was absent.

The results obtained from the experiments tend to show that when epinephrin is perfused through the cerebral circulation it may in certain per cent of cases cause a slowing of the heart and that this slowing is at least in part due to a direct stimulation of the vagus center. There is certain evidence which strongly suggests the probability that the drug also stimulates the vasomotor center. The effect on the respiratory center is very variable. There is evidence of both stimulation and depression and neither of these effects appears to be governed by the size of the dose of the drug. GEORGE E. BRILEY

Diana G. The Behavior of Some Pancreatic Ferments in the Blood After the Ligation of the Pancreatic Ducts (Sul comportamento di alcuni fermenti pancreatici nel sangue dopo la legatura del dotto pancreatico) *Atti di Nest. path. (ser. di Biologia)* 21: 95, 1915.

According to the researches of W. Hageman if the pancreatic ducts of a dog are ligated after a few hours there is a strong increase of diastase in the urine and in the blood. This reaction has maximum within twenty-four hours after the operation, it remains for some days at this maximum and at the end of eight or ten days goes back to its original figure.

The author's research was carried on in an endeavor to find if in addition to diastase other pancreatic fermenta, particularly lipase and esterase increased in the blood after ligation of the pancreatic ducts. His results confirmed Wohlgenuth.

Regarding lipase he was unable to find it immediately after ligation of the ducts, but he constantly found it in the blood of forty-eight hours up to the sixth day after operation, with maximum on the second day.

Esterase exists in the blood serum before operation and increases notably following it.

W. A. BRIDGEMAN

Robertson, T. B. The Effects of Tethelin: Acceleration in the Recovery of Weight Lost During Inanition and in the Healing of Wounds. *J. Am. Med. Ass.* 9: 617, 1916.

The author gives a brief outline of the method of isolating the growth-controlling principle, which he terms tethelin, from the anterior lobe of the pituitary body. Its chemical properties and physiologic actions. The dried tissue of the anterior lobes of the pituitaries is extracted with boiling absolute alcohol and the solution is evaporated under reduced pressure until solid material begins to separate

out on cooling. To this solution is added one and one half times its volume of dry ether. The substance is thus precipitated and after washing in large volumes of alcohol-ether mixture the above-mentioned proportions it is then ready to be dried and pulverized.

Tethelin is soluble in water and in alcohol, ether, chloroform, and carbon tetrachloride and is insoluble in a mixture of absolute alcohol and dry ether. It contains 5.4 per cent of phosphorus and nitrogen. It is markedly hygroscopic and on standing after pulverization in contact with moist air it darkens perceptibly in color and its iodine absorption value decreases, which decomposition is accelerated by warming but if packed in vacuumated glass tubes and kept perfectly dry it may be heated to a high degree without any perceptible discoloration.

The average yield from each anterior lobe may be estimated to be about 0.05 mg. of tethelin. The action of this substance in doses of 4 mg. per diem administered by mouth twelve between 4 and 60 weeks of age consists in a marked retardation of the early (preadolescent) growth in weight and an equally marked acceleration of postadolescent growth. Mice which have received tethelin are much more firmly and compactly built than normal animals of the same age and it also has a favorable effect on the nutrition of the skin of the animals.

Since tethelin appeared to be a strong stimulator of growth it seemed probable to the author that it might also accelerate that species of internal growth which occurs in the replacement of tissue lost through excessive tissue waste consequent on any circumstance leading to an excessive nitrogen output or curtailment of nitrogen input and accordingly made a series of investigations on 10 male and 10 female mice about seven months of age. The animals were deprived of food for twenty-four hours at the end of which time 5 males and 5 females were given tethelin and all the animals were allowed free access to food. At the end of four hours comparison between the animals which received tethelin and the controls showed that the administration of tethelin led to a very remarkable acceleration of the regain of weight following the administration of food.

The author also made experiments to see the effect of tethelin upon another form of tissue repair—the healing of wounds, and while as he states experiments on animals and especially on mice do not afford the most satisfactory means of investigating this process, his results were so favorable as to justify his opinion that tethelin when administered hypodermically to mice repairs remarkably stimulating action on tissue repair as expressed in the healing of granulating wounds. GEORGE E. BRILEY

RADIOLOGY

Kuegler, F. H. Radio-Activity as a Therapeutic Agency. *Med. Herald*, 9: 61, 1916.

After reviewing briefly the event which led to the discovery of the roentgen ray and such radio-

active elements as uranium and radium the author describes their applicability as therapeutic agents. Regarding their relative values he states that they are practically identical in their action, differing only in the quality and quantity of the rays produced. The choice of one or the other depends upon the anatomical location of the diseased tissue and the peculiar requirements of the case to be treated. He lays stress on the matter of proper dosage and technique if beneficial results are to be obtained.

Among the conditions mentioned in which radioactive treatment was found to be particularly useful, were enlarged lymphatic, tuberculous and lymphomatous glands, dysmenorrhea, uterine hemorrhage and fibroids at or near the menopause yielded uniformly good results. Chronic joint diseases and even some selected cases of tuberculous joints showed a fair percentage of cures or improvement. In the latter cases the author believes that the simultaneous use of Bier's hyperæmia treatment enhances the effect of the irradiation. In exophthalmic goiter the results were so favorable that he believes with Sielmann and Schwartz that it is to be preferred to surgery where simple medical treatment has failed.

Regarding the use of radio-activity in cancer the author quotes a summary from an article by Russell to the effect that its use in no wise should supplant operation unless it be in the removal of certain superficial growths but that it be used rather as an adjunct to surgery.

WOLFE HARTMAN.

Perkins, G. W.: The Normal Stomach; Its Size, Position, Form, Tone, Peristalsis and Mobility from a Radiographic Standpoint. *Med Press* C C 96 3 258.

After an examination of 58 normal stomachs radiographed in the vertical position and filled with an opaque meal of buttermilk and bismuth subcarbonate, Perkins draws the following conclusions:

1. Peristalsis does not seem to exert any influence on the tone of the stomach, for we may have exaggerated peristalsis with a hypotonic stomach and diminished peristalsis in a hypertonic stomach.

2. There are no determined fixed points of any type of stomach in the abdominal cavity except the cardiac portion. A stomach may be of any of the types and yet be normal from an X-ray standpoint.

3. The average normal stomach is orthotonic. The usual position of the orthotonic stomach is as follows: greater curvature (lowest point) one to two inches above the interspinous line; lesser median or to the left; lesser curvature (lowest point) three to four inches above the same line; median or one to two inches to the right. The pylorus is placed two or three inches above the line in the median position or one and a half inch to the right. The axis of the stomach is vertical and parallel to the median line. The length is eight to ten inches and the width three to three and a half inches.

4. The tendency of the male stomach is always toward hypertonicity while that of the female is

toward hypotonicity. The stomach is not as full as high in the abdominal cavity as many textbooks of anatomy teach. There is no structure in the human body however that has such variation in form, tone and position.

5. Radiographic examination with the fluorescent screen or plate is the only method of ascertaining the anatomical position of the stomach, its peristalsis and mobility in the living individual. Therefore bearing in mind this fact the physician should be observant of the limitations of the technician in locating pathologic lesions of the stomach that is if he has not a ray of the stomach. Such a chart should also be carried by the radiologist technician in locating intestinal growths.

Herniman Johnson F.: The Uses and Limitations of Stereoscopic Radiography in the Diagnosis of Injury to Bone the After Treatment of Fractures as Carried Out in the Electrical Department of the Cambridge Hospital. *Aldershot P. L.* 1 42.

The method has been employed in orthographic work. It is neither complicated nor employed to the exclusion of the well known procedures as for internal fixation of foreign bodies. It is essential in the diagnosis of injuries to the shoulder, spine, pelvis and hip. In these regions plates in one plane may be misleading and the whole picture is by the stereoscopic view is the only means of checking the ofttimes misleading appearance of an ordinary plate. By reversing the plates in the stereoscope an appearance is produced if one were looking at the other side of the bones under examination. A bone or joint is never explored radiographically until four sets of stereograms have been taken, anteroposterior, posteroanterior, right lateral and left lateral. By means of which plates a general view of the relations of the various bones can be obtained yet one must remember that the exact relationship of distances will be distorted. It is usually possible to say whether a bullet is at one side or the other of the bone or buried within it and to determine the relative position of fragments but the stereoscope must not be regarded as an instrument of precision for localization purposes.

The author finds that the use of electricity in the after treatment of fractures is a distinct advantage where massage and passive motion have not restored the member to normal use. He advises a combination of galvanism with a mild faradism in the form of baths. With a continuous current of 20 to 30 milliamperes used for 20 minutes daily the faradic current must not be of sufficient strength to cause any distinct muscular contraction. Massage and muscular exercises must be used in conjunction with the electrical treatment if the best results are to be obtained. Fractures in the neighborhood of the elbow, wrist and ankle will give a normal result.

under this method within a month to six weeks. Where weakness is complained of in the limb consequent to fracture the author advocates rhythmical electrical stimulation by the faradic current preferably by a Lewis-Jones electrical apparatus arranged to give at least 20 impulses a second. Such condition of weakness may occur after prolonged immobilization in which all the muscles in the vicinity are affected, or where through faulty position a particular muscle group has been over stretched. In the latter case, a relaxation splint is essential for cure. In general up to a certain point the parietic phenomena are no doubt largely physical, but there is from the first certain mental element present, a kind of failure of memory as to how the lost movements are to be provoked, in other words, a lack of action patterns in the memory of the movement of the affected part. Stimulation of the individual muscles electrically therefore, has its greatest usefulness under such conditions. There is a type of pain complained of following fractures, where the presence of the limb has become quite normal again and the movements good. The patients describe it as being like toothache. It is made worse by exercise and often keeps the patient awake at night. The application of the high-frequency current by the vacuum electrode, at first on the skin and later at sparking distance, gives relief in a few days. In case pain is not relieved careful X-ray examination, with view to the possible detection of some definite cause as the presence of a small bony cavity in the middle of the reformed bone should be undertaken. X-rays are often of value in relieving pain and causing the disappearance of previous fibrous accumulation. HARRY C. SLOW.

Turner D. Report on the Radium Treatment at the Royal Infirmary Edinburgh, During the Year 1915. *Edinburgh Med J* 9 6 1, 1916.

Some interesting points have been presented in this detailed report of 64 cases treated during the past year 24 of which were malignant and inoperable of this class 8 being sarcoma in which better results are to be expected if they are favorably situated. He also found carcinoma of the vagina and cervix would usually yield if localized but recurrence after a variable length of time was the rule. However during the interval the patient enjoyed relief from pain, gained in weight, and was in fair health. A preliminary curettage is often of great service. Screening has been found unnecessary in these cases, except to protect the healthy tissues the dosage should be at least 3,000 milligram hours. In rodent ulcers the results are invariably good, and if they recur it is usually due to insufficient primary treatment. The cosmetic result leaves nothing to be desired. For this reason Turner has employed it in the treatment of papillomata, naevi, and recent cheloids. Nine cases of exophthalmic goiter were treated two of them being males. While there was very little change in

the gland, in fact in one instance it became larger yet the treatment had some influence upon the general system, for the symptoms were controlled and the health was greatly improved. In these cases a .4-mm. silver screen was used, 20 mg. of radium bromide being placed 2 cm. from the skin and left in place for twelve hours. Under these conditions no damage was observed to the overlying integument. This treatment was repeated in 3 or 3 months.

The author believes that while the field of utility for the use of radium is limited its value in certain well-defined directions has been firmly established. W. S. NEWCOMB.

Beck, E. G. An Accurate Method of Localization of Foreign Bodies in the Chest and Their Removal. *Internat. Med J* 9 6 xiii, 1916.

The author discusses the value of stereoscopic radiograms in locating foreign bodies particularly stress being laid on the fallacy of attempting to determine from a single radiogram the exact location of foreign bodies, as well as the fallacy of attempting to form a correct view of the position of fragments after fracture. To illustrate this point the author placed a bullet on the center of the sternum. Two radiograms were taken without changing the patient's position but the X-ray tube was shifted to a different angle. On each picture the bullet appeared to be in a different location. The cases cited by the author attest the value of the method. In one instance a would-be suicide shot herself with a .45-caliber pistol. The bullet from a single radiogram seemed to be in the axilla. The stereoscopic readings showed the bullet to be against the scapula. It was found there. Beck uses the method in intestinal work in studying diseases of the cecum, sigmoid, and in estimating the depth of empyema cavities and fractures.

LEONARD CORRY

Millwee R. H. Five Hundred Gastro-Intestinal Examinations by Roentgen Ray. *Texas Med J* 9 6 xiv 45.

Millwee reports upon 500 consecutive gastro-intestinal examinations by the roentgen ray with a barium sulphate meal suspended in artificial butter milk. The roentgen diagnoses in these 500 cases were as follows:

Duodenal ulcer	1
Pyloric atony and stasis	143
Appendix involvement	04
Gastric ulcer	48
Gall bladder involvement	30
Gastric cancer	38
Miscellaneous	10
Negative findings	29

The author was able to follow up 80 per cent of these cases with the following checking. Of the cases operated upon for duodenal ulcer a lesion was found in the duodenum in all but one case.

this case had gall-stone with adhesions. Of the cases treated for duodenal ulcer all responded to treatment except 11.

Fifty per cent of the positive appendix cases were operated upon all of which showed involvement. In the cases of gastric ulcer and gastric cancer all of the cases operated upon revealed either an ulcer or a cancer with the exception of one case in each group which showed gall bladder disease with adhesions.

L. H. SKINNER.

MILITARY SURGERY

Mullally G. T.: A Case of Tetanus like Spasm Localized to the Wounded Limb. *Lancet* 1914, 96, 867.

Mullally describes a case of shell wound of the lower end of the femur which necessitated amputation. The case was complicated by gas infection which necessitated extensive opening up of the thigh. A few days after the injury twitching in the stump began and grew progressively worse the spasm becoming so painful that chloroform had to be given to control the pain. The author thought that he was dealing with an ascending neuritis in the stump and resected the antero-crural and sciatic nerves without relief. The patient died on the tenth day at which time the facial expression was suggestive of risus sardonius. A prophylactic of 1000 unit of antitetanus serum had been given the day of the injury. The author feels that the case was one of tetanus although there were no general spasms.

F. D. DICKSON.

Weinberg M.: Gas Gangrene in the Present War. *Medical Journal* 1914, 96, 1000, 24.

Gas gangrene has been especially prevalent in the present war. The bacteriology of gas gangrene has been carefully worked out. The bacillus aerogenes capsulatus otherwise known as bacillus perfringens is found in nearly all cases. Only in exceptional cases however is it found alone other organisms being usually associated. These other organisms may be diplococci, streptococci bacillus proteus and bacillus sporogenes. Another common form of organisms occurs in which the bacillus of malignant oedema (vibrio septique) is the pre-dominant organism. Other organisms are usually associated with the vibrio septique which is a relatively rare agent in gas gangrene being found in only 4 out of 100 cases.

The toxic form, the bacillus oedematis is found associated with the bacillus perfringens and vibrio septique in the classic form of gas gangrene. From the foregoing it is readily seen that most of the organisms related to the production of gas gangrene belong to the intestinal flora.

Gas gangrene was produced experimentally in the following way any of the above mentioned organisms. In the production of gas gangrene it is necessary to inject a relatively large number of organisms. There must be some contributory cause

to account for the small number of bacteria necessary to produce gas gangrene in wounded soldiers. The dissection of limbs amputated to gas gangrene has demonstrated that the gangrene is not due to the presence of organisms but is a result of the obliteration of the main vessel by the organisms of gas gangrene and this a very fertile soil for growth. Another factor is the importance in the production of gas gangrene of injury to tissues especially to muscle. Experimentally it is very easy to induce thrombosis and artificial injury to muscle with a rubber question.

The treatment of gas gangrene in the early stage is the treatment of wounds which are probably infected. The wound should be thoroughly washed with all germicidal material and kept as wide open as possible. Continuous irrigation with normal saline solution or hypotonic salt solution or sterile insecticide is recommended.

The polyvalent serum of Coleman has been found to have a protective effect in wounds infected especially by gas gangrene. In the opinion of the author the best treatment is one prepared with the serum and antitoxin and an aerobically that are found in the wound to be treated.

Early amputation is often necessary and is considered necessary in many urgent cases. The actual cautery over the whole extent of the infected area. Free incision or a matter of time treatment. Unfortunately many cases result fatally in spite of the best that can be done. J. H. SKINNER.

Lansdown R. G. P.: Removal of Bullets and Other Metallic Foreign Bodies. *British Medical Journal* 1914, 96, 1000, 24.

There are four points which should be emphasized in the localization of bullets by X-ray. (1) Every case should be carefully screened by a skilled skiagrapher accustomed to the work of localization. (2) In determining the direction of the intral ray the smallest diaphragm must be used. (3) It is essential in all difficult cases that the operator should be present when the localization is made as it is of paramount importance that the patient should be in the same position for operation as when the localization was carried out. (4) The localization should be made as short a time as possible before operation owing to the liability of the metallic body shifting its position.

The skin is then marked by a small cross made with a sterilized surgical needle. The patient is taken immediately to the operating room and the following procedure is carried out. A telephone apparatus is connected one electrode being placed on the sound limb of the patient the other being connected with a sterilized probing needle. The needle is inserted at the cross mark on the skin in the direction of the for ign body. When it touches the foreign body the circuit is completed and a distinct tapping sound is heard at the telephone receiver. A small incision is then made, and the

Isnardi, L. Treatment of Septic Wounds Without Drainage (Cura di Bo ferite di guerra atliche senza drenaggio). *Glor d'Accad di med d Torino* 9 5 lxxviii 430

Isnardi is opposed to the employment of drainage in the treatment of septic wounds. Of 290 wounds treated by him in the Reserve Hospital of Vercelli 3 were very grave and septic. Most of them were fracture wounds. The treatment consisted in clearing the wound, immediate reduction of the fracture with traction apparatus, immobilization of the articulation, examination with sound, radioscopic examination only, no searching for no extraction of picule, etc. unless apparent, no manipulation, plentiful use of gauze and absorbent cotton, immobilization and elevation of the limb. No drainage whatever is used. All the 3 cases have recovered with preservation of their limbs.

Isnardi is of the opinion that drainage and incisions disturb the progress of the reparatory process. Drains, whether gauze, rubber, glass, or foreign bodies, irritate the tissues and give harboring stronghold and breeding place to microbes. Incisions expose damaged tissues which would better recover under an intact skin. Drains do not favor the elimination of poisons. The traumas made by the projectile all ways offer better pathway. W. A. BRYAN.

Saint C. F. M. The Principles of Treatment and Their Application to Wounds. *Brd II* 1 9 0 4 30

The principles of treatment are (1) remove the cause (2) combat the effects (3) assist the reaction (4) prevent complications or deal with them if they have arisen.

Removal of the cause depends upon the location as to the probable presence or absence of infection. A superficial metallic body should be removed. When deeply placed it should not be removed unless there is probability of infection and proper X-ray equipment is at hand to aid in its localization. Under special circumstances even sterile bullet may need to be removed for example when from its position it gives rise to irritation of nerves interferes with the movements of joint, etc.

In combating the effects the general condition of the patient is extremely important. Quiet and freedom from pain, secured if necessary by morphine, are absolutely essential. Stimulant must be given with caution, small doses frequently given being preferable to large doses. Transfusion is the chief remedy, saline being usually used preferably by rectum or subcutaneously but occasionally intravenously.

The treatment of the local condition in case of hemorrhage either by pad and pressure or by pressure ligature, or vessel suture. The importance of ascertaining that no tourniquet is left on limb too long is emphasized.

In assisting the reaction the course followed depends upon the condition of the wound when the

case arrives. Since most cases are infected, antiseptics are first used and the wound thoroughly cleansed. Aseptic wounds may be closed and primary union secured.

The complications are numerous, one of the most important being sepsis. This is combated in numerous ways, many antiseptics being used. Hypochlorous acid is the most popular at present. Efficient drainage, lymph lavage secured by hypodermic solution and Bier's hyperemia are all important in hastening recovery. The general resistance should be supported by fresh air, quiet and plenty of nourishing food.

The following rules have been elaborated by the author for the treatment of head injuries.

1. The wound was dressed, the lotion used for the removal of the old dressing being in 20 carbolic. Mercury perchloride was contra-indicated because odine had invariably been used lavishly often producing blistering. If further investigation proved to be necessary the wound was packed with spent gauze wrung out of 1 in 3,000 mercury boric acid.

2. An anesthetic was administered.

3. The head was washed in 20 carbolic lotion, and the hair shaved off while the carbolic was dripping, and following the razor.

4. The bruised edges of the wound were trimmed with mouse-toothed forceps, knife and scissors, and the wound dried and swabbed throughout (including exposed brain) with pure carbolic. All more extensive wounds the excess of carbolic was neutralized by methylated spirit otherwise it was mopped away.

5. A large flap was reflected usually with the wound in its center.

6. The skull was trephined, all loose depressed bone removed, and projecting edges nibbled away. No extensive search was made for distant pieces of bone or foreign body. Bleeding was treated by fine suture muscle tissue or packing.

7. Exposed brain and dura mater were covered with spent gauze wrung out of 1 in 3,000 mercury boric acid, the free end being pulled through the original wound. A tube was introduced in some cases.

8. The operation wound was sutured with silk worm gut.

9. Three days later the gauze was removed, the tube might or might not be removed. If left it was removed at the next dressing.

Where the original wound resembled an incised wound, secondary incisions were inserted on the fifth or sixth day. In punctures this was not necessary and in extensive lacerations and destruction it was not possible. J. H. SCILES.

Sorrel, A. L. Painless, Rational, and Economical Treatment of Wounds (La cura indolore, razionale, ed economica delle ferite). *Glor d'Accad di med d Tori* 9 5 lxxviii 404

Sorrel claims many advantages in the use of paraffin in the surgical treatment of wounds, both

tion. The physiological integrity of the splanchnic vasomotor system and of the musculature of the abdominal wall form the chief only extraneous limitations to expansion of the great abdominal reservoir.

The splanchnic vasomotor mechanism is sufficient to compensate for the effect of gravity on the blood supply of the brain. Deficient vasomotor tone combined with a tonic condition of the abdominal wall of a patulous abdomen must in the erect posture lead to deficient circulation in the brain and cerebral anemia, as well as oligemia of the general circulation.

In the normal subject the fall of carotid blood pressure which tends to occur on changing from the recumbent to the erect posture leads to stimulation of the splanchnic vasomotor center at the same time the tension of the muscles of the abdominal wall is apparently increased as is evidenced by the difficulty found in making a satisfactory palpatory examination of the abdomen with the patient upright. In these ways the hydrostatic pressure tending to surcharge the splanchnic veins is compensated, so that with the venous efflux from the brain accelerated by gravity and the arterial inflow kept high by elevation of systemic arterial pressure the nourishment of the brain may be expected to flourish in the erect posture.

In the debilitated individual we must expect to witness the preponderance of gravity effects proportional to the weakening of the physiological powers which had held the compensation. Now in the erect posture the blood actually stagnates to a degree in the splanchnic veins at the expense of the systemic circulation and the blood pressure in the brain falls.

In the group of complaining more or less healthy looking women in whom it is difficult to localize the pathological condition and which the physician commonly characterizes as neurasthenic measures taken to support the abdominal circulation often seem to give better result than any other whether or not there is evidence of enteroptosis.

The one physical sign which seems indicative of general, and especially of intracranial hydrostatic circulatory deficiency is to be found in the postural changes of the blood-pressure. In the normal person in the erect (least) sitting posture the blood pressure is higher than when recumbent. When the blood-pressure, especially the maximal are found higher in the recumbent than in the sitting posture Sewall concludes there is physiological weakness either of the splanchnic vasomotor system, of the abdominal wall, both, and that potential cerebral anemia and vasomotor overstrain are consequences in the erect posture.

The treatment of abdominal circulatory tasis consists in respiratory and resistance exercises each exerted followed by a period of rest in the recumbent posture. Both with alternating temperatures, combined with massage have favorable effect. The subject should lie down for an hour after each

meal and during the latter half of this period a bag of shot weighing ten to fifteen pounds should be placed on the abdomen. Exercises especially adapted to strengthening the abdominal muscles should be employed, such as the rowing machine. To relieve morbid symptoms in the quickest way an artificial support such as a belt band or corset should be applied over the lower abdomen.

Sewall concludes that plain harness is potentially present and may be the starting-point for vicious circles of derangement in every case of general functional collapse. Laxness of the abdominal wall probably leads in the erect posture to the establishment of a negative pressure within the abdomen, which it is the primary object of treatment to correct. Depletion of the intracranial blood current must follow insufficient compensation of the hydrostatic pressure involved in the erect posture. Virtual anemia of the brain leading to multiplicity of disorders is the natural sequence. It is probable that excess of blood pressure in the recumbent as compared with the erect posture is a trustworthy index of placid nervous system.

MEDICOLEGAL, HOSPITAL, MEDICAL EDUCATION

Malpractice; Expert Evidence as to Treatment;
Patient's Duty to Minimize Damage.
Rev. 9-6-11 608

The case of *D. H. Wagner v. P. 1979*, was that of a mutual doctor for malpractice in which the plaintiff succeeded in obtaining a verdict against the defendant physician. The facts are briefly reviewed as follows:

The plaintiff, a workman, sustained injuries to his foot on a long of dislocation of one of the bones and other injuries and bruises. The defendant physician was called to treat the plaintiff's injury and was called the hospital fee was \$100. Infection followed the wound and the plaintiff was confined in the hospital for over six weeks. After leaving the hospital he called a number of times upon the defendant to treat him. At these visits the defendant advised him to use the foot and do some light work and told him that he would probably have a good foot. The dislocated carpal bone was pressed downward and forward to such an extent that the protruding end of the bone carried the weight of the body causing pain. The specific allegation of the defendant's negligence was that the defendant had neglected to properly reset the bones by manipulation and had failed to perform an operation by cutting the foot open and forcing the dislocated bone back into place.

The jury returned a verdict in favor of the plaintiff and the trial judge set aside the verdict and entered judgment *no obstant verdictum* for the defendant. The case was appealed by the plaintiff and an appeal of the above facts were practically undisputed.

The main point in issue was: Was the defendant guilty of malpractice in not attempting to set the dislocated bones by manipulation the time passing when this should have been done? Should the defendant have performed an operation? A medical expert for the plaintiff expressed the opinion that if there was swelling and infection during the acute stage, an effort should have been made thereafter to restore the functions of the foot, the presence of the swelling and infection would prevent resetting or operation during the acute stage. The sooner the swelling was reduced the better. Medical experts for the defendant testified that it would have been foolhardy to attempt to reset the bones in any way until all danger of infection had passed and the wound healed completely, that the cutting of the tissues prior to this time would have been hazardous, that the bones would not have remained in place if set, that an operation might have made the dormant infective germs active, threatening the loss of the foot and possibly the life of the patient, that the duty of the operating or attending surgeon was first to look to the life of the patient. They testified that the services of the defendant were in keeping with the proper teachings of surgery.

The reviewing court says in substance that when the unimpeached testimony of doctors of equal skill and learning disagree on a given state of fact, the courts cannot hold to the theory of one to the exclusion of the others, that if a number of witnesses recognize the method of procedure as proper and approved, the court could not hold the surgeon guilty of malpractice, giving reasons as follows:

That a surgeon is called upon to exercise only reasonable care, learning and diligence in his profession and that he uses a method recognized and approved by

members of his profession of equal learning and standing, he should not be held liable for mistake, nor will the court deem a man guilty of malpractice where doctors disagree as to method, if it is not even though a more modern method than the adopted is suggested, a third party is not the duty of the attending surgeon to do that is reasonable within the limits of professional skill to relieve pain and suffering.

The question then arises: Did the defendant in the case at bar violate any duty to the plaintiff after the plaintiff had left the hospital? The court holds that although the defendant, together with the employer of the plaintiff, made it known to the plaintiff that the hospital had left the plaintiff was continuing a continuing duty to the plaintiff, reasonable professional duty, although not clearly stated, that an operation might be necessary and a full proof of the duty of the plaintiff, so far as the plaintiff was concerned, was offered to show that the reasonable duty of the operation would amount to \$500.00, the jury therefore directed a judgment for the plaintiff for \$500.00. However, the plaintiff was not held liable for the pain and suffering resulting therefrom. The reason was that the defendant was not liable for the original injury, being not liable for proper care and treatment until the time the plaintiff left the hospital, he was not liable for the pain and suffering resulting therefrom. He was under a legal duty to minimize his damages. It followed therefore that he could not recover to the extent of pain and suffering because it was his duty if he thought he had been malpracticed to have the operation performed and bring suit for the reasonable costs thereof.

GYNECOLOGY

UTERUS

Carvalho C. The Technique of a New Procedure for Subtotal Abdominal Hysterectomy in Cases of Uterine Fibroma or Inflammation of the Adnexa. *S. g. Gynec. & Obs.* 96 viii 64

For some time past the author has performed subtotal abdominal hysterectomies in cases of uterine fibroma or inflammation of the adnexa by what he considers an improvement of various methods already known. The improvement in his method he claims to be founded on the fact that the circulation of the uterus and the adnexa is controlled by means of the forceps.

The technique is as follows. After median laparotomy incision is made, the uterus is pulled as high as possible with the hysterostat and the finger is directed toward the pubis.

The thumb and the index finger of the left hand grasp the broad ligament just outside the adnexa and seek the cervix through the walls of the vagina ascending slowly from there to the point where the beating of the uterine vessels is felt. The right hand seizes the fundus of the uterus with the finger and compresses the area covered by the thumb and the index finger of the left hand. The whole breadth of the broad ligament is thus compressed above the point of the finger which touches the borders of the cervix and the forceps are slightly but tightly locked to completely close the three arteries of the uterus.

The section of the broad ligaments and the cervix is carried out from left to right following the edges of the forceps. The ligation of the uterine arteries is made directly if the ends are still visible, if not by U-shaped ligature below the forceps. The fundular and the ovarian arteries are ligated connected with the peritonization.

The peritonization is made with catgut and pedicle needle. The needle is passed all around the stem of the pedicle of the uterus in the peritoneum; the loop is closed and the ovarian vessel ligated. Still here are then made in any that spirals formed by the catgut enclose both the borders of the remaining part of the broad ligament and the forceps compressing this part one of these spirals encloses the artery of the broad ligament. When the cervix is reached the forceps are removed and the catgut pulled just as if it were a curtain string. The ligature and peritonization of the cervix and of the other half is done the same way.

The disadvantages of the method are: (1) the use of few instruments, (2) the absence of bleeding, (3) the ease with which the peritonization is accomplished and (4) the avoidance of injury to the uterus and the bladder.

Laroque G. P. The First 118 Cases of Operation for Posterior Displacement of the Uterus. *Am. J. S. g.* 96 xvi 5

In the 118 cases that furnish the basis of the author's report suspension was performed 7 times. In the early cases by the Gilliam technique, but by the so-called Kelly method in a few the temporary suspension of Ochaner was used and, as a part of the treatment of extensive suppurative disease in one case, the uterus was held up as a result of tightening the broad ligaments incident to removal of the uterus. In one case hysterectomy was performed. 93 cases of this group the J. H. Hoston-Wallis operation was employed.

This method has given complete satisfaction. It conforms to the standard principles necessary in performing operations to produce a normality and is what the author calls the anatomical method. It is followed by the least painful and convalescence and the least end result both as to position of the uterus and the relief of symptoms, have been perfect. All the cases have been followed at least three months and most of them examined again. Some report have come from patients and from doctors many cases after from three to five years. Many of the women have given birth to children. The operation without difficulty. Dilatation of the cervix was performed. If current was necessary in good number of cases. Kernal's catheter of the cervix perineum both was necessary. 58 of the 118 cases. Removal of the tube or of an ovary of an ovarian cyst in conjunction with suspension has been recorded in 4 cases. In 4 cases myomectomy was performed for benign uterine tumors. The procedure was invariably removed in every case. When the abdomen was opened the uterus was found to have been previously removed. Seventy-eight cases showed disease of the appendix. There has been no mortality either from the disease or from the operation.

EDWARD L. CORNELL.

Kellogg, J. H. A Simple Method of Shortening the Round Ligaments of the Uterus for the Cure of Retroversion. *Med. Rec.* 96 l xvi 79

The method which the author describes has been used by him for more than twenty-seven years. He has employed it in more than 600 cases and many other surgeons also have used it extensively.

In this operation almost without exception curettage is required when the uterus has been long retroverted as a pathological condition of the endometrium is almost invariably present.

When the pelvic floor is greatly weakened, result

Fig. Skin incision (a-a)

Fig. Poupart's ligament

ing in rectocele or cystocele these conditions must be corrected by a plastic operation.

Before or after the curettage the uterus is carefully replaced by bimanual manipulation. Great care must be taken to see that both the uterus and the appendages are brought well forward. When released the uterus should remain in position. If it falls backward at once or settles down into a retroverted position adhesions are probably present.

When marked antelexion or retroflexion exists a stem pessary is introduced. A carefully fitted lever pessary is placed to support the fundus and to prevent all straining upon the ligaments. The pessaries are usually retained for two or three months while the intestines are becoming readjusted and the abdominal walls strengthened.

A separate incision is required for each ligament (Fig. 1) and it is important that the incision should be made at the right point. With the finger in the middle of Poupart's ligament the incision is started at a point about one centimeter nearer to the pubic spine and two centimeters internal to the ligament of Poupart.

After the skin has been incised, the remaining dissection is made entirely with the blunt hooks. The two points of the hooks are placed together in the center of the wound, pressed into the tissues and separated by drawing toward the angles of the wound. By lifting the angles of the wound with the hooks the wound is made to gape and the retractors are then introduced. First one then the

other this procedure is repeated a many times as may be necessary to reach the aponeurosis of the external oblique. When the aponeurosis first comes into sight it must be divided and drawn aside by the retractors in order to bring Poupart's ligament plainly into view.

Fixing a point along the ligament about one third the distance from the pubic spine to the anterior superior spine of the ilium one centimeter internal to this point a puncture is made through the roof of the inguinal canal with the blunt hook held in the left hand and the tendinous fibers of the aponeurosis are split for about one half centimeter and the other hook introduced with the point turned outward toward Poupart's ligament. The hook is dipped close beneath Poupart's ligament and whatever the hook engages is carefully pulled up (Fig. 2). If the ligament does not appear the hook is introduced again and made to explore the tissues one or two centimeters in each direction along Poupart's ligament. If the ligament is not discovered the hook is turned inward and an effort made to find it beneath the outer border of the internal oblique where it is sometimes found.

The round ligament may be recognized by the following factors: (1) It is a distinct structure. (2) It differs in color from other structures, looks white like a tendon although not quite so smooth and glistening as a tendon. (3) Over the surface of the ligament small tortuous veins may be seen which disappear when traction is made upon the ligament.

Fig. 3. Ligament fully drawn out and peritoneum stripped off.

Fig. 4. Ligament drawn out above the external ring.

and fill when the tension is relaxed. It should be noted that these veins are sometimes greatly enlarged and varicose. (4) The ligament is pulled out more easily than other structures. When, however, the nerve which comes with the ligament is caught with it by the hook, the ligament is held back somewhat but by separating or cutting the nerve the ligament may be very easily drawn up and does not snap back into the canal as do other tissues when released.

Failure to find the ligament may be due to several causes.

The ligament may be drawn down under the internal oblique to an unusual degree by long continuous and excessive strain.

In very stout persons the ligament may be buried in fat in the lower part of the canal.

3. The ligament is sometimes obscured by a mass of veins, due to a condition analogous to varicocele in men.

4. A more common cause of failure is incorrect placing of the incision or of the puncture through the roof of the inguinal canal. The ligament must be sought in exactly the right spot as above described. If the hook is introduced even one centimeter away from the proper point the ligament will be found only with much difficulty.

The ligament should always be sought at the outer border of the internal oblique and should be

drawn out from under the muscle instead of being pulled up through it.

5. The ligament is sometimes so slender that its recognition is very difficult. Small ligaments are most likely to be found in poorly developed women who have not borne children and in whom the uterus is retroverted to an extreme degree.

6. The ligament is sometimes so large that it is not readily caught by the hook and one is sometimes surprised after several minutes of fruitless search by the sudden appearance of a large strong ligament, fully half an inch or more in diameter.

7. The ligament is sometimes invested by fascia and fat and not so easily recognizable as in normal cases.

8. Anomalous conditions of the ligament are sometimes though very rarely found. In 1,603 cases the author has encountered conditions which may fairly be regarded as anomalous in not more than half a dozen instances.

9. Occasionally the ligaments are held back by adhesions, the result of pelvic cellulitis involving the round ligaments.

The ligament should not be seized with forceps. Traction is made while the pouch of peritoneum, which forms the canal of Nuck, and other tissues are separated and pushed back along the ligament with narrow-bladed forceps which are not released when the peritoneum is fully stripped back but remain attached as one pair after another is used.

As the peritoneum is stripped off the ligament may be pulled out more and more until finally so much resistance is felt that the uterus appears to be drawn up against the abdominal wall in the suprapubic region. The ligament will be seven to nine centimeters in length representing a shortening of fourteen to eighteen centimeters. No matter how slender the distal portion of the ligament may be the proximal portion at the point where it emerges from the canal will show a width of half a centimeter to three centimeters.

The ligament having been fully drawn out (Fig 3) the next step is to attach it at its thickest part to the aponeurosis of the external oblique at the upper angle of the puncture by means of a strong chromicized gut suture passed from beneath the aponeurosis. A ligature is now applied to the shreds of peritoneum held by the forceps. This closes the canal of Nuck and also ligates vessels which might be a source of trouble.

If the ligament is anchored in this position by attaching the loop of surplus ligament to the anterior surface of the external oblique muscle the patient may possibly sooner or later develop hernia as the small intestine will gradually work its way out alongside the round ligament. To obviate this danger the loop of ligament is drawn back into the canal and pulled up through the aponeurosis at a point five or six centimeters higher up and toward the median line. To accomplish this an aneurysm needle is passed into the canal along the inner side of the ligament and made to emerge at a point five or six centimeters higher up and two or three centimeters toward the median line. About an inch of the loop of ligament is passed through the silk loop and the ligament is drawn back into the canal and up through the aponeurosis. By this means all danger of hernia is eliminated (Fig 4).

The end of the loop of ligament is again drawn under the aponeurosis of the external oblique and made to emerge at the original opening through which it was first pulled out. Thus the surplus ligament is woven into the aponeurosis of the external oblique to which it in a few days becomes firmly attached forming a very secure and permanent anchorage for the ligament (Fig 5).

The next step is to close the opening in the roof of the canal. Care is taken to pass the suture through the end of the loop of ligament so that when the opening in the aponeurosis of the external oblique is closed the ligament is closely applied to the under side. The roof of the inguinal canal is thus reinforced instead of being weakened.

The superficial fascia is closed with No. 1 plain catgut and the edges of the skin incision are approximated by two or three skin clips.

The advantages claimed for this method of operation over other methods are:

1. The abdomen is not opened hence there is no risk and no risk of formation of peritoneal adhesions and no abnormal conditions created which might lead to intestinal obstruction.

Fig. 5. End of ligament drawn through inguinal opening into roof of canal.

2. The ligament is so secured that the recurrence of prolapse is almost impossible. In the original method of Alexander the ligament was cut off and attached to the fascia about the spine of the pubes. This method did not give secure anchorage and frequently resulted in complete failure because the ligament tore loose.

3. The ligament is not injured and no mutilation of any sort occurs so the patient cannot possibly be made worse as not infrequently occurs with several other methods.

4. The technique is simple and the operation may be quickly done. The time required is rarely more than fifteen minutes and often only ten or twelve minutes for both sides.

5. The small and superficial incision and the short time occupied by the operation give no occasion for shock.

6. The operation does not give rise to complications in pregnancy as do some other methods.

7. The results when the cases are properly selected are better than those obtained from other methods.

Conditions which contra-indicate shortening of the round ligaments by this method are:

1. Prolapsed uterus in which the ligaments are not strong enough to sustain the weight of the entire abdominal contents and a more radical procedure is necessary.

3. The absence of symptoms as in cases of retroversion of long standing in which the uterus is small and free from disease as often noted in women who have passed the menopause.

3. The presence of adhesions of the uterus, tubes, ovaries either to the pelvic walls or to other pelvic viscera, unless very slight.

The following suggestions are made as to the after care:

1. The patient should be kept in bed for in the lying position most of the time for a week or 10 days but may sit up some in a wheel chair and walk about some each day.

2. The lever pessary applied at the time of the operation is retained for three or four months.

3. A spring abdominal supporter is adjusted when the dressings are removed and must be worn constantly except at night until the abdominal muscles become strong enough to support the weight.

4. The bowels must be trained to move normally without straining. This should be accomplished before the operation.

5. The abdominal muscles must be developed to enable them to support the abdominal viscera in a normal way. This must be accomplished by systematic and carefully graduated exercises.

6. The constrictive and tight bands must be discarded definitely and permanently.

The patient must live the simple life, and must make the care of the health a matter of serious and constant concern. It is especially important that she should understand that the operation alone may not effect a permanent cure, but that with her thorough co-operation it makes permanent cure possible.

ADNEAL AND PERIUTERINE CONDITIONS

Rosenow, E. G., and Davis, C. H. The Bacteriology and Experimental Production of Ovaritis. *J. Am. Med. Ass.* 9:6161 75.

The authors record briefly the results of cultures made from the tissues and cystic fluid in a series of 64 ovaries removed at operation. The histories of a few illustrative cases and the results of animal experimentation made with some of the strains isolated are given.

Of 3 patients with acute tubo-ovarian abscesses, 2 showed pure cultures of streptococcus viridians in countless numbers in the involved tissues. The pus of one of these was sterile while the other showed a moderate number of the same streptococcus. The third case yielded gonococci in large numbers. In 10 cases the cultures remained permanently sterile. In the remaining 51 cases, in which the ovaries showed the usual fibrocystic degeneration, streptococci were isolated in 20, the number of the colonies ranging from one or relatively few usually in the depths of the ascorbic-dextrose agar to hundreds, and in a few instances to countless numbers. They were present in pure culture in 7 cases and

associated in the others with the Welch bacillus and a few staphylococci or colon bacilli. Welch bacilli were found in small numbers in 2 cases diptheroid-like bacilli in 10 a few colonies of staphylococcus albus in 9 the gonococcus in 2 the colon bacillus in 3 and an erobic atreptothrix in one.

The following facts support the view that the streptococci isolated from the chronic lesions when there was no history of a previous acute infection, as well as those causing acute infections of the ovary are carried to these structures by the blood more often than is generally believed.

The occurrence of fibrocystic degeneration of the ovaries in which the usual streptococcus was isolated in pure form in a young woman with an imperforate vagina.

2. The history of tonsillitis followed by symptoms of pelvic infection in a number of patients in the series.

3. The not uncommon occurrence of pelvic infection noted in gynecologic practice following angrinal attacks during the menstrual period.

4. The far more frequent occurrence of so-called idiopathic streptococcal peritonitis following angrinal attacks, in the female than the male which, according to Wilder who reviews the literature and reports a case in point is due to the occurrence of primary haematogenous ovaritis and a secondary peritonitis.

5. The absence of colon bacilli in all but three ovaries in this series, a fact contrary to expectations if local invasion occurred commonly.

6. The frequent concurrence of appendicitis, cholecystitis and arthritis in these patients, diseases proved to be due usually to streptococci from a distant focus of infection.

The occurrence of fibrous and cystic degeneration in the ovary secondary to acute infection is already well established. But as pointed out the cause of this condition without an acute infection had not previously been worked out. In this work the authors have isolated streptococci, often in pure culture, and demonstrated them in the tissues in the areas showing infiltration roughly in proportion to the amount of tissue reaction in a large proportion of the ovaries studied. Two of the strains isolated showed a marked affinity for the ovary in two species of animals—rabbit and dog—producing hemorrhage and leucocytic infiltration (precursors of sclerotic changes) in and surrounding the graafian follicles and in the ovarian tissuestroma containing interstitial cells in the fully developed corpus luteum in a pregnant rabbit.

Hence, the conclusion seems warranted that fibrocystic degeneration of the ovary even in the absence of previous acute infection is due commonly to a low grade haematogenous infection by streptococci having elective affinity for these structures. Owing to the fact however that the number of bacteria found is relatively small and that the experimental lesions in the ovary are not due to an overwhelming growth it is clear that while excretion

and resection of ovaries is indicated in some instances, it should no longer be done without due regard for the existence of chronic foci of infection which may serve not only as the place of entrance but also as the place for the bacteria to acquire the peculiar properties necessary to infect the ovary. There is little indication for the removal of this type of ovary with the idea that it may play the rôle of a secondary focus of infection yet the second case in the series indicates that at times is possible. The results suggest however that the early eradication of primary foci of infection in this type of patient might in some cases prevent the premature sclerotic degeneration of the ovary.

McGlinn J. A. The End Result of Resection of the Ovaries for Microcystic Disease. *Am J Obst & Gynec* 9:6 1913 435

From his own experience and that of other operators the author concludes that there is nothing to be gained by resecting the ovary which has undergone small cystic degeneration. He believes that resection tends to make the condition worse and either removes the more diseased ovary or simply punctures the cysts which are near the surface. The associated pathology in the pelvis must also be cleaned up. Following the operation the patients are treated to relieve pelvic congestion and if possible to prevent its future development. Five brief histories are given to show the futility of resecting the ovaries.

C. H. DAVIS

Llewellyn T. H. and Block F. B.: Hydrops Tubae Profusa. *J Am Med Ass* 9:6 1913 18

The patient was a very stout woman aged 33. She had been married for fourteen years, but had one child some years previous and no miscarriages. The menstrual periods were never regular. Every other month the flow was profuse while in the intervening month it was scanty. The previous history presented nothing of importance except that she had had her left tube removed four years before. She complained of throbbing pains in the sacral and right ovarian regions associated with a vaginal discharge. A short time before while stepping from the sidewalk to the street she felt a sharp stabbing pain in the right side and felt a sensation as though something burst. Immediately afterward a brownish discharge issued from the vagina and has continued to do so ever since.

At operation the left ovary was found to be transformed into a follicular cyst about the size of a peach the right tube was enlarged and contained fluid while the right ovary seemed to be in good condition. The operation consisted of a supra-inguinal hysterectomy, right salpingectomy, and left oophorectomy. On examination of the pathologic specimen after the operation was completed it was found that when gentle pressure was made on the tube there was a flow of clear watery fluid from the tubal ostium at the uterine

EDWARD L. COXELL

EXTERNAL GENITALIA

Salvador J.: A Case of External Genital Deformity in a Woman Due to Retardation in Morphologic Evolution. (*U. de Chile*) 1913 100

The author reports a case of external genital deformity in a woman aged 25 married four years and nullipara. Coitus has always been very painful. Examination has led her to be a well formed woman with a scrotal anal abnormality. In the first part of the urogenital tract with a part of the unruptured hymen with the normality. The vulva was that of nullipara. The vagina was short only 6 cm. There was no apparent hymen nor any hymenial sulcus. There was no external genitalia. The hymen is situated deeply within the scrotal canal and abnormally developed in the vaginal canal being behind it.

The immediate cause of the deformity was a retardation in morphologic development of the genitalia and not an interruption in the genital growth. The organ represents a fetal type with uterine aplasia. It is due to a pathologic interruption during embryonic life.

On account of this abnormal condition conjugal relation was impossible and sterility. Added to this had for the past two years been annoyed by an abundant mucopurulent leucorrhoea.

The treatment included a surgical and the author made a hymenotomy followed by a double colpoplasty with good results. However he is of the opinion that if pregnancy should result and go to term the structure of a portion of the vaginal canal would undoubtedly cause dystocia.

W. A. BRENNAN

Young E. B.: A Simple After Treatment for Perineal Wounds. *Bull Am Med Ass* 9:6 1913 65

The method at the Boston City Hospital has been used for nearly ten years and has been generally adopted for some time as the standard treatment. The aim is to maintain the greatest possible degree of cleanliness and dryness as under such conditions infection and irritation are least likely to occur.

After twenty-four hours when the bleeding has ceased the gauze perineal pad is omitted and the genitals and fissure between the buttocks kept liberally covered with a drying and antiseptic powder. For this purpose various mixtures have been used the best being the compound zinc oxide with boric acid. Results have been good with the stearate of zinc alone but rather better with the boric acid added as there is less tendency to decomposition of whatever discharge may come from the wound or elsewhere. The greatest living of

the stearate of zinc is that it sheds water and keeps the parts dry. In practice it has been found that mixtures of tereate of zinc and boric acid made by the physician are not so satisfactory as those prepared by the pharmaceutical firms.

The powder is best applied with the patient lying on the side the upper buttock being raised and the powder thrown into every fold. It is not sufficient to dust lightly or use the powder blower. The parts must be thickly covered, especially between the buttocks, and kept so throughout the healing. If the best results are to be obtained. Although the powder gradually becomes moist, it gives excellent protection to the skin, is mildly antiseptic, and sheds water to an amazing degree. With reasonable care it is usually possible to maintain a skin of dryness.

If, as occasionally happens, there is considerable tendency to moisture and maceration of the skin, the application of a 1 per cent aqueous solution of ichthol before dusting with the powder will be found effective.

The patient free from any dressing lies upon a small pad which collects any discharge from the vagina or elsewhere and can be changed whenever necessary. The genitals are carefully washed after urination and defecation and as often as may otherwise seem necessary.

The advantage claimed for this method of treatment are dryness of the parts and hence less tendency to irritation and infection. There is also no perineal dressing to increase perspiration, absorb discharges, and form a poultice.

MISCELLANEOUS

Barnes, F. M. J. Psychiatry and Gynecology
Surg. Gynec. & Obst. 9 6 1914, 579.

The origin of the belief in the causal relationship of genital to mental disorder, a review of the theories which have been advanced in explanation of the character of such relationship and an analysis of the data which has been presented in support of such theories are considered. Absolutely contradictory views have been held at different periods and the full gamut has been run from disavowal of complete oophorectomy in genitally normal females to no-operative treatment in females with demonstrable genital disease. Of the various theories which have been proposed the toxic and endocrine are today receiving the greatest attention.

The facts available do not warrant the assumption that diseases of the ovary or disorders of its internal secretion are in themselves responsible for the production of any psychoses. Statistics do not bear out the contention that gynecologic disease deserves the importance credited to it by some. The vast majority of mental cures reported have occurred in psychoses which were more or less acute and self-limited. Where operative indications exist, and it is now the consensus of opinion that these are

the same as the insane as the sane, the results obtained by operation have been considered apart from the possible effect of such measures as are instituted during the period of post-operative care.

Although the menstrual period is accompanied normally by a certain group of phenomena referable in part to alterations of function of the nervous system and although these are sometimes exaggerated in so-called nervous women, it has been shown that menstruation itself is the cause of a psychosis. The calm judgment of the majority both psychiatrists and gynecologists, tends at present strongly to the belief that cause of insanity is to be found in fetal genital disease or dysfunction and that gynecological treatment even where dictated by the gynecological condition, cannot be recommended as a cure for psychoses.

T. H. E. Hydridiform Mole. *La Presse Méd.*
9 6 1914, 339.

The above report of a case of hydridiform mole occurring in a primipara 2 years old. The last regular menstruation occurred July 7 and the usual early symptoms of pregnancy were noted. A light flow began in September and continued till the mole was expelled. In November the fundus was 10 to 12 breadths below the umbilicus, the cervix soft and the uterus had a decidedly boggy feel. On December 7 the mole was expelled. A fetus was found. There was no operative treatment but the patient is being kept under close observation on account of the possibility of deciduoma malignum following a case of vesicular mole. This point was emphasized in the discussion. The anomalous features of this case were that there had been no coagulative hemorrhage and no cysts had been expelled. It was further pointed out that normal pregnancy and labor can occur after the expulsion of such cysts. C. D. H. TUN.

Vignes, H. Experimental Researches on the Mechanism of Menstruation (Recherches sur le mécanisme de la menstruation). *J. d'obst.*
9 6 1914, 24.

From Vignes' experiments both *in vitro* and on living animals he finds that the ovum attracts to itself certain number of heterogeneous and auto-genous toxic substances. Certain of these substances are necessary for the development of the ovule. However the method of their production is not known.

In whatever way the phenomena of ovulation are produced, there is produced at the same time modification of the uterine mucosa which prepares it for nidation. If this is not effected menstrual hemorrhage is produced and this hemorrhage carries off at once all the reserves prepared for the early stages of development.

Menstruation is not only a cellular abortion, the abortion of an ovule, but it is a chemical abortion.

W. A. BREIDEN.

dation. He claims that it keeps the uterus well contracted and the muscular power of the fasciæ, and stimulates the breasts.

I conclude Bo did later that in private practice he has not applied forceps in two years. He gave a patient thirty small hypodermatic injections of pituitrin and delivered her safely without and without the aid of instruments. F. C. LEVINSKY

Fonyo J. Transperitoneal Suprasympphysal Cesarean Section on Account of Scariform Growth in the Vagina (Transperitonealer suprasympphysaler erhaltender Kaiserschchnitt wegen totaler narbiger Verwachsung der Vagina). *Zentralblatt f. Gynäk.* 9: 621 N. 4

The case reported occurred in a II para, 24 years old who after the first birth had suffered complete peritonitis for which she received no treatment. The vestibulum became almost entirely filled with dense hard, scarry connective tissue with resulting hamatometra. The woman however became pregnant again and the pregnancy proceeded to term. When labor was indicated the author having made several deep incisions (under narcosis) in the vagina with the episiotome stretched the vagina in order to afford means for escape of the lochia. Finally using this suprasympphysal cervical cesarean section was done and the child was delivered in good condition. The tubes were ligated. The case recovered normally. W. A. BRUNN

Adair F. L. Hemorrhage Associated with Partial and Complete Detachment of the Normally Implanted Placenta. *Am. J. Surg.* 9: 622, 54

Two clinical types are recognized, one with relatively concealed hemorrhage, the other in which the bleeding is absolutely concealed. So far as the etiology is concerned the author speaks of two groups, the mechanical and the toxic. In the former both intra and extra uterine trauma may produce the hemorrhage, in the latter any toxin which produces degenerative conditions in the maternal or fetal placenta may be responsible for the bleeding.

Certain milder forms are relatively important and cannot be diagnosed a parturient. In the more severe forms the symptoms to be kept in mind are pain, shock, and those manifestations associated with hemorrhage.

There may be diffuse distention of the uterus or this may be localized producing the so-called accessory tumor.

Mensuration may show progressively enlarging uterus.

The hemoglobin estimation may show increasingly severe anemia.

On of the main conditions to be differentiated is placenta previa. The chief differential point is the palpation of the placenta through the cervix uteri.

The objects to be accomplished by treatment are the maintenance of intra and extra uterine pressure throughout the early rapid, and complete evacuation.

It is the uterus through the parturient canal if the condition is favorable but if not cesarean section should be performed. There should be symptomatic treatment to combat the shock and anemia.

Wilson, A. M. Nitrogen Metabolism During Pregnancy. *Bull. J. Biol. Chem.* 11: 95

The nitrogen metabolism of three normal pregnancies was studied in one patient for a period of four weeks from the tenth to the fourteenth week of pregnancy. The other two patients were studied for the last 35 and 60 days of their respective pregnancies of short time in the puerperal period.

A fully liberal diet was allowed. Each article of food was weighed or measured before being given to the patient and ymorrhoidal excretion and gain weighed and measured. The patients were kept under normal conditions possible in regard to exercise.

The urine was collected for twenty-four hour periods and daily analyses made. From these daily analyses the daily average nitrogen content of the urine for periods of one week of time was estimated. Daily estimations of the ammonia nitrogen were made on all specimens and the amino-acid nitrogen was estimated for variable periods. The total nitrogen was determined by the Kjeldahl method, the ammonia by the method of Løwen, and the amino nitrogen by the Van Slyke method. The feces were preserved and analyzed weekly and from the results obtained, the daily average nitrogen content was calculated. The patient was weighed at frequent intervals.

All three patients were perfectly normal without nausea, vomiting or other gastro-intestinal disturbance.

The conclusions drawn were as follows:

1. In the perfectly normal pregnant woman at the beginning of pregnancy the nitrogen content of the body has hitherto been supposed possibly the organism may acquire the capacity for storing nitrogen from the very beginning of the pregnancy.

In the early months this storage is far in excess of the actual needs of the developing ovum, and this excess must be added to the general maternal organism.

2. Storage of nitrogen continues throughout the entire duration of pregnancy, being most marked during the last few weeks, when the fetal needs are at a maximum.

3. The nitrogen stored is greatly in excess of the actual needs of the developing ovum, so that apart from the amount needed for the hypertrophy and development of the genitalia and breasts, a large proportion of the nitrogen stored is added to the general maternal organism as reserve material, though concerning the form in which this reserve is stored it is impossible to make any positive statement. The nitrogen capital of the maternal organism

ism is thus increased though the reserve supply may possibly be entirely exhausted during the puerperium and period of lactation.

5 In the healthy woman who goes through a normal pregnancy the period of gestation does not necessarily represent a sacrifice of the individual for the sake of the species but may actually be a period of gain.

6 There is a relative increase in the percentage of urinary nitrogen excreted in the form of free amino-acids though not necessarily an absolute increase in this form of nitrogen.

7 There is also a tendency for the percentage of ammonia nitrogen to become increased during the last weeks of pregnancy although at other times during the pregnancy there is practically no variation from the percentages noted in non pregnant individuals upon a similar diet. D. H. B. YD.

Kohlmann W. Fibroids Complicating Pregnancy. S. A. M. J. 9:6 445.

In considering the treatment of fibroids complicating pregnancy Kohlmann classifies the cases as follows:

1 The first class includes probably the majority of cases which are without any clinical significance and do not interfere with either pregnancy or labor. The tumor may be discovered accidentally during an examination or post partum bleeding may lead to its discovery.

2 The second class includes cases in which the fibroid causes pronounced symptoms which may prove dangerous to the mother and fetus. In these cases enucleation of the tumor is advised.

3 The third class includes cases in which the location or size of the tumor or the associated displacement of the uterus make an expectant treatment extremely dangerous to mother and child. In some cases a delivery through the natural channel is impossible. In such cases pregnancy should be allowed to go to term but at the end of pregnancy or the beginning of labor radical treatment should be instituted. The operation of choice should be cesarean section with supravaginal (Forro's) or total hysterectomy.

4 The fourth class includes cases in which the progress of pregnancy would increase the suffering and even endanger the life of the patient while abortion would be very difficult and dangerous on account of the distorted uterine channel. Even after successful termination of one pregnancy there is danger of succeeding ones. In such cases the author advises total hysteromyomectomy of the gravid uterus or supravaginal as recommended by Landau.

L. K. COLEMAN

LABOR AND ITS COMPLICATIONS

Saltbury W.: Three Cases of Labor Obstructed by Ovarian Cyst. Proc. R. Soc. Med. 9:6 1. Ob. G. & S. 1.

A case seen late in pregnancy or early labor is most safely treated by cesarean section. Seen

late in labor—especially if the uterus be infected—the safer course is to turn the uterus out of the abdomen, remove the cyst, and deliver the child per *partu* *vivum* after closing the abdomen. The method of induction of labor late in pregnancy followed by water bathing until dilatation is complete, the delivery by forceps or craniotomy has a very favorable prognosis. The obstructive frequency of late in pregnancy rupture of the membranes, the uterine torsion, dilatation of the os, and the cystic rupture of the bladder, not having been performed. W. H. H. V.

PUERPERIUM AND ITS COMPLICATIONS

Huxley F. M. Fatal Rupture of the Bladder During the Puerperium. F. R. S. Med. (Ob. G. & S.) 4.

A primipara delivered by forceps per *partu* *vivum* at 9 P. M. on the 11th day of the pregnancy. On the 12th day the patient was attacked with severe abdominal pain, micturition, and loss of control of the bladder. The urine was free in the bladder, the bladder was not enlarged, and the patient was not in pain. The rupture of the bladder was probably due to pressure during delivery on the distended bladder. The pressure produced an avulsion of the bladder musculature so that the patient was unable to void. The abdominal contraction at the time of micturition was sufficient to produce the rupture. W. H. H. V.

Porritt N. The Treatment of Puerperal Septicæ by Uterine Suction and Drainage. B. J. O. G. & S. 10.

The uterine tube has all the advantage with none of the danger of the uterine tube. In at least two cases the author has seen the uterine tube, or a part of it, protrude into the vagina rapidly fatal general infection while in another case it set up an acute purulent chorioamnionitis.

Three cases are reported in which the uterine contents are removed. The following instruments were used:

A glass Budin catheter to which the inlet end of a Higginson's syringe was attached. The syringe was passed into the uterus. To secure the syringe to the Budin catheter the inlet valve was removed. The tube of the syringe between the bulb and the catheter was held firmly and the bulb squeezed so as to drive out the retained air through the nozzle. On releasing the pressure on the bulb, the valve behind the nozzle closed and prevented the return of the air. There was then a vacuum in the syringe and on releasing the pressure on the tube between the bulb and the Budin catheter, suction was exercised through the catheter within the uterus. No air was drawn into the uterus although the suction drew into the orifices of the catheter thick grumous semipurulent masses which were too large to pass through and with the catheter

was withdrawn, came with it. Reintroduction of the catheter and suction drew out more of these thick pieces.

Uterine suction discloses the condition in the interior of the uterus. It is most instructive to watch the gradual alteration of the matter with drawn from a thick, offensive fluid, loaded with semisolid purulent masses, to a clear red liquid and from that to an inoffensive mucus. Moreover it prevents the physician from being misled by the deceptive character of the discharge found upon the pad. The pad may be covered with discharge which may be only an overflow or may not come from the penthouse in the uterus at all, for there may be odorless discharge on the pad and a profuse fluid in the uterus. Efficient drainage of the uterus is the key to successful treatment of puerperal sepsis.

Two of the three cases reported recovered.

EDWARD L. CORNELL.

Mitchell, A. G. The Duration of the Nursing Period in Women of the United States. *J. Am. M. Ass.* 9, 6, 1911, 600.

An analysis is presented of almost 3,000 cases taken from the records of the Children's Hospital Philadelphia, during the last fifteen years. As it was the desire to determine, as far as possible, the ability of the mother to nurse her cases were excluded. It was the duration of the physiologic period of lactation, apart from disease or deliberate act of the mother which was the problem to be solved. Thus when the records showed that the mother stopped nursing from some such cause as going to work, or lactation was terminated by an acute infection or mammary abscess, the case was not included.

It may certainly be stated, however, that the statistics to be presented show with reasonable accuracy the length of breast feeding in the hospital class of Philadelphia women. These women are of different nationalities, including Italian, German, Russian, Armenian, Irish, and others. Many of them are native born Americans and a fairly large percentage consist of Jewish and colored women.

From the beginning of 1900 to the end of 1903 there were 734 cases in which the average length of lactation was 5.92 months. From the beginning of 1905 to the end of 1909 there were 87 cases with an average of 6.36 months. From the beginning of 1911 to the end of 1914 there were 58 cases with an average of 5.76 months, therefore of a total of 879 cases during the fifteen years, the average length of lactation was 6 months.

If it is borne in mind that this is a study of the statements of the poorer class of city women, the following conclusions may be justly drawn.

There has been no decline in breast feeding in the last 5 years.

The women of the poorer class compare favorably in the period of lactation with the women of the more prosperous class in this country.

3 The women of this country compare favorably to the period of lactation with European women.

4 The average period of lactation in children entered at the hospital was 6 months.

5 Twenty per cent of the women did not nurse their children. 80 per cent nursed a week or longer. 55 per cent nursed three months or longer. 42 per cent nursed six months or longer. 34 per cent nursed nine months or longer. 2 per cent nursed a year or longer. 9 per cent nursed eighteen months or longer and 6 per cent nursed 19 years.

6 For the reason that artificially fed babies are more susceptible to gastro-intestinal and nutritional disturbance the infants brought to the hospital were in the large majority of cases bottle fed at the time of their entrance there. This conclusion is inevitable that the figures given represent the minimum of lactation.

Table II was a study of the statements of 819 mothers when questioned regarding the length of time their children were breast fed.

Period of Breast Feeding in Months	1900-1904 Per Cent	1905-1909 Per Cent	1910-1914 Per Cent	1915-1919 Per Cent
Not breast fed	20	14.1	17.3	29

Gentili A. Histochemical Research Regarding the Function of the Decidua (Indagini istochimiche riguardanti la funzione della decidua).

A. d. ostet. ginec. 9, 6, XVIII, 8.

As the results of his researches on human and animal decidua Gentili finds that the decidual cells possess an essential function in the elaboration of lipid substances belonging to the group of phospholipids.

The lipoid function is in clear and precise correlation with the cellular vitality. If these elements are defective either there is lack of lipid production or it passes into true fatty degeneration. The disposition of lipoids among the protoplasm and the presence of granules of this substance in the intercellular spaces indicate the method of elimination followed by the lipoids.

W. A. BRENNAN

Ireato D: Analgesics in Parturition Clinical and Experimental Contribution (Los analgesicos en el parto contribucion clinica y experimental) Rev Med Argent 9 6 xu 93

The author has carried out extensive clinical investigations on parturient women supplemented by animal experiments in an endeavor to determine the action of morphia, pantopon, hydrate of chloral, etc., on the physiological progress of parturition.

Hysterographic methods were formerly employed but the older apparatus in which the uterine movements were transmitted from within the uterus have been discarded in favor of external hysterography, the movements being transmitted from the abdominal wall in the region of the uterine fundus and beyond the influence of respiratory action. The transmitted movements are registered on a revolving drum.

The results as summed up by the author are as follows:

1 The toxic dose of morphia for guinea pigs may be taken as 0.005 gr per gram weight of the animal.

2 Hypophysary solutions do not disintoxicate morphia.

3 Maltose ferments not only do not disintoxicate morphia but appear to increase its toxic power in animals.

4 The physiologic action of analgesics and parto-analgesics upon the arterial pressure and the uterus is equal to that of morphia.

5 The union of large doses of morphia to small doses of hypophysary extract annuls the oxytocic action.

6 Solutions of malt ferments have an oxytocic action although more ephemeral than those of the hypophysis.

The general opinion that pain and efforts are factors which are opposed to morphia intoxication is without foundation. The properties of morphia injected during pregnancy may be transferred without modification on to the fetal circulation. Sensibility to the toxic action of morphia is greater in the infant. Personal susceptibility toward morphia varies greatly with the subject. In 40 per cent of the cases there was not sufficient sedation of the labor pains to justify the use of large doses of morphia.

7 Products with a morphia base destined to produce analgesia are constant in their action and inject a few such substances during the expulsion period have little effect; moreover their administration in cases of obstetrical intervention is not only useless but prejudicial.

8 Derratives of opium like all analgesics do not lessen the pains of labor but alter the uterine rhythm because they diminish the number and intensity of the contractions. Compositions with a morphia base may intoxicate without lessening labor pains.

10 Generally the dilatation and expulsion periods are prolonged in analgesic parturition. The duration of labor may be 48 hours in multiparae and 24 hours in primiparae. Artificial rupture of the membranes must be resorted to more frequently in analgesic women likewise with obstetrical intervention.

11 Opium derivatives used in analgesic parturition vary in degree of effect on the tissues and muscles of the larynx. Chloroform is the best. It is the method of inducing an anesthetic analgesia in parturition and should be used in preference to all others.

Regnault J: Choice of an Anesthetic and General Anesthetic in Surgery and in Obstetrics. J

ho dun 3 th 1 t 1 an lg m 1
m d 1 l 5

Regnault discusses the use of chloroform, chloroform for which he finds that analgesia appears before complete loss of consciousness, nitrous oxide in the half-conscious state, more or less, the diminution of the larger the larynx, all an open rapid anesthesia almost always without a considerable diminution of the quantity of chloroform necessary to maintain anesthesia, rapid awakening and habitual absence of vomiting.

Walker J: The Technique at the Jewish Maternity Hospital and Its Results. J Med N Y

9 1 xu 4

The author outlines the general management of patients at the Jewish Maternity Hospital and states that they have found the following rules necessary to good result:

1 All deliveries shall be conducted on the same basis as a surgical operation, sterile draping of the patient and proper preparation, proper cleansing of the operator's hands and the use of a steril gown and gloves.

2 Making the smallest number of vaginal examinations, limiting oneself to one or two and depending a good deal on external palpation for general information and the use of rectal examination for definite information.

3 By allowing the patient to have the proper rest of labor and eliminating meddling obstetricals.

4 The careful watching of the fetal heart sounds and uterine contraction by an intelligent nurse thus saving children which otherwise would be stillborn.

5 The more restricted use of pituitrin to cases in which full induction is not.

6 All cases showing a temperature above 99.3 should be regarded as suspicious and be isolated until proved otherwise.

GENITO-URINARY SURGERY

ADRENAL, KIDNEY AND URETER

Shannon, W. R. Experimental Cloudy Swelling of the Kidney in the Rabbit. *J. Lab. & Clin. Med.* 9, 6, 1, 54

Shannon defines Virchow's cloudy swelling (*trübe Schwellung* 1838) of the kidney and quotes the opinion of others regarding albuminous granules and darkened tubuli.

Claiming that turbidity and swelling of an organ are not always associated with increase of albuminous granules, yet on the other hand, there may be a marked increase of albuminous granules in the cells without the presence of turbidity or swelling, an experimental study on rabbits was undertaken.

1. In the first experiment compensatory circulatory increase was produced by unilateral nephrectomy or ureteral ligation with removal of the other kidney in forty-eight hours.

In the second experiment chemical irritants (tartrates) were injected subcutaneously and the kidneys were removed twenty-eight hours thereafter.

In the third experiment, autolyzed liver solution was injected intraperitoneally. In eighteen hours one kidney was removed, the other was removed after the death of the animal.

In the fourth experiment infection was produced by injecting cultures from *Pasteurella shoenleae*. The kidneys were removed from the rabbits during the different stages of infection, thus getting the different degrees of the cloudy swelling.

The summary of the findings are as follows:

1. The normal rabbit kidney always contains, in the convoluted tubules, coarse albuminous granules. Usually these granules are so numerous in few tubules that they appear dark in the fresh tissue. The granules are apparently thin-walled vesicles filled with fluid. They are best fixed by solutions containing formalin. They are not fixed in solutions containing acetic acid.

2. When one kidney is removed the dark tubules are increased in the opposite kidney during the first twenty-four or forty-eight hours, but the increase of albuminous granules is not sufficient to cause any definite change in the gross appearance of the kidney.

3. Subcutaneous injections of tartrates produce swollen, cloudy kidney but there is no increase of albuminous granules. The cloudiness and swelling are apparently due to edema, anemia, tissue disintegration, etc.

4. Intraperitoneal injections of autolyzed liver tissue produce a markedly cloudy and swollen kidney. The albuminous granules disappear en-

tirely. The gross changes are apparently due to the same factors concerned in the tartrate experiments.

5. Chronic suppurative processes attended with marked emaciation cause an enormous increase of albuminous granules in the kidneys. These granules are often larger than the normal and irregular in shape but they seem to have the same chemical composition.

6. Acute toxemia causes rapid disappearance of normal albuminous granules.

7. A subacute toxemia superimposed upon a chronic suppurative process causes disappearance of the albuminous granules.

8. Kidneys which show an enormous increase of albuminous granules usually give normal phythalein output and the cells are usually intact. This form of cloudy swelling is therefore probably not degenerative change but a physiological response to an increase of proteid waste product in the blood.

9. There is relation between the formation of albuminous granules and fatty metamorphosis.

It is suggested that the term cloudy swelling be discarded and that the several processes producing this appearance be considered separately.

C. E. BARNETT

Newman, D. Pyuria, Symptoms; Its Causes and Diagnosis. *Glasgow M. J.* 9, 6, 1907, 6

Pyuria is a symptom of many different lesions. Pus may emanate from any point of the urinary tract from the kidney to the urethral meatus. In every case of pyuria the important factors to determine are the nature of the infection, the location of the lesion, and the extent of harm which has resulted from the invasion.

To discover the presence of pus in the urine is important but to trace the cause and recognize the particular lesion producing the pyuria is necessary before any intelligent and effective treatment can be undertaken. Pyuria is nearly always due to bacterial infection. In some cases the organisms are abundant and easily found and cultivated, in others, e.g. tuberculosis and gonococcal infection they may be hard to find and difficult or impossible to cultivate. All so-called sterile pyurias are indicative of quiescent tuberculosis.

The reaction has been considered a guide to the place from which pus comes, acidity pointing to renal and alkalinity to vesical origin. There is no foundation for this widespread belief. The reaction in these cases depends upon the organisms present. The organisms associated with acid pyuria are bacillus coli, tubercle bacillus, streptococcus

pyogenes pneumococcus bacillus typhosus and pyogenic cocci. The organisms which decompose urea and which therefore are found in alkaline urine are staphylococcus pyogenes aureus and albus gonococcus and bacillus proteus. In general it may be said that of all infections of the urinary tract in one third of the cases the reaction is alkaline and in two-thirds acid.

Following a brief discussion of the subject the author states that as a result of experimental inquiry the following assertions may be made:

1. Simple retention of the urine does not give rise to septic inflammation.

2. Small cultures of pyogenic micro-organisms such as staphylococcus pyogenes aureus staphylococcus pyogenes albus tubercle bacillus or bacillus coli communis when introduced into a healthy bladder fail to produce sepsis.

3. If the mucous membrane of the bladder be injured or diseased prior to the introduction of micro-organisms sepsis immediately occurs.

4. If the artificial retention of the urine is induced from six to twenty hours after the introduction of a septic organism into the bladder suppurative inflammation of the mucous membrane follows.

The avenues of invasion are by the blood, the lymphatics along the lumina of the excretor ducts and by continuity and through wounds.

The septic renal diseases are classified as follows:

1. Purulent embolic nephritis a descending septic and suppurative lesion of the kidney without pre-existing disease of the conducting and collecting portions of the urinary tract the septic virus being conveyed to the kidney by the blood.

2. Turulent interstitial nephritis an ascending interstitial nephritis infection being by the lymphatics from a primary septic focus in the lower urinary passages.

3. Acute septic nephritis without suppuration an ascending septic lesion of the kidney without suppuration the virus being carried to the kidney (most commonly to theortex) by the lymphatics.

4. Pyelonephritis suppurative nephritis with the antecedent septic diseases of the pelvis the secondary foci in the parenchyma of the kidney being always due to direct contamination through the uniferous tubules and lymphatics.

5. Pyelitis suppurative disease of the mucous membrane of the pelvis without distention of the cavity.

6. Hyonephrosis accumulation of pus or of purulent urine in the pelvis of the kidney the accumulation being a result of mechanical obstruction with atrophy of the renal tissue but with uterine secondary infective foci or independent accumulations of pus in the parenchyma of the organ.

In inflammation of the bladder the two most frequent sources of infection are the intestines and the urethra. Three modes of infection are enumerated.

Ascending infection by way of the urethra which for obvious reasons is more common in

women than in men is the simplest in general and colon bacillus infection.

2. Descending infection is the most common in men in which the organisms are introduced from a primary focus in the intestine by the blood and are excreted through the kidney. The highest number of cases is in typhoid fever and in malaria.

In addition to determining the presence of the urine the clinical manifestations of the urinary tract are of great importance. The following is a list of the most common symptoms.

In the majority of cases the first manifestation is the presence of pus in the urine. This is usually accompanied by a change in the color of the urine and by a change in the odor.

In all of the preceding cases the inflammation is in the form of a suppurative process. The symptoms are those of a suppurative process. The first symptom is the presence of pus in the urine. This is usually accompanied by a change in the color of the urine and by a change in the odor.

In case of marked pyuria the urine is turbid and contains many pus cells. The urine is usually accompanied by a change in the color of the urine and by a change in the odor.

The author states that in the case of the interstitial nephritis the urine is usually accompanied by a change in the color of the urine and by a change in the odor. The urine is usually accompanied by a change in the color of the urine and by a change in the odor.

1. Albuminuria entirely due to pus in the urine.
2. Interstitial nephritis from the kidney from the lower urinary tract.
3. Interstitial nephritis from the kidney due to Bright's disease or to a calculous cause.

Webster J. C. Some Observations on Pyelitis in Pregnancy. *Urologic Review*, 1904, 4.

The author does not believe that pregnant women are more prone to pyelitis than those who have never been pregnant.

The following is a list of the most common symptoms of pyelitis in pregnancy.

1. The disease usually begins between the fifth and eighth months of gestation.

2. The colon bacillus is the most frequent cause. The following are the most common symptoms.

3. In a majority of cases the disease occurs on the right side though it may be bilateral or limited to the left side.

Various speculations are advanced regarding the special influences exerted by pregnancy in causing pyelitis. Although it is possible for the pregnant uterus to so mould itself as to exert direct pressure on the ureters, we have absolutely no exact knowledge as to the frequency or the degree of obstruction to the flow of urine in the ureters.

Dilatation of the ureters and renal pelvis may be found in pregnant women at autopsy or operation but this condition may have existed prior to pregnancy. Interference with the ureters such as is produced by pelvic tumors is comparatively rarely associated with pyelitis. Moreover in a very considerable percentage of cases of hydro-ureter pyelitis is found. In those cases in which there is the greatest intra-abdominal pressure e.g. primiparity, hydramnion, twin pregnancy, tumors and pregnancy there is no greater tendency to pyelitis than in other gestation cases.

As to the greater frequency of right-sided pyelitis without ureteral catheterization no one is competent to judge whether one or both sides are affected as pain on one side only is no proof that the other side may not be affected. Nor does the pressure of the iliac vessels explain it. Dextroversion or dextrotorsion hardly explain it either for unless there is a very lax abdominal wall no appreciable movement of the pregnant uterus in advanced pregnancy can take place, and then it tends to fall forward when the woman is erect.

The greater mobility of the right kidney in non-pregnant women which leads to dilatation of the renal pelvis may cause the development of pyelitis by micro-organisms. Colon bacilli are the most common organisms found in pyelitis. As to the mode of entrance of the organism the following views are held:

From the vulva through the urethra, bladder and ureter probably rare.

Lymphatic extension from infected bladder. This is difficult to prove and must be rare.

3. The most common source is undoubtedly the large intestine, either by direct lymphatic extension or by the blood stream.

4. Distant focal infections especially those due to streptococci and staphylococci may cause pyelitis by blood transmission though definite proof has not been established.

The symptoms and signs of the disease are the same as in non-pregnant women. In some cases the patient may complain only of malaise and slight fever without pain. The fever may be high and may be accompanied by chills. There is often aching in the loins. Frequently attention is first called to a pain in the affected side accompanied by fever, nausea, vomiting. In some cases there is frequency of urination. Rarely is there actual bladder distress except where the viscous is involved. Right sided pyelitis may simulate appendicitis or

even gall-bladder disease, and serious mistakes in diagnosis may be avoided if this is borne in mind.

As to treatment Rest, bed, soft non-irritating diet, free fluids and urinary antiseptics are most widely employed and will suffice for a large percentage of cases. Autogenous culture has been disappointing. Irrigation of the kidney pelvis through the cystoscope has also been unsatisfactory.

C. C. O'CROWLEY

Smith E. O. Diagnosis and Treatment of Renal Tuberculosis. *Brit. Med. J.* 1906, 3, 7

The cystoscope has demonstrated that urinary tuberculosis is usually a primary kidney lesion. It is found in 4 per cent of the topicals, and about 20 per cent of all autopsies made on subjects that die from tuberculosis in other organs. The military form is usually found in children and young adults, while the caseous chronic varieties are more common in later life.

The route of entry is by the arterial blood stream. Infection by way of the ureter where the bacilli would have to travel against the stream and by way of the lymphatics—there are several lymph-vessels to the kidney—is generally discarded. A normal kidney will excrete tubercle bacilli but in the presence of a pathological condition of either kidney or ureter tuberculosis focus may originate with serious result.

Some writers believe that the glomerulus is the site of onset while Widdows and Weylin found the papillae the most common point. Several of the author's cases showed destruction in the pyramidal areas having apparently advanced from the papillae and calyces. Only a small area may be involved the remainder functioning but the entire organ may be broken down, forming a pocket of pus and necrotic tissue. There is usually mixed infection.

The symptoms are indefinite and cover a long period of time. Bladder symptoms are first. Frequency and pain during urination increase in direct proportion to the length of time involved. Pain in the lumbar region, unless the ureter is partially or completely blocked the palpation of a mass, pyuria, hæmaturia, and the presence of tubercle bacilli easily found indicate an advanced condition. The onset as insidious. Intermittent hæmaturia and acid urine on taking pus should be closely investigated. Guinea-pig inoculation is valuable but it takes time. Diagnosis is made by finding tubercle bacilli in the catheterized kidney urine. Repeated examinations are usually necessary. The various general tests are not of much value in localizing focus.

When one kidney is involved complete removal is indicated. The ureter should be thoroughly cauterized to prevent infection of the surrounding tissue. The instillation of 1 per cent iodoform in liquid alcohol or venereal irrigations of bichloride 1:3000 to 1:5000 will in time relieve the bladder inflammation and symptoms.

1. In conclusion the following point are emphasized
2. Frequent persistent micturition is often the earliest symptom of renal tuberculosis
3. Intermittent renal hemorrhage is frequently of tuberculous origin
4. Acid urine containing pus cells which do not culture out bacterial colonies is usually due to renal tuberculosis
5. Many cases require repeated examinations for tubercle bacilli even before stating a tuberculous reaction to establish a diagnosis

The earlier nephrectomy is done the better it is for the patient (C. D. PRAPPELL)

Macht D. I. The Pharmacology of the Ureter. Action of Drugs Affecting the Sacral Autonomics. *J. Pharm. & Exp. Med.* 1910, 19

Macht has added materially to our knowledge as to the action of certain drugs on the ureter. As a result of his original investigations he reaches the following conclusions:

1. Pilocarpine physostigmine muscarine pseud muscarine and choline in suitable doses all stimulate the rate and force of the ureteral contractions and increase the tonus of the excised ureter. Large doses of pilocarpine may however secondarily paralyze that organ
2. The pressor action of pilocarpine physostigmine and muscarine is not inhibited by previous exhibition of ergotamine
3. Atropine in sufficient rather large doses inhibit the contractions and decreases the tonus of the ureter. Small doses of atropine may produce though not invariably a primary stimulation of the ureteral contractions
4. The same effect as in the ureteral preparations described by the author were noted in rabbits by observing the ureters *in situ* after administration of pilocarpine physostigmine and atropine
5. The behavior of the ureter toward the drug studied gives pharmacological proof of its innervation by the autonomic nervous system of practical interest (H. W. L. WILSON)

Simon A. R. and Vertz, H. O. The Supernumerary Ureter. Report of a Case of Complete Unilateral Duplication. *J. Am. M. A.* 1910, 55

The authors report a case of supernumerary ureter on the right side. The three ureters all opened in the bladder without any anastomoses between them. The extra large right opening often gives the appearance of being a division of the ureter. The trigone of the bladder showed that the right kidney had its separate pelvis and excretory system revealed that it related posteriorly to the ureter on that side. The two opened just below the internal bladder.

Complete bilateral duplication of the ureter is rare but supernumerary ureter is not infrequently met. The most common anatomical

double pelvis and ureter with the ureters uniting below the bladder.

The supernumerary ureter is governed by the local nerves. It has opening in the bladder. It is not infrequently associated with a large renal pelvis and has a pyramidal shape. It is often found in the lower part of the bladder. It is not infrequently associated with a large renal pelvis and has a pyramidal shape. It is often found in the lower part of the bladder.

A supernumerary ureter is not infrequently associated with a large renal pelvis and has a pyramidal shape. It is often found in the lower part of the bladder. It is not infrequently associated with a large renal pelvis and has a pyramidal shape. It is often found in the lower part of the bladder.

SURGERY OF THE EYE AND EAR

EYE

Argonzaraz, R. Contribution to the Study of Intra-ocular Cancer—Sarcoma of the Choroid (Contribucion al estudio del cancer intra-ocular sarcoma coroidal) *Rev. Asoc. med. Argent.* 9 6 xii 75

In the ophthalmological service of the National Hospital of the Argentine Republic, out of 84,000 patients, 3 cases ofveal sarcoma were found, a percentage of 0.3 per cent. The statistical table given by Powell gives for the various large ophthalmological clinics of the world the percentages for choroid sarcoma varying from 0.03 to 0.1 per cent. It occurs as a general rule more frequently in men than in women and in the ages between 45 and 65.

Of the 3 cases referred to by the author, 2 were in the ciliary body and 1 in the choroid. In 5 cases exact location was not possible on account of the condition. The statistics of Sattler, from Leipzig, shows 82 per cent as choroid tumors and 8 per cent as ciliary body tumors.

With regard to the treatment it is essentially surgical, either extirpation of the tumor with preservation of the ocular globe or enucleation or exenteration.

Extirpation with preservation of the globe is usually accomplished by indirect myotomy. The procedure is usually unsatisfactory as most of the interventions recur. Enucleation is the method of election in all cases of neoplasms of the uveal tract to place the patient beyond the chance of recurrence, and intervention should be as early as possible.

When neoplastic nodules show the superficiality of the ocular globe, enucleation ought not to be considered as absolutely indicated and in such cases it will be prudent to proceed with extirpation of the orbit. Metastases of the internal organs contraindicate any operative intervention.

W. A. BREWER

Jacobs and Duclos. Ocular Tuberculosis Secondary to an Industrial Accident; Clinical and Anatomical Study (Tuberculose oculaire secondaire un accident de travail; étude clinique et anatomique) *Cl. Méd. Par.* 9 6, 37

This case reported occurred in a boy of 5 who in November 1905 was struck in the right eye by a piece of iron. The resulting ulcer was treated with iodine and the boy recovered but a pronounced perkeratic injection and an intense photophobia persisted. By December whitish spots appeared in the cornea, the cornea was transparent, except where these spots occurred lat on yellowish

granulations covered the whole surface of the iris. The eye became hypotonous without any evidences of pain.

The clinical evidence, aspect of the lesions, and complete absence of pain suggested tuberculosis and the subsequent histological examination confirmed it. The authors think that there are two theories to account for the pathogenesis. Direct inoculation through the wound or localization of the organ of tuberculosis already existing in the organism. It is very difficult to choose between the two theories.

The eye was enucleated. Histological examinations were made from different sections and these are given in detail. The authors found from these examinations that small tubercle follicles existed in the cornea that there was passage of granulation tissue into the ciliary body and the base of the retina that following the general rule lesions of tuberculosis and ocularis remained in the territory of the posterior ciliary circuit that the structure had the same aspect described by other authors, i.e. in the transition from there were epithelial tubercle lymphocytes and ureol in the posterior parts was diffuse granulation composition (parenchymatous tubercles). W. A. BREWER

Huguenin, M. Traumatic Rupture of the Ciliary Arteries (Rupture traumatique des artères ciliaries) *Cl. Méd. Par.* 9 6, 8

Siegrist. Vogt described the first case of traumatic rupture of the ciliary arteries and the fundus lateration habits were necrotic. These cases are very rare. Besides Siegrist, 4 published cases the author has found only 5 more in the literature. He adds more of his own personal cases and notes from Siegrist, practice a summary is given of these cases also bibliography. The treatment is directed generally in these cases either subconjunctival injections or cauterization of the sclerotic does not usually effect very great improvement in the double with vasoconstrictors.

W. A. BREWER

Fernandez, J. Digital Compression of the Lacrymal Sac in Dacryocystitis of the Newborn. Especially La compression digital del saco lagrimal en la dacriocistitis del recién nacido especialmente) *Rev. d. med.* 9 6, 4

The author details on the value of massage of the sac in congenital dacryocystitis, applied continuously and by digital pressure, this being the simplest method of procedure.

Fully satisfactory results were obtained in the newborn as in the adult. The compression

of the lacrimal sac requires manual lexterity especially in cases of inflammations or redness in the proximity of the sac. In mono-ocular affections it is best to search for the rest of the lacrimal bone and press upon it immediately whereupon the lacrimal sac will move from that place in the fossa.

To determine the permeability of the nasal canal the author instills a drop of fluor-scin solution. He believes in Berard's teaching that by compression of the sac and antiseptic injections in those lacrimal parts previously dilated one can properly treat and cure a case of dacryocystitis. As to catheterization of the nasal canal the author considers it improper treatment; he quotes Hippel's statement that the sounding of the nasal canal is not easy or offensive and the inexperienced will make false moves which will give rise to new cicatrices.

The author describes the case of a babe 55 days old, in whom he noticed on the fifteenth day of life a dacryocystitis and an encephaloid tumor both of which responded equally well to compression practiced continually for several months when the two conditions disappeared entirely.

He considers it unnecessary to recall that in the diagnosis of a dacryocystitis in general the first thing to do is to ascertain whether the nasal canal is more or less free so that when the dacryocystitis is relieved the tears will flow their normal course.

Another case is described of a woman suffering for two years with a subacute dacryocystitis in which compression and lavage of the sac brought about a complete cure. A year after however the patient having discontinued washing the sac from time to time had another inflammation of the sac. Besides the employment of compression the inferior lacrimal point was dilated to facilitate the egress of all accumulations in the sac.

The author considers digital compression very valuable as the initial treatment in general dacryocystitis. When the condition is so acute and painful as to prohibit its use he advises applications of ice and abstention from making any incisions to avoid cicatrices upon the skin of the eyelids.

R. O. L. VI. 18.

Posey W. C. Tenotomy of the Inferior Oblique Muscle. *1896 Opht. 6: 13*

Duane is quoted as giving as indications for the operation any deviation due either to actual over-

action (spasm) of the inferior oblique muscle whether primary or secondary relaxation in which with no actual involvement of the inferior oblique the diplopia and symptoms are such as would be produced by spasm of that muscle.

The condition usually simulating spasm of the inferior oblique is paralysis of the superior rectus and the conditions are given causing true spasm or overaction of the inferior oblique: (1) paralysis of other muscles (2) paralysis of the superior rectus which along with the same cause secondary spasm of the inferior oblique of the fellow eye (3) paralysis of the superior rectus or some other depressor muscle with secondary spasm of the inferior oblique (4) the same as (3) paralysis of the abducens with compensatory innervation of the inferior oblique with spasm.

Primary spasm of the inferior oblique is rare.

The author has operated upon a child with the following results: (1) effect in all.

The patient is now able to read and is just upon the parallel of the level of the normal rim of the orbit through the muscle and is located with the trismus which is now forward and level with the cornea.

It is recommended in children who have squinted from birth that operation be postponed until long after the period of ten years at which time the child is more amenable to the operation and the muscular deviation negligible and operation is avoided.

S. S. H. W.

EAR

Good R. H. Acute Otitis Media. *III 11 J 96 133*

A brief review is given of the etiology, symptoms, differential diagnosis and treatment prophylactic local and general of acute otitis media with the object of urging the general practitioner to make an early diagnosis and avoid unfortunate complications.

The author insists upon the necessity of early diagnosis before the drum membrane ruptures and serious pathological changes have taken place in the tympanum. He advises early incision of the drum membrane by an otologist under aseptic conditions and early operation in cases where mastoid symptoms supervene together with proper general medical treatment. *1895 J. P. Peters*

SURGERY OF THE NOSE, THROAT, AND MOUTH

NOSE

Lansier L. H. Importance of Treatment of Diseases of the Accessory Sinuses of the Nose. *J. A. M. A.* 1911, Sec. 9, 6, vol. 278

In catarrhus and ethmoiditis, the thor has had favorable results with the following medication. The nasal cavities are first irrigated freely with mild alkaline antiseptic solution. The inflamed and swollen membranes are treated with a 4 per cent cocaine solution applied by means of a cotton wound probe. This is followed after five minutes by the application of a 1 per cent dilute pyril solution prolonging local anæmia produced by the cocaine. Benzoin vapor is then applied. Bishop's coryza ointment and an acetanilide compound are prescribed to be taken alternately as indicated. An ointment of bismuth and dresalin is also given, to be applied to the nasal cavities three times daily.

Where the above is not sufficient, intranasal operation consisting of removal of the anterior end of the middle turbinate and curveting the ethmoidal labyrinth is employed. After the operation is completed, the cavity is packed with half inch strip of terrilled gauze saturated with sterilized benzoated vaseline. After twenty-four hours the packing is removed and the cavity gently irrigated with a warm saline colored solution of potassium permanganate. It is then loosely packed with half inch strip of gauze saturated with a 1 per cent aqueous solution of ichthyol. After twenty minutes this is removed. This treatment is given once or twice daily for the first three days after which mild alkaline antiseptic solution is used by the patient once or three times daily. Benzoin vapor is to be used after each irrigation. In frontal sinusitis the middle turbinate may be either inflected or resected after which sound is passed followed by irrigation.

If more operative work is indicated the unilateral process is resected and the tensor ethmoidalis curvated. If this fails the total operation is indicated, the indications of which are thus tabulated:

1. When other forms of operation have failed.
2. The appearance of fistula, abscess, necrosis.
3. When symptoms of intracranial complications appear.
4. When during the course of chronic frontal sinusitis pain and fever suddenly appear and the discharge becomes fetid.
5. When the headache referred to the eye is not influenced by intranasal procedures.

6. When the discharge remains fetid despite frequent irrigation.

7. When the sinus inflammation gives rise to recurrent polypoid hypertrophies and polyp formation.

8. When simple purulent discharge is not relieved by nasal measures and the patient is anxious to procure permanent relief from his annoying symptom.

Otto M. Rott

Quintan, F. J. Significance of Hemorrhage in Operations on the Nose and Throat. *Med. Rev.* 1907

In discussing the etiological factors of hemorrhages it operates upon the nose and throat the author divides them into local and constitutional.

The chief local factors mentioned in the order of importance are:

Incomplete removal of tissue due to faulty technique.

Local lesions of blood vessels particularly where the vessels are abnormally placed or when adjacent tissues are injured.

3. Local tissue anomalies such as inflammatory processes or areas of congestion. Anesthetics contribute to the condition. General anesthetics at the time of operation and local anesthetics secondary to the operation.

The constitutional causes are hemophilia, purpura, hemorrhagic leucæmia, mæmia, and exophthalmic goiter.

The local measures mentioned for the control of post-operative nasal hemorrhage are:

Pinching the alæ close together and bending the head forward to direct the clot in position until organized.

Local injections of 20 to 30 cc. of warm liquid gelatin.

4. Yankauer method of stitching the posterior tip of the turbinate.

4. Anterior packing.

5. Post-nasal tamponade with anterior packing.

Local measures for the control of post-operative tonsillar hemorrhage are:

1. Absolute rest of mouth, throat and body.

2. Digital compression by means of gauze wrapped around the finger and dipped in peroxide or antipyrine.

3. Tonsil hæmostat.

4. Bringing the tonsil pillars together by means of large metal clamps after a gauze tampon has been inserted into the fossa.

5. Suturing the pillars.

6. Constriction of the bleeding stump.

7. Ligation of the common carotid.

Other procedures are the application of precipitated blood sera in the form of serum powder whether the bleeding be from the turbinates or the tonsil fossae. Coagulin is also used.

The constitutional homeostatic measures are

1. Injection of serum 20 to 40 cc. If bleeding continues the dose — 10 to 30 cc. subcutaneous or 10 to 1 cc. intravenously — may be repeated at intervals of 2 to 6 hour or longer.

2. Injection of pituitrin 1 ccm

THROAT

Lack, H. L. Partial Excision of the Thyroid Cartilage as an Alternative to Thyrotomy in Malignant Disease of the Vocal Cord. *J. Soc. Med.* 11, 1, 1918, 5.

The larynx and trachea were exposed through the usual median incision and a Hahn annular incision. The right ala of the thyroid cartilage was split and the perichondrium detached from its surface. The thyroid cartilage was divided in the middle line as in thyrotoxy and then the hyoid apparatus was turned at right angles so as to split the trachea horizontally about its center. The upper and lower larynx were carefully divided in the median line in front and then the incision was carried back through the ventricle of the larynx. The aperture being held open with retractors gave a good view of the grith and it was extended through the tracheal membrane and the muco-membrane of the larynx and below the grith. The quicquid of the lip consisting of the lower half of the right larynx and the trachea with the vocal cord attached in front was removed. This gave a much better view than is presented by the thyrotomy and all the greater facilities for removing the posterior portion of the cartilage and for arranging the tubecompleting the

The advantages mentioned are: (1) Better hearing and clearer speech and more thorough operation. (2) The removal of the underlying rind certainly aids in thoroughness. (3) The central bleeding means less trouble with anesthesia and less danger of blood entering the lungs. (4) Spinal packing for the wound is unnecessary. It is much easier to introduce and retract the incision. It eliminates the necessity of flapping the thyroidal membrane and the resultant pull apart of the two halves of the thyroid which then lead to much subsequent difficulty and difficulty in closing.

the new type B Pulmotor

The first and only hand-operated resuscitation machine to recognize that lung capacities and volume of air breathed vary greatly with the individual while lung pressures are uniform

And it is because Type "B" Pulmotor completely complies with this basic principle that it adapts itself to any patient and applies his lungs with their normal breathing volumes assuring natural and not pump-forced respiration

This is achieved by means of a remarkable new invention—the Pulmotor Pressure Control Valve. Interposed between the patient's lungs and the pump this valve accurately registers the lungs' action on both inhalation and exhalation.

And so delicately adjusted are

the indicators of the valve that they immediately signal the patient's first faint attempts at voluntary breathing and enable the operator to time the working of the machine to harmonize with the patient's effort thereby speeding recovery

A result of these and other patented features, Type "B" Pulmotor is completely free from the defects inseparable from pump-controlled resuscitation machines. It is impossible with Type "B" Pulmotor to gag or suffocate the patient, or to injure his lungs in any way. The ordinary layman can operate Type "B" Pulmotor fully.

Type "B" Pulmotor weighs but 14 lb. complete with carrying case and all accessories—in ideal outfit—readily taken anywhere in emergency. Price complete \$415.00. To order lay in delivery place, or order prompt

Queen Oats

Starved Oats

Which Oats Do You Advise?

A bushel of choice oats contains about ten pounds of big plump luscious grains

The rest are little grains underfed puny and insipid

In Quaker Oats to get extra flavor we flake the queen grains only But we use the small grains in other ways So Quaker Oats costs no extra price to users

If you approve this plan please tell the facts to people you advise

Quaker Oats

Extra-Flavory Flakes

Quaker Oats dominates all the world over Even in the British Isles—the home of Scotch and Irish oats All because of the big white flakes and extra luscious flavor

Regular Package 10c
Except in Far West and South

GLASS VIALS
2%, 5 and 10 grams each

N.B.—The intravenous and hypodermic administration of Coagulen Ciba is contraindicated in cases where there is a tendency to thrombosis or embolism.

HEMORRHAGES

Hematuria and Uterin	5% solut on locally or subcutaneous	Dose: 2½ to 5 grams. Repeat if necessary
Neonatorum	3½ to 5% sol. on subcutaneous	Dose: 2½ grams in two injections, 1 to 2 hours apart
Postpartum	20 to 50 c. of 3½ sol. on I. transvenously and 120 to 90 subcutaneous	Dose: 5 grams in 140 c. c. solution as directed. Repeat if necessary

COAGULEN CIBA

Solution should be freshly prepared

As much as ten grams of Coagulen Ciba (solution) may be given hypodermically without untoward results

The intravenous injection of Coagulen Ciba should be given with care and on the first sign of dizziness or flushing of periphery blood vessels, stop the intravenous and substitute the subcutaneous injection.

EASTMAN KODAK CO ROCHESTER N Y

Diphtheria Antitoxin Mulford

For the Treatment and Prevention of Diphtheria

Diphtheria Antitoxin has reduced the mortality of diphtheria from 40 per cent to less than 10 per cent.

This mortality may be still further reduced

By using Diphtheria Antitoxin earlier

By giving larger doses—5000 to 10,000 units.

By intravenous injections in severe or late-treated cases.

The Time of Administering Antitoxin is Vital.—In the Philadelphia Hospital for Contagious Diseases, from 1904 to 1910, 256 diphtheria patients were treated on the first day of the disease and all recovered.

Patients treated on the second day the mortality was 5.4 per cent.

In those treated on and after the third day the mortality was much higher

The early administration of Antitoxin is imperative

Larger Doses are Necessary.—The object in administering Diphtheria Antitoxin is to neutralize, in the shortest possible time, the poison (toxin) circulating in the blood stream and tissue fluids. Dr. William H. Park advises 10,000 units in severe cases for little children, and 20,000 units in severe cases for adults. This is practiced in many leading hospitals.

Intravenous Injection.—No case should be considered hopeless. In malignant cases

and late stages of diphtheria recovery may be brought about by the intravenous use of Antitoxin in large doses. The Antitoxin is thus carried directly into the circulation and its activity exerted at once, whereas, if given subcutaneously only one-tenth of the amount reaches the blood stream at the end of 4 hours.

The importance of large doses is appreciated when we consider the impossibility of ascertaining the amount of toxin circulating in the patient's blood. The only safe rule is to give sufficient antitoxin. The giving of larger doses than are necessary does no harm; but an insufficient first dose and in some cases the lack of intravenous injection, may be serious mistakes.

Diphtheria Antitoxin Mulford is accurately standardized and repeatedly tested. It is supplied in the Mulford aseptic antitoxin syringes, ready for immediate use containing 1000, 3000, 5000 and 10,000 units. 20,000 units supplied on special request.

Order states: In 122,036 cases of diphtheria treated in 120 cases previous to the use of antitoxin, the mortality was 39.4. Since the introduction of the antitoxin treatment, records of 122,844 cases show a mortality of 14.6 and leaving out those cases which did not receive serum injections, the mortality is reduced to 8.5. It is estimated that without antitoxin there would be, in the United States, over 50,000 deaths yearly from diphtheria, while the mortality has been reduced by the use of antitoxin to less than 13,000 in the United States alone. This means a saving of over 40,000 lives yearly.

Liquid Paraffin

(Medium Heavy)

Tasteless—Odo-less—Colorless

Is Neither Absorbed Nor Digested

The fact that it is not absorbed by the epithelial cells and consequently not excreted through the milk makes it a most satisfactory agent for nursing mothers.

Furthermore, Stanolind Liquid Paraffin removes the intestinal toxins that would otherwise be absorbed into the blood.

Stanolind Liquid Paraffin acts on the whole intestinal canal, reaching the rectum intact, differing from a vegetable oil the larger portion of which is digested and absorbed.

Stanolind Liquid Paraffin is a safe and dependable agent for continued internal administration

New Device for Treatment of Oblique Fractures

(By F. W. Parkman, M. D. and E. Demaree Martin, M. D.)

A new simple and valuable method of treating oblique fractures. No more screws, no chance of loss of apposition as with Lane plates.

The force of the lever fits the band snugly around the bones. Slightly relaxing screw as instrument is turned over all five bands in position.

No Screws Required

No screwing means time saved. This device consists of band six inches by 3/16 inches, with slit one end and small hole in other. This band is passed easily around the bones, the free end is inserted through slot and made fast to pin on screw lever.

Price with two bands \$7.50

Strain Eliminated

The strain involved in holding fragments in place while bony union takes place is eliminated. The band is set in any desired position by screw pin at screw or bone screw. The cut end is then pressed down and the band releases itself. If desired, fragments held in apposition in three bands are mechanically tightened by the overlocking action by examiner's construction.

Extra bands, each \$0.25

"AMBUMATIC"

WASHABLE ABDOMINAL SUPPORTERS

Made buckled or laced. Adjustable as a binder to lower middle or upper part of abdomen or as an uplift, carrying the abdomen in a sling.

"AMBUMATIC" Supporters never slip up out of position from sudden strains giving the incision unprotected.

"AMBUMATIC" Supporters are light and comfortable to the wearer yet durably made and absolutely efficient. They enable the patient to resume work or business with perfect safety as long as the wound otherwise so be possible.

The "AMBUMATIC" Supporter is the best all-around assurance that anyone can have following laparotomy.

See How Easy to Apply the

**E. Z. SELF CEMENTING
SELF VULCANIZING PATCH**

You can time the whole operation, and be thru in less than 60 seconds. Now—ready!

Put the faulty glove on your hand (so that the surface around the tear or puncture is smooth) then, a few brisk rubs with sandpaper to rough the fabric. Now with pair of tweezers or forceps, remove an E. Z. Patch from the mounting card, moisten its E. Z. rubbery side with a drop of water. Next, place the moist side on the surface to be patched. In a few moments, place the moist side down over the puncture or tear and press the patch with your thumb for a few seconds so it can firmly adhere.

All done, and all ready for circulation, when the patch will actually conform to the glove.

It's there permanently—extra proof is come off, and it's non-poisonous and non-infecting.

A trial package containing 12 E. Z. Patches with full directions for use. Hospital size pkg. 500 Patches for \$5.00. Samples on request.

Gas Oxygen Anesthesia and Analgesia

The McKesson Apparatus

These machines are designed and constructed by a physician who knows the requirements of an apparatus for Hospital Office and Home use. Every element leading to perfection has been carefully worked out in the operating room and embodied in the apparatus mechanically.

To secure accuracy and constancy the patient's breathing automatically regulates the flow of gas and oxygen with each breath. All rebreathing is controlled by a graduated adjustable bag which also measures the size of the respiration and operates automatically. An emergency valve is provided for artificial respiration with pure oxygen.

The Junior is designed especially for Analgesia! Obstetrics and painful dental work, also for short anesthesia in minor surgery. In its carrying case it weighs only 15 lbs., tube larger than microscope case.

The Junior model is light, simple and automatic for analgesia, requiring no one with experience to adjust or regulate it. The patient herself can apply and remove the mask as directed by the obstetrician, and secure good results.

How is Surgery to be Taught?

You are interested in these questions Where can I get instruction and practice in surgical technique? How can I improve my technique? How long can I afford to be away from my practice?

For over a year the Laboratory of Surgical Technique of Chicago has been answering the above questions by satisfying practitioners from all over the United States and Canada.

They have worked out an *original plan* of teaching the *technique of surgery* that not only gives the man the instruction but allows him time to do the operations over and over until he is *satisfied* that he *knows* the technique

They have taken care of the busy surgeon as well as the practitioner whose experience has been more or less limited. Men realize that time is a factor in every operation and they want their technique improved so that they can get their patient off the table quicker

The laboratory is open daily from 8 to 5 o'clock, which makes it possible for the man whose *time away from his practice is limited* to get the work in the *shortest time possible*

As to the Plan, Time, Fee, etc. Address

Surgery Gynecology and Obstetrics per volume	1.50
International Abstract of Surgery per volume	1.50

The prices quoted here include arrange for postage on shipments to point in the United States and Canada. Express or freight charges on journals returned for binding must be prepaid.

First Aids

to The Practitioner

Aid No. 1. The Art of Diagnosis

Have you ever taken a few minutes off to analyze your own ability or weakness as a Diagnostician? Have you considered what it means to be a Good Diagnostician measured in Prestige and ultimately in Dollars and Cents?

THERE never was a time in the history of the profession when more attention was being devoted to the art of diagnosis. The men with whom the practitioner must measure arms on the morrow are taking up the practice of medicine with a better knowledge of the means and methods of diagnosis than it was the fortune of the men of a generation ago to possess. It is said that today less than fifty per cent of the diagnosis made during life tally with the conditions found on necropsy. Yet there is hardly a practitioner in the country who can take time from his work for post-graduate training in more up-to-date diagnostic methods.

What About an Investment in Reliable Literature on Diagnosis?

Here are Nine Volumes by Experts in Every Phase of Diagnosis comprising an unusually well-balanced Diagnostic Library. Check the ones or all that you are interested in. We will send you detailed information as well as a new Pamphlet as you get out on THE ART OF DIAGNOSIS

FLAGG

ANAESTHESIA

By PALUEL J FLAGG M.D.

Lecturer in Anaesthesia, Fordham University Medical School, Anaesthetist, Roosevelt Hospital; Instructor in Anaesthesia to Bellevue and Allied Hospital, Fordham Division, Consulting Anaesthetist, St. Joseph's Hospital, Yonkers, N.Y.; Formerly Anaesthetist, Woman's Hospital, New York City.

Octavo

341 pages

136 illustrations

Cloth \$3.50

THIS book is a groundwork upon which the student, intern, and general practitioner may acquire a more comprehensive knowledge of the Art of Anaesthesia. A bird's-eye view of the entire field of anaesthesia is given by defining and describing general, local, and mixed anaesthesia. General anaesthesia is taken up in detail.

Ether anaesthesia, oral insufflation, intrapharyngeal insufflation, intratracheal insufflation, rectal and intravenous methods, are followed by general anaesthesia by ethyl chloride, chloroform, nitrous oxide, nitrous oxide-oxygen ether. Local anaesthesia is then discussed. A chapter on mixed or spinal anaesthesia follows.

Medication preliminary to anaesthesia is followed by carbon dioxide and re-breathing. Bearing in mind the needs of the general practitioner, a chapter on emergency anaesthesia has been prepared.

Most thoroughly and practically illustrated and moderately priced.

ROBERTS AND KELLY

FRACTURES

By JOHN B. ROBERTS, M.D., F.A.C.S.,

and

JAMES M. KELLY, A.M., M.D.

Professor of Surgery in the Philadelphia Polyclinic

Associate in Surgery in the Philadelphia Polyclinic

Octavo

677 pages

909 illustrations.

Cloth \$6.00

LONG hospital training, observation in America and Europe, and undergraduate and postgraduate teaching have fitted the authors to produce a book acceptable to experienced practitioners. Statistics, normal anatomy, pathology, the types of fracture, complications, methods of treatment, and results are included in the discussion of each region of the body.

By a great number of X-ray plates are indicated the types of injury met in the different bones, and by this side of these are placed illustrations of original drawings showing the muscular attachments by which the usual deformity of the limb is caused. The need for treatment of the soft parts in fractures has been insisted upon.

The management of these injuries by the early mobilization and massage methods of Lucas Champagnière, and the traction appliances of Bardenheuer are discussed. The necessity of recognizing muscular contraction and of providing against displacement through particular muscular attachments is insisted upon.

Luenn's plating method, Albee's autogenous inlay procedure, Steinmann's suggestion for nail extension, and other direct methods of restoring skeletal integrity are discussed.

SHEARS

OBSTETRICS

By GEORGE PEASLEE SHEARS, M.D.

Professor of Obstetrics, New York Polytechnic Medical School and Hospital

Octavo

745 pages.

419 illustrations.

Cloth \$6.00

DR. SHEARS' originality both in his viewpoint and in his methods is the result of a very wide private and hospital experience, in which he formed and corroborated his own opinions. In other words, the book is a *laboratory* rather than a *library* product.

The same care has been applied in selecting the illustrations, which are designed to *illustrate* rather than to *ornament* the book.

Dr. Shears has written his book from the *practical* rather than from the purely *academic* standpoint and has laid emphasis upon the fact that not every practitioner has at his disposal the facilities of a hospital or clinic and while the methods advocated in the book are thorough and up-to-date, Dr. Shears has aimed to present them in such a way as to require the least complicated apparatus.

Many common sense hints not usually met with in works of the kind are of inestimable value for the welfare and comfort of the patient.

The author has shown that it is quite possible to be *exhaustive* without being *exhausting*.

THE SOUTHWORTH COMPANY, Publishers
TROY NEW YORK U S A

NEW and REVISED WORKS on SURGERY

Speed's Fractures and Dislocations

NEW WORK
JUST READY

A clear conception of osseous injuries and their repair is essential to an understanding of fractures. For this reason the author has selected examples of different types of usual fracture pathology and endeavored to bring them before the reader's eye by means of line drawings which illustrate the essential points. Every illustration of this character is a careful reproduction of a tracing made from a Röntgen gram for actual use.

Octavo, 888 pages, with 696 engravings. By KELLEROS SPEED, M.D., F.A.C.S., Associate in Surgery, Northwestern University Medical School, Associate Surgeon, Mercy Hospital, Attending Surgeon, Cook County and Provident Hospitals, Chicago. Cloth, \$6.00 net.

Warren's Surgery

NEW WORK
JUST READY

Special features of the book are the sections dealing with subjects in which great advance has been made in the last few years. A clear account is given of the best methods at present in use and, very helpfully, the author directs attention particularly to those which in his experience have proved sound and satisfactory. The *Surgical Anatomy* of and the *Method of Dissection* appropriate to the various regions and organs also receive full consideration.

Two octavo volumes of about 750 pages each, with 504 illustrations. By RICHARD WARREN, M.D., M.Ch., Otago, F.R.C.S., Assistant Surgeon in and Teacher of Clinical Surgery, the London Hospital, Senior Surgeon to the East London Hospital for Children, Examiner in Surgery at the University of Oxford. Cloth, \$7.50 net.

Brewer's Text Book of Surgery

THIRD EDITION
THOROUGHLY REVISED

This is a complete reference work—student's text in one volume covering the whole subject of surgery, by a master of clinical surgery and clinical teaching. In the third edition the same broad survey of modern surgery manifest with rich clear statement and careful selection of the tried and proven procedures for presentation are again evident. Its scope, however, is broadened and its use increased to provide the adequate treatment of the numerous recent advances in surgery.

Octavo, 1027 pages, in 500 engravings and 23 plates in color and monochrome. By GEORGE BREWER, A.M., M.D., Professor of Surgery in the College of Physicians and Surgeons, Columbia University, Surgical Director of the Jos. M. H. Hospital, New York. Assisted by LOUIS J. S. LAZARUS, M.D., Associate Professor of Surgery, Columbia University, and Member of the Surgical Teaching Staff of Columbia University. Cloth, \$5.50 net.

Kanavel's Infections of the Hand

NEW (3d) EDITION
JUST READY

The urgent demand for a third edition of this work has given the author an opportunity to enhance the value of his monograph by a thorough revision and by the addition of new chapters upon the Relation of Acute Infective Processes to Industrial Pursuits and upon Plastic Procedures Instituted for the Correction of Deformities. The surgeon who does casualty work or has charge of industrial accidents will find this book invaluable.

Octavo, 405 pages, with 6 engravings. By ALLEN B. KANAVAL, M.D., Assistant Professor of Surgery, Northwestern University Medical School, Attending Surgeon, Wesley and Cook County Hospitals, Chicago. Cloth, \$3.75 net.

Cryer's Internal Anatomy of the Face

NEW (2d) EDITION
JUST READY

In the preparation of this edition the text has been thoroughly and carefully revised to meet the requirements of those making special studies upon or operating in the region of which it treats. New matter has been added to the extent of about 80 pages.

Octavo, 360 pages, with 377 engravings. By M. H. CRYER, M.D., D.D.S., Professor of Oral Surgery, University of Pennsylvania, Oral Surgeon to Philadelphia General Hospital. Cloth, \$3.50 net.

Davison & Smith's Autoplastic Bone Surgery

NEW WORK
JUST READY

The authors have endeavored to place the subject on a practical working basis by presenting in a concrete manner the results of their own clinical and experimental work in autoplasmic bone surgery. They have further succeeded in boiling down the voluminous literature of the surgery of bones in such a way that the reader may draw his own conclusions as to the efficacy of the various methods, in technique dictated by authorities. Repair of intractable recent simple fractures by autoplasmic transplantation of bone is fully described and is an important part of this work.

Octavo, 356 pages, with 74 illustrations. By CHARLES DAVISON, M.D., F.A.C.S., Professor of Surgery and Clinical Surgery, University of Illinois, College of Medicine, Surgeon to Cook County and University Hospitals, Chicago, and FRANKLIN D. SMITH, M.D., Clinical Pathologist to University Hospital, Chicago. Cloth, \$3.50 net.

THE ETIOLOGY AND PATHOLOGY OF NON TUBERCULOUS RENAL INFECTIONS¹

By HUGH CABOT M.D. BOSTON

Assistant Professor of Genito-Urinary Surgery, Harvard Medical School, and Chief of Genito-Urinary Department, Massachusetts General Hospital

AND

E. GRANVILLE CRABTREE M.D. BOSTON

Assistant in Genito-Urinary Surgery, Harvard Medical School, and Assistant Genito-Urinary Surgeon, Out-Patient Department, Massachusetts General Hospital

WHILE it is almost literally true that a satisfactory comprehension of the diseases of the genito-urinary tract depends upon a clear appreciation of the nature and probable course of renal infection there is no subject in which there is so little uniformity of opinion and so much confusion. The literature of the subject is stupefying both in quantity and in complexity and anyone who has attempted to master it will be convinced of the fact that it is more likely to confound than to enlighten the reader. Not a little of the confusion arises from a somewhat inaccurate use of terms. Thus the great majority of writers using the term ascending renal infection mean a process which ascends from the lower to the upper urinary tract, but Mallory has for some reason seen fit to use the term to mean ascension from the renal pelvis into the kidney substance and has confused without enlightening. The phrases metastatic, embolic, hematogenous, bloodborne have been used with a looseness which defies comprehension and finally the persistent description of various stages in the same process as different pathological entities has rendered confusion worse confounded. Not

the least serious difficulty has arisen in the almost entire failure of collaboration between the clinician and the pathologist. Thus 10 years ago Orth showed a very interesting understanding of the etiology of renal infections which the clinicians have apparently largely overlooked. On the other hand as in the ancient history of renal tuberculosis the pathologist has wrought havoc with an understanding of this subject because his opinions have been based considerably upon post mortem material which it might be suggested is likely to represent fatal cases and has therefore jumped to the conclusion that a given type of lesion is generally bilateral whereas in fact it is bilateral only in the fatal cases.

A more or less intimate association with the subject of these infections early impressed us with the complexity of the picture which may be presented by kidneys which are the site of long standing infection. It is not rare to find kidneys showing the evidences of at least three infections differing in point of time and often in the nature of the organism involved. That these should present to the pathologist a situation almost too complicated for satisfactory solution is not surprising and

¹Read before the American Association of Genito-Urinary Surgeons, Washington, May 6.

we have come to believe that many of them can be interpreted only in the light of considerable knowledge of the clinical history coupled with great familiarity with renal pathology. In the attempt to solve the intricate problems of renal infections much assistance has been rendered by the use of animal experimentation and yet it has in some hands led to wholly erroneous conclusions which have done considerable damage the error arising very largely from the attempt to draw conclusions from the effect upon animals of organisms whose behavior is very different from that which they exhibit in the human body. Thus, the colon bacillus rarely produces suppurative lesions of the kidney in man while in animals it may readily do so and this has given rise to the quite erroneous assertion that the colon bacillus commonly or even regularly produces abscesses of the kidney. Where so much turns upon the exact nature of the lesion produced a study of the lesions in animals must be surrounded with every precaution, if the conclusions are to have validity. Our experience has led us to the conclusion that it is wholly unsafe to use the same organisms commonly found in human renal infections in carrying out animal experiments and we incline to the view that the safest procedure is to select organisms which produce similar lesions in other organs and reason from parallel rather than from identical lesions. In studying this subject we have come to regard it as important to consider the lesions produced by various organisms upon kidneys previously normal, in order to get a clear understanding. It has seemed to us that in the past, attempts to explain the lesions produced by infection upon kidneys previously damaged has been a potent source of error and that an understanding of the lesions found under these conditions is most likely to come through a study of the lesions produced in previously healthy kidneys. Therefore, in discussing the subject we have divided the field of renal infections into two groups. Group I, including only those kidneys which were previously normal as far as the clinical evidence will permit of a decision, and Group II those in which infection was

grafted upon some other lesion of the kidney such as stone tumor or dilatation due to obstruction.

BACTERIA CIRCULATE IN THE BLOOD AND ARE EXCRETED BY THE KIDNEY WITHOUT PRODUCING GROSS LESIONS

Many years ago various observers including Hoffman Roehrig Maas Wiener Rutimeyer and Cohnheim showed that insoluble substances such as cinabar and fat could be made to pass through the healthy kidney. Particles of these substances were found in the capsule of the glomerulus in the tubules, and in the urine. In 1896 Biedl and Kraus showed that the staphylococcus aureus the bacillus coli and the anthrax bacillus passed through the healthy kidney. The same fact was demonstrated for the typhoid bacillus by Lumiere and Abram by Rovsing for the bacillus coli by Cuturi for the same organism and by Patrick for various organisms in the course of typhoid fever. Meyer Walschmann Heyer Kramer Buday Wysokowitch Roliv Brown and Cunningham have shown that in the course of tuberculous lesions elsewhere in the body tubercle bacilli appear in the urine at various times and in varying quantities without any evidence of damage to the kidney. Horney has made a similar observation for the bacillus of leprosy. In this connection should be mentioned an interesting series of observations noted by Swart and Craig that, following the administration of salvarsan to patients with leprosy or patients with tuberculosis, the bacilli appear in the urine in large numbers and the course of the disease is often unfavorably affected. On the other hand Wysokowitch in 1886 experimenting with a variety of pathogenic bacteria including the pneumococcus the typhoid bacillus anthrax bacillus, and the staphylococcus aureus found them appearing in the urine with evidence of the production of kidney lesions. Similar conclusions were drawn by Coccardi in 1888 Pernice and Scagliosi in 1892 Sherrington in 1893 Cotton in 1895 and Jahn in 1910. This array of apparently conflicting testimony has brought certain eminent observers to the conclusion that in the cases

where no lesion was discovered it was because a slight lesion had been overlooked. This we believe to be an entirely unwarranted conclusion. In view of the fact that insoluble substances have been shown to pass the kidneys without damage in view of the fact that many competent observers have passed bacteria through the kidney repeatedly and then examined these kidneys after sacrifice of the animal and in view of the fact that we are daily accepting the clinical evidence obtained by the study of patients in regard to the integrity of their kidneys we cannot avoid the conclusion that bacteria pass the healthy kidney. That they do not do so always or under all conditions simply confirms the well known fact that local conditions in the kidney and general conditions in the organism influence the occurrence or non occurrence of infections. While we are prepared to admit the accuracy of all the observations above quoted they seem to us to prove conclusively that organisms circulate in the blood and pass through the kidney in many cases without producing any lesion and in many other cases with the production of various lesions.

BACTERIA CIRCULATE IN THE BLOOD AND ARE EXCRETED THROUGH THE KIDNEYS WITH LESIONS MILD OR SEVERE

In 1915 Kowitz studying a group of children with infectious diarrhoea found the following sequence of events in five cases.

Blood cultures showed the bacillus coli. Promptly thereafter there appeared in the urine first albumin then bacteria and finally pus. Exploration of the records of the medical services at the Massachusetts General Hospital has yielded us an interesting series of 8 cases of bacillæmia and bacilluria which it may be noted occurred entirely in women. They entered the hospital with the diagnosis of fever of unknown origin.

CASE 1 Woman age 35. Blood culture showed bacillus coli urine profuse growth of the same organism. Physical examination negative except for elevation of pulse and temperature. Recovery.

CASE 2 Woman age 29. Physical examination negative. Temperature 103. Pulse 120. Widal negative. Blood culture unknown bacillus urine bacillus coli stool persistently negative for typhoid bacilli.

CASE 3 Woman age 30. Entrance diagnosis paratyphoid. Blood culture bacillus coli urine culture colon like bacilli. Recovery.

CASE 4 Woman age 23. Sister of Case 3. Entrance diagnosis paratyphoid. Blood cultures lost urine culture bacillus coli. Recovery.

CASE 5 Woman age 30. Entrance diagnosis question of typhoid. Blood cultures profuse growth colon bacillus bladder urine colon bacillus right ureter colon bacillus left ureter no growth. Persist at right pyelitis.

CASE 6 Woman age 35. Entrance diagnosis unknown fever. Temperature 102. Pulse 95. Blood culture colon bacillus urine culture colon bacillus. Recovery.

CASE 7 Woman age 30. Entrance diagnosis acute infection. Temperature 100.5. Pulse 98. Blood culture motile bacillus (bacillus paratyphoid?) urine bacillus coli. Death in one week. No autopsy.

CASE 8 Woman age 62. Entrance diagnosis convulsions. Temperature 100. Pulse 110. Blood culture colon like bacilli urine culture colon like bacilli. Death in one week. Autopsy calculus pyonephrosis bilateral suppurative nephritis.

This group of cases is interesting from several points of view. Most of them were regarded as cases of probable typhoid and attention was particularly directed to this condition. Their blood however failed to show a Widal or to react to cultures of the paratyphoid bacillus and they were finally proved to be due to the other member of this group the colon bacillus. We believe that these cases simulating typhoid and due in fact to the colon bacillus in other words cases of colon bacillus bacillæmia are much more common than has been generally supposed. The records of any large hospital during recent years will show a considerable number of these cases in which clinical symptoms suggested typhoid but the diagnosis could not be confirmed and they were finally discharged cured often with a diagnosis of paratyphoid. A correct solution can be obtained only by careful study of the blood and urine with good technique and particularly when they are seen at an early stage of the disease.

That the colon bacillus can be obtained from the blood in cases of acute pyelonephritis with considerable frequency has recently been shown by one of us (E. G. C.) who in a series of 32 cases obtained positive blood cultures in 40 per cent a ratio larger than that

ordinarily obtainable in typhoid fever which is admitted to be a bacillæmia. One case occurring under our observation and carefully studied throws considerable light upon the natural history of this process.

The patient was a man of 55 with benign enlargement of the prostate gland and residual urine. Cultures controlled by stained sediment showed the urine free from infection at entrance to the hospital. He was immediately placed upon constant drainage with an indwelling catheter. Cultures from the bladder urine were taken the evening of the seventh day up to which time he had complained of no symptoms whatever. These were sterile. At eleven o'clock of the eighth day he complained of a burning sensation in the urethra and two hours later had chill and sudden sharp rise in temperature. Blood cultures were taken two and one half hours from the beginning of symptoms of prostatic irritation and one-half hour after the appearance of the chill and rise of temperature. A pure growth of colon bacilli was obtained. Centrifuged urine obtained from the bladder at the time the blood culture was taken showed no bacteria in stained sediment. Cultures taken from the bladder urine the following morning showed an abundant growth of colon bacilli. Pus was present in very small amount. The renal functional test with phenolsulphonethylphthalein showed a drop in 24 hours of 50 points. The patient complained of right-sided costovertebral tenderness and headache and presented the usual symptom complex commonly called pyelitis, which we believe to be a pyelonephritis. He was allowed to remain on constant drainage for a week longer during which time his phthalein output returned to within five points of its former level. Perineal prostatectomy was then done. The patient made an uneventful recovery until the ninth day when he bled. The wound was packed and bleeding controlled. The temperature rose and the patient died. Necropsy showed anemia and streptococcus septicaemia. The kidneys were pale with normal markings and little, if any dilatation of the pelvis (Fig. A). They were passed by the pathologist as normal kidneys.

This case clearly shows bacillæmia, bacilluria, pyelitis and pyelonephritis. The evidence of pyelonephritis is based chiefly upon the sudden great drop in kidney function which we think may be taken as evidence of acute cloudy swelling of the kidney probably involving chiefly the tubular portion. That this process is short-lived and goes on rapidly to practically complete recovery is suggested by the return of kidney function and conclusively proved by the appearance of the kidney post mortem.

Finally in support of the above mentioned proposition we submit the results of the inoculation of a rabbit with the paratyphoid bacillus alpha. It should be remembered that the paratyphoid bacillus has for rabbits a pathogenicity quite similar to that shown by the colon bacillus in man. The cultures used in this experiment were three year old cultures. At the beginning of the experiment the bladder urine was shown to be sterile. An emulsion of the organisms, about 3 cubic centimeters in amount was introduced into the ear vein on three separate occasions during a period of five weeks. Following each infection the organisms appeared in the urine promptly and in enormous numbers. Five days following the last injection the animal was sacrificed. Sections of the kidneys carefully studied showed practically no lesion and were certainly within normal limits for laboratory animals (Fig. B).

ASCENDING INFECTION BY WAY OF THE URINARY PASSAGES

The theory that infections reach the kidney by direct extension from the lower urinary passages has acquired the dignity associated with old age and has been a widely held and attractive theory because of its extreme anatomic simplicity. We believe that it can be shown that its simplicity is apparent rather than real, that most of the cases in which it has been supposed to occur were based upon a complete misconception of the facts and that this method must in reality be regarded as exceptional. It has been customary to assume that in this method of renal infection the bacteria reached the kidney by one of three ways:

1. By continuity from a bladder infection by direct extension of the process within the lumen of the ureter
2. By the transportation of the bacteria in a column of urine which is supposed to exist within the ureter. By this conception the bacteria float upward, apparently impelled also by their own motive power in contemptuous disregard of the descending stream of urine and ureteral peristalsis.
3. By reverse peristalsis within the ureter. This, of course presupposes obstruction of

the ureter since as far as we know there is no warrant for the assumption of reverse peristalsis in the absence of obstruction. That reverse peristalsis occurs in the presence of obstruction we believe to be a demonstrated fact, the best evidence of which in our personal experience has been the movement of ureteral calculi from the kidney to the lower end of the ureter and then back again a journey which could hardly be expected to take place under any force other than reverse peristalsis.

The whole theory of ascending infection rests primarily upon the proposition that infection of the bladder takes place under a great variety of conditions unassociated either with trauma or with retention for unless a pre-existing cystitis is assumed the whole proposition falls to the ground as applied to a great majority of the cases.

More than a quarter of a century ago Rovsing and Melchior showed that (a) experimentally cystitis could not be produced in animals without retention or trauma, that (b) with retention of urine experimentally produced there generally resulted no pyelitis, that (c) trauma to the bladder with or without retention produced pyelitis and pyelonephritis. In passing it should be noted that in these later cases sections of the bladder wall showed extensive hæmorrhage with bacteria in the blood and lymph channels, an observation the importance of which will later appear.

Baurelien, concerning himself wholly with the lesions produced by the tubercle bacillus, drew three conclusions: (1) A bladder with intact mucosa cannot be infected. (2) With the flow of urine unobstructed tubercle bacilli cannot reach the kidney through the ureter. (3) Obstruction of the urinary stream will as a rule result in urogeous ascending infection of the kidney. This last conclusion implies a dilatation of the ureter and an incompetent ureterovesical valve.

Draper and Braasch, in a very thorough piece of work in which they attempted to produce ascending renal infections, wholly failed to do so except by maintaining an abnormal amount of pressure in the bladder over a long period of time.

It thus appears that the experimental work

wholly fails to support the assumption of ascending infection by means of the urinary passages. When produced as by Rovsing and Melchior there is no warrant for the assumption that it ascended since the blood and lymph channels were shown to contain bacteria and it is far more probable that the bacteria reached the kidneys by one or both of these routes. It is notorious that bacteria in the bladder, whether introduced from above or from below, will over a long period of time produce lesion. There is a mass of clinical evidence showing that tubercle bacilli coming from an infected kidney will pass for years through the bladder without producing a lesion. Of late years when the cystoscope and ureter catheter have made accurate diagnosis of conditions in the upper urinary tract possible a multitude of observations have been recorded of colon bacillus pyelitis and pyelonephritis from which the colon bacillus passed to and through the bladder for years without producing a lesion.

A recent communication by Hess, in which he described the result of investigations of the bacteriology of bladder immediately following cystoscopy, throws considerable light upon this question. He showed that in the first days following instrumentation bacteria of various kinds could be found in the bladder with regularity, that they produced neither the symptoms nor the sign of cystitis and that in a few days they disappeared. We have become wholly accustomed to regarding the cystoscopic examination of the bladder under normal conditions as a harmless procedure. If these observations of Hess be confirmed it shows that the harmlessness consists not in the aseptic character of our procedure but in the vitality of the vesical mucous membrane and its ability to shake off the milder degrees of infection.

We do not intend to convey the impression that we believe that ascending infection from the lower to the upper urinary tract must be wholly discarded for there are two conditions under which it is theoretically possible and practically probable. The first of these is ureteral obstruction which may theoretically be of three types: that due to stone, that due to inflammatory stricture, and that produced

by the abnormal constriction of the lower end of the ureter by hypertrophy of the bladder such as is seen in diverticulum, in tuberculous and in obstructive conditions at or below the neck of the bladder. In hollow viscera elsewhere in the body obstruction is followed by reverse peristalsis with singular regularity and it is but reasonable to assume that the ureter, a hollow muscular organ, behaves in a similar fashion. Further warrant is given to this belief by the observation in regard to stone in the ureter above referred to. Now under conditions of reverse peristalsis bladder infection with extension by direct continuity, to the lowest portion of the ureter would give rise to conditions highly favorable to renal infection if assisted by reverse peristalsis. The other condition clearly opening the way to ascending infection is incompetence of the ureterovesical sphincter such as undoubtedly exists in a certain number of cases of obstruction at or below the vesical outlet. In these cases the dilatation has become so extreme that the renal pelvis is for all practical purposes in direct open communication with the bladder cavity and any condition existing in the latter will promptly be communicated to the former by the simple method of back wash. Under these circumstances, if the kidney is not already infected it will promptly become so.

The pyelitis, so called, of pregnancy and the equally improperly termed pyelitis of childhood have been the great strongholds of the ascending infectionists. Their theory has been based chiefly on anatomical fact unsupported by clinical or experimental evidence. The short urethra and the comparative ease with which the region of the urinary meatus might be contaminated with the colon bacillus, together with the fact that in the adult female vesical irritability is often the first thing to attract attention, have been the two important premises. It has not been shown that the cystitis antedates the pyelitis, for the good and sufficient reason that such is rarely the case. Furthermore should it be shown that the cystitis was primary there is no basis either in man or animals for the assumption that with neither retention nor trauma ascension could occur.

The fact that this disease occurs with far greater frequency in the female whether child or adult is important but its significance has been wholly misunderstood. It is interesting to note that in the eight cases reported above of proved bacillæmia and bacilluria all were women. In the adult female we think there can be no doubt that the conditions normally existing in the large intestine are more favorable to the occurrence of bacillæmia than in the male. There is as yet no adequate explanation of the greater frequency of these infections in the female child but we think that existing evidence points to the view that this explanation will be found not in the anatomical peculiarities of the female urethra, but in the anatomical peculiarities of the female intestine.

ASCENDING INFECTION BY THE LYMPHATICS

For many years occasional observers have called attention to the possibility that bacteria might reach the kidney by way of the lymphatics. It has perhaps been most extensively discussed in connection with renal tuberculosis but of late years the discussion has been extended to include other organisms and a variety of publications showing careful anatomical study have tended to support the theoretical contentions.

Mascagni showed that the lymphatics of the upper ureter drained into the lymphatic system in the region of the kidney pelvis and that organisms might reach the kidney along these channels. He also showed that the lymphatics of the lower ureter drained into the lymph nodes of the anatomical pelvis.

Sakata confirmed the above observations and further showed that the system of lymphatics of the upper ureter and the system of lymphatics of the lower ureter and bladder were connected by an intermediate chain of lymphatics embracing the central portion of the ureter. It is easy however to exaggerate the importance of this observation since Sakata's work shows that this chain is not continuous, but is, on the contrary, highly interrupted. Organisms in order to extend from bladder to kidney by this route would have to pass through several systems of lymph-nodes, contingency which importantly decreases the probability of such an occurrence.

Supinura's series of cases and showed that in the presence of acute cystitis the lower third of the ureter was constantly involved, apparently through the medium of the lymphatics. It drew

this conclusion because there was very slight involvement of the mucous membrane of the lower ureter while the lymph-channels of the muscularis and adventitia were extensively involved.

Francke has shown a lymphatic communication between the right kidney capsule and the adjacent ascending colon.

Kumata has demonstrated a system of superficial and deep lymphatics in the fatty capsule of the kidney. This system apparently drains away from the kidney communicating with the subdiaphragmatic lymphatics.

A recent paper by Eisendrath states his belief that he has demonstrated that bacteria ascend by the lymphatics from the bladder to the kidney and produce renal infection. After a careful study of this paper we regret that we are entirely unable to follow him to his conclusion. The method by which the lesions were produced is nowhere stated. The lesions are not strikingly different from those which are found in blood born infections and finally the evidence which he submits of the lesions of the kidney is so meager and differs in such important particulars from the infectious lesions ordinarily found in the kidney that we must question their similarity.

Upon the framework of the above mentioned anatomical observations several writers have attempted to erect a theory of lymphogenous infection of the kidney. Though the framework is valid in its individual members the complete structure seems to us frail and insecure. It is generally believed and upon sufficient evidence that the lymphatic currents throughout the body follow the flow of blood in the blood vessels. Unless we are prepared to disregard this doctrine it will be difficult to trace lymphatic processes over areas which are totally lacking in continuous vascular channels. Now there are no blood vessels running an uninterrupted course from the bladder to the kidney. The blood supply of the ureter is distinctively segmental and the only vessels which run in this general direction are the spermatic vessels in the male and the ovarian vessels in the female. These run in different sheaths and would be with difficulty accessible to organisms passing outward from the bladder. Furthermore assuming the probable fact that organisms reach the lymphatics about the bladder and over the lower segment of the ureter the probability of their reaching the blood stream rather than continuing in devious lymphatic channels seems to us overwhelming. That

organisms pass from the bladder into the perivesical lymphatics reach the blood stream and ultimately the kidney we not only believe but are prepared to show¹ and this possibility must always be reckoned with. Reasoning from lesion produced by lymphatic infections elsewhere in the body progress by this method is comparatively slow and on account of the interrupting lymph nodes is more likely to produce highly localized lesions than lesions spreading rapidly over long distances and flooding a distant area with organism.

Finally the evidence of the lesions actually produced in urinary tuberculosis is enlightening. It is generally recognized that the involvement of the ureter is earliest and most marked at its two extremities and it is not uncommon to find a central portion of the ureter wholly or comparatively free from tubercular disease. Those who have regarded the work of Francke concerning the lymphatic communication between the ascending colon and the right kidney as conclusive seem to us to be reasoning upon highly insecure premises. Arbiter has shown that when organisms leave the intestine by the lymphatics they rapidly appear in the blood and this tendency is amply confirmed by a large series of observations which concern themselves not only with the migration of bacteria of the intestine into the lymphatics but with the ways in which foreign proteids leave the intestine under abnormal conditions.

Thiele and Embleton have shown that after peritoneal infections the organisms rapidly reach the blood stream and are excreted by the normal kidney. If however the thoracic duct be opened so that bacteria can escape no such excretion occurs.

If for a moment we disregard the large probability that bacteria leaving the intestine by the lymphatics will reach the blood stream rather than the kidney we must yet believe that a lesion of the kidney thus produced would in all probability be a localized lesion rather than a widespread diffuse lesion such as is notoriously produced by bacteria of intestinal origin.

¹See author's case p. 64.

WHY ASSUME THAT COCCI GENERALLY REACH THE KIDNEY BY THE HÆMATOGENOUS ROUTE, WHILE ASSUMING THAT COLON BACILLI GENERALLY REACH THE KIDNEY BY ASCENSION FROM THE BLADDER?

It has been long assumed and following the work of Brewer has been almost universally admitted that the staphylococcus infections of the kidney are of hæmatogenous origin. These infections have been shown to be associated with furunculosis, carbuncle, and various septic foci elsewhere in the body. The identity of the organisms in both places and the impossibility of sustaining any assumption of transference other than the blood has led to these lesions being regarded not only as hæmatogenous lesions but the proposition has been even reversed and the hæmatogenous lesion has become almost synonymous with coccus infection. On the other hand the infection of the kidney with the colon bacillus, of which the purist types are the pyelonephritis of infancy and pregnancy has been regarded as ascending chiefly because of the delightful simplicity of the assumption. If however one inquires as to the evidence of the hæmatogenous origin of both these types of infection one is at once struck by the fact that the hæmatogenous origin of colon bacillus infections has been demonstrated beyond the shadow of a doubt, the organisms having been repeatedly found in the blood and subsequently in the urine while as far as we are aware there are but few cases on record in which the cocci concerned in the so-called hæmatogenous coccus infection of the kidney has been captured during his journey through the blood. While this should not be taken as in any way tending to invalidate the hæmatogenous origin of the coccus lesion it seems to us to at once put upon the defensive those who would assume that colon bacillus infections of the kidney are produced by any method other than the hæmatogenous one. At least as far as concerns the pyelonephritis of the group above referred to we shall later submit evidence which seems to us to show that they can be produced only by organisms reaching the kidney through the blood stream and that the theory of ascension is wholly mythical.

POSSIBLE SOURCES OF CONFUSION IN PREVIOUS STUDIES OF RENAL INFECTION

That the literature of renal infections is both confusing and confused no one who has attempted to digest it is likely to deny. There appear to us to be two chief sources of this confusion first a considerable lack of uniformity in the use of terms which at times amounts to a use so loose as to be positively misleading and second an attempt to study complicated and mixed lesions which are likely to almost defy analysis.

1. At the outset, therefore of the discussion of our own findings we desire to state clearly our understanding of the terms emboli, metastatic, hæmatogenous, excretory lymphogenous and ascending as applied to renal infection.

A suppurative lesion of the kidney we regard as embolic when a definite embolus shown to contain micro-organisms has been demonstrated in a blood-vessel at the apex of the lesion. This term has we think frequently been used to cover a mucous lesion which were a no proper sense emboli in character.

A metastatic lesion of the kidney we understand to mean a suppurative lesion produced by an organism of the same character as one concerned in a demonstrable suppurative lesion elsewhere in the body.

The term hæmatogenous we hold to mean simply that the organisms reach the kidney by the blood.

An excretory lesion is one produced during the process of excretion of organisms by the kidney. It will thus be seen that the terms hæmatogenous and excretory cover very nearly the same ground. Clearly no excretory lesions can occur unless the organisms have arrived by the blood and we expect to show that organism which arrive by the blood and do not produce emboli very generally do produce excretory lesions.

Lymphogenous covers all the suppurative processes demonstrated to be produced in the kidney by bacteria which have arrived solely via the lymphatics.

And finally ascending infection in which abused term, we hold to mean the direct ascension of organisms from bladder to kidney by the lumen of the ureter. This process may involve either a direct extension along a mucous membrane or a direct transference from bladder to kidney with the urine as vehicle.

2. We believe that a comprehension of renal infections is very much simplified if they be separated into two main groups. Group I including all those infections of the kidney which occur in an organ previously

sound and Group II those infections which occur in a kidney previously unsound such as those damaged by stone tumor obstruction or chronic nephritis.

A classification of the infections occurring in Group I has seemed to us after a not inconsiderable experience to be comparatively simple. We have a rule been able to come to a satisfactory conclusion as to the cause and nature of the process and to arrange the lesions in an orderly and comprehensible fashion. On the other hand there have been many cases falling under the classification of Group II in which the complication of lesions of various dates and of essentially different pathological characteristics was such as to largely defy satisfactory explanation. For example a kidney long the resting place of a stone may show a variety of practically healed lesions the original nature of which must be permanently in doubt. Coupled with these may be two or even three more recent infection overlapping each other in position and perhaps in point of time and giving a picture so confusing as to be quite beyond us. It may well be that a more extensive study of the cases in Group I will enable one to make a fairly accurate guess as to the probable cause of the various lesions of such a kidney as above described.

A STUDY OF THE LESIONS ACTUALLY FOUND IN RENAL INFECTIONS.¹

For this study we have utilized a group of 118 cases classified as suppurative nephritis. These include both cases studied at autopsy and specimens obtained at operation so that we have not been confined to one particular type of material. Of these 118 cases we have been obliged to discard 58 either because they represented material obtained at autopsies done several years ago from which the paraffin blocks had been lost or the lesions were too chronic and too complicated to lend themselves satisfactorily to classification or finally those in which we were unable

to demonstrate bacteria. There thus remains a group of 60 cases divided as follows:

- 23 were caused by and were demonstrated to contain staphylococci alone
 - 4 streptococci alone
 - 3 staphylococci and streptococci
- 25 were demonstrated to contain mixed cocci and bacilli —
 - 10 of these showed staphylococci and bacilli
 - 4 showed streptococci and bacilli
 - 2 showed staphylococci streptococci and bacilli
- 5 showed bacilli only —
 - 3 the bacillus coli and
 - the bacillus coli and another bacillus clearly a pyogenic organism

I EVIDENCE OF THE PRODUCTION OF LESION DURING THE PROCESS OF EXCRETION OF BACTERIA

The case for this proposition was clearly stated by J. W. Thomson Walker in his work on *Surgical Diseases and Injuries of the Genito-Urinary Organs* p. 120.

It is now recognized that bacteria are constantly entering the lymphatics from the intestine and other sources in healthy individuals. The bacteria may be destroyed at the point of entry or at the lymphatic glands, or they may pass through the lymphatic system into the blood stream in which they circulate. The endothelium and cells of the liver destroy bacteria which are introduced by way of the portal system and bacteria are excreted in the bile. Similarly a function of the renal parenchyma especially of the convoluted tubules is to remove the bacteria present in the systemic circulation.

It has been proved that the virulence of these bacteria is not reduced in their passage through the body. The excretion of bacteria in this way does not give rise to any symptoms which show that the kidneys are damaged. It is stated however as the result of experiments on animals, that the secreting membrane is injured by the passage of the bacteria. The damage is probably slight and is repaired partly or completely by the regenerative powers of the kidney. In some cases long-continued excretion of bacteria or their toxins may be the cause of patches of interstitial nephritis in the kidney.

It is held that the excretion of bacteria does not cause pyelonephritis unless some additional factor is present. Predisposing causes of pyelonephritis are traumatism excessive functional activity the elimination of toxic bodies such as cathartics previous disease of the kidney such as urinary obstruction calculus, new growth. It is exceptional

¹ All the following case reports are descriptions and macroscopical examinations of sections re-ported from the autopsy protocols of Dr. J. H. Wright and Dr. Oscar Richardson. Where specimens from operations are used the above descriptions re-ported from the report detail: 1 by Dr. Whitney and Dr. Hart all of the following are of the surgical pathology department. Where more detailed observations than is possible in routine work are required they are given under the heading of sections stained for bacteria which have appended.

however to find any of these factors present and it is more likely that chronic toxemia from constipation, an excessive dose and an exceptionally virulent strain of bacteria, are the decisive factors.

It was also clearly stated by Orth in 1893

The question of the method by which bacteria reach the tubules in the pyramidal zones can, in my opinion, only be explained by assuming their passage from the blood into the capsule of the glomerulus and their being carried along into the collecting tubules with the urine where they group together become arrested, and continue to grow

We append three cases which seem to us to clearly support the doctrines thus laid down.

CASE 1. Autopsy No 3539 West Medical, 193300. Female, age 36 November 5 1915. *Diagnosis* diabetes mellitus. Past history negative save for present symptoms which appeared four years ago. Present illness—only symptoms are those of diabetes. Physical examination negative as regards urinary tract. Patient was made and kept sugar free with great difficulty and lost weight and strength under the treatment. *Urine examination* at entrance showed sugar 7.8 per cent diacetyl acid and acetone no albumin occasional pus-cell. *Urine examination* January 14 1915, showed traces of albumin but scanty sediment containing only a few cells no sugar. Temperature remained normal to subnormal from entrance to January 9 when it suddenly became a swinging septil temperature ranging from normal to 102. Blood cultures were negative white count never above 9000. Renal function phthalein fell to 15 per cent for two hours. Death attributed clinically to acidosis and terminal infection. *Clinical diagnosis* diabetes mellitus. Terminal infection.

Autopsy 95 hours post mortem. *Anatomical diagnosis* diabetes mellitus. Lobar pneumonia, acute pleuritis with effusion, arteriosclerosis fibromatosis of uterus, chronic peritonitis and chronic salpingitis, chronic interstitial hepatitis, chronic interstitial pneumonia, nephritis papillaris mycetozoa, colon bacillus and streptococcus septicaemia.

Kidneys (Fig 1 frontpiece). Combined weight 500 grams. Organs are enlarged. Capsules trip easily leaving a fairly smooth dark brownish surface generally mottled with small brownish areas dotted over which are numerous grayish points. The surface of one kidney shows in two places small, pale yellowish white areas 3 to 5 millimeters across. On section the tissue is of increased consistence and shows in the regions of nearly all the pyramids of one kidney and in many pyramids of the other numerous pale yellowish, necrotic, homogeneous, rather firm masses of various size and shape, some of them measuring only a few millimeters across, and others occupying the entire pyramid. As a rule the masses reach to within 3 or 4 millimeters of the cortex although in two places there are slender prolonga-

tions of the masses through the cortex to the surface where they appear as the two pale yellowish areas previously mentioned. Margins of these masses in the pyramidal region are slightly serrated and the mass extends to the tip of the pyramid. The tissue bordering the mass is purplish black and homogeneous. From this blackish area dark lines extend in places up through the cortex and are in relation with the blackish areas mentioned as present on the surface. The cut surface of the cortex shows generally pale brownish to dark brownish background mottled in places with the blackish areas mentioned. The kidney markings are visible. Pelvis and ureters negative. Bladder negative.

Bacteriological part. Culture from heartblood growth fecal bacilli and streptococci spleen colon bacilli kidney tissue colon bacilli. *Microscopic sections* show on the surface of the cortex, in the regions previously mentioned mottling rare infiltration of the interstitial tissue with polymuclear leucocytes and lymphocytes. Extending from these areas in the interstitial tissue between the tubules are lines of similar infiltration extending down to meet the areas of necrosis. The glomeruli are normal, the tubular epithelium of the tubules of the cortical region is for the most part unchanged. In some of the convoluted tubules are masses of desquamating epithelial cells and leucocytes (Fig 2). In many cases these tubules and their contents appear to form the centers of abscesses surrounded by tense polymuclear infiltration of the interstitial tissues. The blood vessels throughout the cortex are much engorged. In the region of the distal convoluted tubules and the bases of the pyramids there is an extensive suppurative process extending transversely across the base of the pyramid, in some instances completely separating it from the cortical tissue. This area corresponds with the previously mentioned purplish black area seen in gross section (Fig 3). There is complete transverse necrosis of all structures including blood vessels tubules, and interstitial tissue to the level of the bases of the pyramids (Figs 3 and 4). The blood vessels are often found ruptured with liberation of blood corpuscles into the necrotic area and there is profuse infiltration of polymuclear leucocytes, fragments of renal epithelium, and red blood cells. The necrotic tips of the pyramids previously mentioned show a homogeneous smooth structure with necrosis as well as fragmentation of nuclei and loss of cell outline without any evidence of infiltration (Fig 5). The blood vessels of the pyramids are empty. The lumina of the straight tubules are filled with masses of detritus. In some areas in which the necrotic process is not so complete the contents of the tubule is the center of abscess formation (Fig 6). The cells of the tubule, containing the masses of detritus, and the interstitial tissue as well as the neighboring tubules show a narrow zone of necrosis outside of which is extensive infiltration of polymuclear cells. *Sediment stained* for bacteria show very rarely a short chain of streptococci in the blood stream and

capillary tufts of the glomeruli. The masses of cells found in the convoluted tubules of the cortex are shown to contain large numbers of bacilli and a few chains of streptococci (Fig. 1). In many places tubules which contain no cell detritus show considerable numbers of bacilli within the epithelial cells. A few streptococci and bacilli are found in the infiltrated interstitial tissues. The necrotic area at the base of the pyramid already described shows an extensive bacterial invasion of bacilli and streptococci but with fragments of tubules loaded with bacteria apparently covering the center of necrosis. Streptococci are much more numerous in this region than in any other portion of the kidney. The masses of detritus in the tubules of the pyramids are seen to consist almost entirely of large masses of bacilli (Fig. 5). Very few streptococci are found in this region.

NOTE.—The explanation of the pathological picture presented by this kidney seems to point to an early infection with colon bacilli in which the bacilli have been arrested through normal glomerular function. Some have been arrested high in the convoluted tubules many more in the distal portion of the tubules while large numbers have reached the straight tubules and some even to the pelvis of the kidney. A subsequent infection with streptococci in which most of the streptococci have also passed the glomerulus seems to have taken place. The streptococci have been arrested in the already damaged distal convoluted tubules and have produced along with the colon bacilli an extensive upward process at the bases of the pyramid with resulting complete transverse lesion of all structures at that level. Inasmuch as the blood supply of the pyramid is from below downward from the pole of each lobe at the base of the pyramid the transverse lesion as with rupture of blood vessels at this point has resulted in anemia and subsequent necrosis of the pyramid. There are but two areas in this kidney in which a justifiable embolism need to be considered namely the two areas of pyramidal necrosis of the pyramids previously described.

CASE 2. *Intopsy No. 342.* East Medical 967-89. Female, age 21, January 13, 1915. Admission diagnosis pneumonia arthritis. Present illness. No previous urinary difficulties. Normal delivery four days ago following which the patient began to have abdominal pain with chills and fever. Urine acid, very slight trace of albumin, many granular casts, red blood-cells and leucocytes. Blood culture no growth. Culture from cervix showed staphylococci and bacilli, one a fusiform bacillus. Smear from cervix showed many staphylococci and streptococci. Patient died on seventh day. *Chief diagnosis.* Puerperal septicemia, bronchopneumonia, endocarditis, septic arthritis. *Autopsy 94 hours post mortem.* Anatomical diagnosis. Puerperal septicemia, diphtheritic endometritis, rupture of vagina with necrosis of perivaginal tissue, septic arthritis, diphtheritic colitis, soft spleen with infarcts, pyelitis, nephritis, papillitis, mycotic streptococcus septicaemia.

Kidneys much enlarged. Combined weight 558 grams. Capsules strip leaving a pale brownish red smooth surface. On section the tissue is swollen

but markings are retained. The cortex is not narrowed. The cortices are pale brown red with a slight purplish cast. The pyramids are dark brown and in the region of the apex many of them show pale yellowish opaque smooth discrete and confluent streaks. The glomeruli show no definite prominence. The pelvis shows injection of the blood vessels with minute reddish spots. The ureters and bladder are normal.

Misopimplia examination. Throughout the whole tissue there is marked edema. The cortical portions of the kidney show normal glomeruli with some congestion of the blood vessels and the great majority of the cortical tubules free from pus but the epithelium shows cloudy swelling. In one portion of the kidney there is an area of extensive infiltration and necrosis of all renal tissue extending transversely across a portion of one of the pyramids. In this area the tubular epithelium is necrotic, the blood vessels are ruptured and the portion of the pyramid beyond is anemic. Above the area of necrosis the blood vessels are congested. In the remaining pyramids there are fine streaks of polymorphonuclear infiltration extending from the bases of the pyramids toward the apex (Fig. 7). In the least extensive of these processes the lumen of the tubule is seen to contain clumps of bacteria surrounding which is a lens-shaped area of necrosis including the epithelium of the tubule and the interstitial tissue on each side sometimes extending far enough to include the adjacent tubule on each side. Beyond this area is a border of pus-cell infiltration. Occasionally throughout the cortical regions there are a few tubules containing pus-cells.

Bacteriological report. Cultures from the spleen show profuse growth of streptococci and question bacilli. Cultures from the heart blood show profuse growth of streptococci.

Sections stained for bacteria show a few streptococci and bacilli without attending suppurative processes in the glomeruli and tubules of the cortex. In some instances considerable numbers of these organisms are found in the tubules containing the pus-cells previously described (Fig. 8). In the area of transverse lesion of a portion of a pyramid previously described the tubules at the level of the necrotic area are found in many cases almost completely destroyed yet the portions of the tubular epithelium remaining present the picture of necrosis due to the presence of a large number of streptococci and a few bacilli within the lumen. Between these remnants of tubules is extensive infiltration with polymorphonuclear leucocytes, fragments of renal epithelium and some free blood. The bacteria found in the whole area of necrosis just described are chiefly situated in the remnants of tubules with a few scattered bacteria among the blood and pus-cells between the tubules. In the anemic area at the tip of the pyramid just described the blood vessels are entirely empty. There is no infiltration of the interstitial tissue. The tubules consist of large plugs of streptococci and bacilli the former greatly

predominate. In the small lozenge-shaped areas in the region of the straight tubules previously described the central area, that is the lumen of the tubule, is seen to consist of large numbers of streptococci and a few bacilli. Surrounding this group of bacteria is to be seen necrotic tubular epithelium surrounded by a zone of pus-cells. Among the pus-cells of the periphery bacteria are found with great difficulty. The pelvis of the kidney contains streptococci and bacilli.

CASE 3 Autopsy No 3575 West Surgical 307462 Male, age 22 March 26, 1906. *Admission diagnosis* Carbuncle of neck. *Present illness.* N previous urinary symptoms. Carbuncle of neck one week's duration. *Operation.* Incision of carbuncle followed by secondary operation for cellulitis of neck. Patient died fifth day. Culture from carbuncle, staphylococci. *U. inc.* acid, albumin, slightest possible trace rare epithelial and pus-cell. *Clinical diagnosis* septicemia.

Autopsy 18 1/2 hours post mortem. Anat. micro diagnosis *Operation wound* carbuncle of neck, abscesses of lungs, myocardium, kidneys, and rectus muscle, small mural thrombus right ventricle, acute pericarditis, peritonitis, soft spleen, staphylococcus septicemia.

Kidney Combined weight 306 grams. Capsules strip easily. Surfaces show at several points minute yellowish spots situated singly and in groups. On section these are seen to be the surfaces of small collections of pus. Usually they arise within the cortex but in many instances they extend down often within the central portion of a pyramid as far as the middle of the pyramid. Markings retained cortex not narrowed. The pelvis, ureters, bladder and urethra are negative.

Microscopic picture in section. There is edema with some few areas of acute degeneration throughout the otherwise normal kidney tissue. Numerous sections show the presence of abscesses, mostly in the cortex (Figs. 9, 10, and 11) some in the pyramids and one or two at the tips of the pyramids (Fig. 12). In none of these is there evidence of embolism. The majority of the abscesses of the cortex appear to take origin in glomeruli. The abscess is surrounded by a generous polymorphous clear infiltration. In most instances the abscess is situated a few millimeters below the surface (Fig. 9). In these instances the tubules leading down into the kidney substance are seen filled with polymorphonuclear leucocytes and surrounded by considerable polymorphous infiltration of the interstitial tissue (Fig. 11). These tubules often lead downward to a second and even third abscess apparently of more recent origin than the one near the surface (Fig. 12). These secondary abscesses show the tubules both above and below them to be filled with polymorphous clear leucocytes to a considerable distance from the abscess. In one instance a third abscess was found located just beneath the mucosa of the pelvis in the tip of the pyramid and showing a fine line of interstitial pus-cell infiltration connecting it with the overlying

two abscesses (Fig. 13). A noteworthy observation found with constancy is that where an abscess is situated a few millimeters below the surface of the kidney the tubules above, although they may be surrounded by pus-cell infiltration do not contain pus (Fig. 9) while those tubules below the abscess contain considerable pus (Fig. 10).

Bacteriological facts. Cultures from the heart blood, operation wound, abscess of the rectus muscle and fluid from the peritoneal cavity show profuse growth of staphylococcus albus.

Sections stained for bacteria show only staphylococci. These are found in large masses within the abscesses, are almost universally found within the tubules containing pus, are occasionally found in apparently undamaged tubules immediately beneath abscesses, and are found in large plugs apparently arrested within the tubules at the tips of the pyramids. The pelvis contains considerable number of staphylococci.

2 THE LESIONS PRODUCED BY PYOGENIC ORGANISMS DIFFER IN ESSENTIAL PARTICULARS AND ARE DISTINGUISHABLE FROM THOSE PRODUCED BY NON PYOGENIC ORGANISMS

In much of the literature of renal infections one must inevitably infer that the authors believe that no definite distinction can be drawn between lesions produced by different types of bacteria. Thus Mallory in his *Principles of Pathological Histology* p. 573 says:

The lesions produced by a number of organisms may closely resemble one another. On this account an etiological classification is ordinarily carried out with only a few organisms such as the tubercle bacillus and *treponema pallidum*.

Following the same idea he says somewhat later:

Infectious agents which most commonly produce lesions of the kidney are the staphylococcus aureus, the streptococcus pyogenes, the bacillus coli, and the tubercle bacillus. Other organisms which occur less commonly are micrococcus lanceolatus, the bacillus m. osus capsulatus, actinomyces, and *treponema pallidum*.

Thomson Walker has this to say upon the subject of the bacteriology of renal infections:

The bacillus coli communis is the most common cause of renal infection occurring in 75 per cent of cases. The next most frequent are the staphylococcus (especially the aureus) the streptococcus, the proteus of H. user and the bacillus pyocyaneus.

A little later under the heading of Pylitis of Pregnancy he says:

The bacteriology is similar to that of other renal infections.

In contradistinction to these views we believe that the lesion produced by the pyogenic and pyogenic bacilli, the pyogenic group, differ essentially from the lesion produced by non-suppurative organisms, chiefly the colon typhoid group.

3. THE LESIONS PRODUCED BY THE PYOGENIC GROUP

These lesions consist of perinephritic abscess, capsular abscess, capsule, cortical abscess, septicaemia and diffuse suppuration. In support of this proposition we submit case 4 to be inclusive.

CASE 4. *Sp. men.* 15 3-30 West Surgical 93-3 Male age 40 February 6 1901 Admission diagnosis: Stone in right kidney. *Present illness.* No previous bladder symptoms. Three months ago sudden sharp non-radiating pain in right flank accompanied by nausea and vomiting with temperature which has continued. He has had some haematuria. *Physical examination.* Shows much spasm and enlarged kidney on right. *Urine at admission.* Aid very light trace of albumin, many leucocytes, rare red blood-corpuscle. *Cystoscopy.* Bladder normal, right kidney infected with staphylococci, renal pelvis not abnormal, which excludes tumor and pyonephrosis.

Diagnosis. Staphylococcus infection of right kidney, nephrectomy advised. *Ray* showed right kidney enlarged, no evidence of stone. *Culture* from urine showed staphylococcus pyogenes aureus. *Operation.* Nephrectomy. Kidney found enlarged, covered by a thick fibrous capsule which was oedematous. Capsule which was 1 to 2 centimeters thick stripped on with difficulty and several small abscesses evacuated in the process. The kidney was large, whitish, with red yellow mottling. The pelvis was not dilated, the ureter was normal. Uneventful recovery.

Pathological report. A somewhat enlarged kidney with adherent perirenal fat. Sections show multiple abscesses scattered throughout the cortex and medulla. Intervening tissue opaque. Examination shows extensive infiltration with round cells with here and there abscess formation. Tubular epithelium is swollen. Multiple abscesses present.

Sections stained for bacteria. Show many staphylococci in clumps in the abscesses. A few bacteria are to be seen in the areas of infiltration above described. These areas show subacute infectious processes with obliteration of the tubules to such an extent that the bacteria outside abscesses can

not be located with a certainty. Cocci are present in the pelvis without any evidence of pyelitis.

CASE 5. Autopsy No. 10 West Surgical 331-111 Male age 60 March 10 1901 *Present illness.* Septicæmia two weeks duration. On admission 101.5 Pus from hand showed staphylococcus pyogenes aureus and bacilli. Patient died on sixth day with symptoms of pneumonia. *At autopsy.* 55 per cent hand metastatic pneumonia.

Autopsy. hour post mortem. Anatomical diagnosis: Gangrene of finger, phlegmon of arm, secondary abscess, sternoclavicular articulation and upper connective tissue abscesses, pneumonia and kidneys acute hyperplasia of spleen.

Kidneys. Considerably enlarged. Capsules strip easily revealing numerous small abscesses in the substance of the kidneys. On section similar abscesses are seen scattered irregularly through the cortex and less abundantly in the pyramids. Cortical tissues opaque and swollen.

Bacteriology. Abscesses of kidney and lung and heart blood show growths of staphylococcus pyogenes aureus.

Staphylococcus aureus. Numerous staphylococci in the abscesses, sometimes in the bloodstream. The majority of glomeruli and tubules are apparently undamaged. Many abscesses in the pyramids appear from the location of bacteria to take origin from the lumen of the tubules. Many epithelial cells are filled with phagocytosed cocci. In one or two areas abscesses appear to take origin in the interstitial tissue in one of which an embolus can be demonstrated.

CASE 6. Autopsy No. 49 West Surgical 64-5 Male age 34 November 3 1909 *Present illness.* Admitted with diagnosis of tumor of the bladder with cystitis. Temperature 101. *Urine.* Neutral reaction, albumin per cent, sediment much blood. Patient unable to void on account of hæmaturia placed on constant drainage. Amount of urine extremely small. Patient died without operation on the twentieth day. *Clinical diagnosis.* Tuberculosis of the prostate () uremia.

Autopsy. 11 hours post mortem. Anatomical diagnosis: Squamous cell carcinoma of bladder with bone formation in the stroma, suppurative nephritis of right kidney, occlusion of ureters in bladder wall, atrophy of right kidney with pelvic dilation, compensatory hypertrophy of left kidney, dilation of ureters.

Kidneys. Right kidney weighs 109 grams, left 263 grams. Capsules strip easily. Markings of the left kidney are retained, right kidney not clearly defined. Cortex of right kidney is narrowed, that of left is normal. The pelvis of the right kidney is dilated leaving only a small amount of kidney tissue. Scattered throughout the kidney tissue are numerous small dark red hemorrhagic areas. The left kidney shows a slightly dilated pelvis. Both ureters are markedly dilated, the right filled with blood.

Probe cannot be made to pass through the urethrovaginal orifice on either side. The bladder wall is markedly thickened especially on the right where there is a large grayish white mass extending beyond the median line and infiltrating the bladder wall.

Microscopic examination. Right kidney shows much fibroid atrophy of the tubules and glomeruli and infiltration with lymphocytes. Here and there small abscesses are present. Left kidney shows edema. Here and there a small focus of atrophy with lymphocytic infiltration is seen.

Bacteriological report. Cultures from the heart blood show no growth. *Sections stained for bacteria.* The sections preserved from this autopsy show no true abscesses but only low grade kidney changes. Large coagula are found in the glomeruli of the tubules and scattered throughout the interstitial tissue, may be post mortem invasion.

CASE 7. Autopsy No. 2364. South Surgical 79-203. Female age 1 year 10 months, M y 1909. *Present illness.* Came in for tumor of the left kidney. For past two weeks has had hematuria followed by fever. *Temperature* at entrance, 1.2.

Second day after admission to the hospital, while eating, child suddenly uttered a piercing shriek, turned cyanotic, and died. *Clinical diagnosis.* Sarcoma of kidney pulmonary embolism.

Autopsy 4 hours post mortem. Anatomical diagnosis. Adenosarcoma of the left kidney with metastasis in the abdominal lymph nodes, suppurative nephritis, pulmonary embolism.

Kidney. The left ureter when followed upward opens into an irregular yellow mass which contains considerable broken down creamy white material. Just beyond the opening of the ureter there is a small strip of tissue showing markings with pyramids and glomeruli. In one place there is a streak of yellow running through what appears to be a pyramid. This kidney tissue is continuous with and passes over into large tumor mass. The ureters and bladder are normal.

Microscopic examination. Kidney shows the tumor to consist of adenocarcinoma of the kidney. In one section in some of the renal tissue are foci of lymphoid tissue. In the right kidney there are foci of suppurative nephritis.

Bacteriological report. Culture from the heart blood shows no growth. *Sections stained for bacteria.* In three places in the kidney small arteries are found plugged with hyaline masses containing a few partly disintegrated cells and large numbers of staphylococci. In one instance there is evidence of some suppuration about the plug while the other two there is no evidence of tissue change.

CASE 8. Autopsy No. 63. South Surgical 48-148. Male age 15. November 8, 1900. *Admission diagnosis.* Septic arm. *Present illness.* Five months ago patient had felon of finger which is now healed. Two days ago without apparent cause, the right elbow became swollen and painful.

Temperature. 3. *Operation.* Incision and drainage of elbow joint. Pus showed staphylococcus pyogenes aureus. Died ninth day. *Urine examination* not recorded. *Diagnosis.* Septicemia, osteomyelitis.

Autopsy 9 1/4 hours post mortem. Anatomical diagnosis. Operation wound of right arm with osteomyelitis of the humerus, multiple abscesses of the lungs serofibrinous pericarditis, abscesses of the myocardium, abscesses of the prostate suppurative nephritis, acute degeneration of the liver acute hyperplasia of spleen, ecchymosis in the mucosa of the stomach, tuberculosis of the left epididymis and testis staphylococcus septicemia.

Kidney. At several points in each kidney just beneath the capsule are yellowish purulent foci the size of a pinhead.

Bacteriological report. Cultures from the heart blood show staphylococcus pyogenes aureus. Liver spleen, lung and pericardium show the same.

Microscopic examination. The cells of the tubules of the cortex show some swelling and granulation. There are a few small abscesses apparently originating in glomeruli. One or two of the convoluted tubules show beginning bacilli formation.

Sections stained for bacteria. show large numbers of staphylococci in the basement. Staphylococci are found in the tufts of glomeruli capsule of Bowman, tubules, and a few in the lymph spaces. Small abscesses in the lower tubules show the coagula mostly confined to the lumen of the tubule.

CASE 9. Autopsy No. 2784. East Surgical 7-20. Male age 42. January 8, 1911. *Present illness.* Uremia, hematuria, and pyuria at entrance to hospital. *Urine examination* not recorded. *Temperature* 99. *White blood count* 8,000. *Cytoscopy* showed inoperable carcinoma of the bladder. Patient died the following day. *Clinical diagnosis.* Uremia carcinoma of the bladder infected kidneys.

Autopsy 6 1/2 hours post mortem. Anatomical diagnosis. Carcinoma of the bladder pyelonephrosis suppurative nephritis pyelonephritis abscess, soft spleen.

Kidneys. Right kidney weighs 260 grams. The pyelonephritic tissue is markedly thickened and shows extensive infiltration with pus. The capsule strips with difficulty leaving an irregular surface dotted over with numerous minute yellow points which yield pus. The cortex is 5 to 8 millimeters. On section the surface shows minute collections of pus situated mainly in the cortical region. The pelvis and ureter are slightly dilated. The right ureter is somewhat occluded by a new-growth of tissue in the bladder. The left kidney weighs 93 grams. The pyelonephritic tissue is greatly thickened and shows extensive infiltration with pus. The capsule strips leaving lumpy surface dotted over with abscesses. The cortex measures 5 to 6 millimeters. Section surfaces show minute collections of pus mainly in the cortical region. In some places the tubules are dilated. The calices show yellow necrotic flakes.

The left ureter is dilated and partly occluded by new growth of bladder. The bladder mucosa is inflamed. The prostate is not enlarged. The upper part of the organ is involved in a new growth of the bladder wall which extends down onto the posterior portion of the prostate.

Microscopic examination of the kidney is not recorded.

Bacteriological report. Culture from heart blood. No growth. Sections stained for bacteria show no bacteria other than staphylococci. They are found in the lymph spaces and within the lumina of tubules, sometimes phagocytized in the epithelium of the tubules and diffusely in the abscesses. No bacilli are seen in the kidney tissue. There are a few living free in the pelvis.

CASE 10. Autopsy No. 2381. South Surgical 182-180. Male age 24. June 12, 1909. *Present illness.* Injury to right forearm eight days ago. Three days ago became delirious. Arm much swollen. *Blood cultures* showed staphylococcus pyogenes aureus cultures from arm staphylococcus aureus. *Urine examination* not recorded. *White blood count* 17,200. *Temperature* 103-108. Died second day after entrance.

Clinical diagnosis. Septicæmia, septic wound. *Autopsy* 17½ hours post mortem. Anatomical diagnosis. Septic wound of forearm, right, multiple abscess of myocardium, liver, kidneys, brain, acute splenic tumor.

Kidneys. Combined weight 312 grams. Capsules free. The surface is marked by numerous round and oval abscesses surrounded by reddish zones. The stellate veins are injected. On section cortex is of normal thickness. Both cortex and medulla show numerous fairly sharply circumscribed round spots, many of them surrounded by reddish zones. Both kidneys present practically the same picture. The bladder shows injected mucosa and dark colored areas. Pelvis and ureters are normal. *No microscopic examination or bacteriological report is recorded.* Sections stained for bacteria show large numbers of staphylococci found only within the small abscesses.

CASE 11. Surgical Case No. 12-90. South Surgical 15-30. Male age 28. December 24, 1907. *Past history.* Gonorrheal infection one year ago.

Present illness. For three weeks has had hæmaturia and pyuria with dull aching pain in the right kidney. No stricture.

Urine. acid, large trace of albumin, pus and blood. *Temperature* 100. *Operation* nephrectomy with drainage, uneventful recovery. *Clinical diagnosis.* Local suppurative nephritis.

Pathological report. Large kidney, fibrous at one end with abscess. Several small purulent foci scattered through the substance. Sections stained for bacteria showed only staphylococci present; these are found only in abscesses.

CASE 12. Autopsy No. 138. East Surgical vol. 328 p. 1. 176. Male age 62. July 9, 1890.

Diagnosis. Carcinoma pancreas. *Past history.* Eight years ago had pain in right lumbar region referred to groin and testes. *Present illness.* Admitted to the hospital for gastric symptoms. *Urine examination* on admission was negative, save for slight trace of albumin, occasional pus-cells, no cast. *Operation.* Exploratory laparotomy for carcinoma of pancreas. *Operation* continued became septic. Small abscesses developed about the holes withiliary abscesses in deep part throughout the length of the wound. *Continued* temperature after operation ranging from 100 to 104. After one month from operation patient wound gradually became lean, showing good granulations. The patient however continued to lie on ground and became progressively weaker. The temperature again rose. He developed phlebitis in right leg, apasticty in right hand and arm and swelling of left parotid region. Died on the thirty-eighth day.

Autopsy hours post mortem. Anatomical diagnosis. Carcinoma pancreas and adjacent glands involve most of the liver and glands along the abdominal aorta and iliac vessels. Abscess in tissue of the abdominal wall, acute purulent phlebitis, oedema lungs with abscesses of upper right lobe and lower left lobe, degeneration of the kidneys with subacute abscess formation.

Kidneys enlarged. Combined weight 544 grams. Cortices 5 to 6 millimeters. Capsules strip with a few adhesions. Surfaces yellowish red with thickly sown pinholes to bean sized areas, yielding on section whit semi fluid pus. These areas are more numerous in the right kidney. On section the pelvis is not remarkable. The markings are indistinct in places. Scattered through the tissue are small yellowish areas and patches mostly in or near the cortex. In the left kidney, but also showing every where in the right kidney, are yellowish streaks extending down from the cortex into the pyramids. The bladder shows nothing abnormal.

Bacteriological report. Cultures from the heart blood, liver, kidneys, pleura, spleen, and pus in the peritoneal cavity show staphylococcus pyogenes aureus. Pus from the peritoneal cavity shows in addition bacillus coli communis.

Microscopic examination shows a few scattered darkly stained areas equally distributed through the cortex and pyramids. These areas are on the average the size of a pinhead. In the pyramids they seem elongated in the direction of the tubules. On examination they are seen to consist of numerous pus-cells closely packed together in the midst of which remains of kidney structure are rather faintly indicated. Interspersed among the pus are small granulation tissue-cells. This condition would indicate that the process had lasted for some time. These areas are abscesses in the process of healing. Considerable granular detritus and colorless ring like bodies lie in the lumen of the tubules. No emboli are made out.

Sections stained for bacteria. Right kidney shows in one corner of the section several small abscesses.

two or three times the size of a glomerulus, all of which seem to take origin from glomeruli or the neighboring proximal convoluted tubules (Fig. 13). In the centers of these areas are large masses of staphylococci. There are many new connective-tissue cells. Surrounding the abscess areas there is a diffuse infiltration with new connective-tissue cells and polymuclear leucocytes. Many of the tubules leading toward the pelvis from these areas show plugs of pus and desquamated epithelial cells thickly studded with phagocytized bacteria. In the region of the distal convoluted tubules such bacterial plugs are seen to form the centers of small abscesses. Throughout the remainder of the section the tissue is for the most part unchanged. In some areas, however, there is considerable desquamation of the epithelium of the tubuli contorti. In all such portions of the sections the blood vessels are seen to contain large numbers of staphylococci, most of which are within the leucocytes (Fig. 14). In several areas the capillary entering the glomerulus and the tuft of the glomerulus contain large numbers of staphylococci (Fig. 15). In the glomeruli the staphylococci are seen lying in the capillaries and also free in the capsule of Bowman (Fig. 16). In none of these glomeruli was there any extravasation of blood into the capsule indicating a rupture of the capillary. In one of the glomeruli, in which a fortunate plane of section shows a considerable portion of the first part of the tubule, bacteria are seen not only lying in the capsule of Bowman but entering the tubule (Fig. 17). In all portions of the convoluted tubules considerable numbers of bacteria are seen in the tubules but mostly contained within the epithelial cells (Figs. 18 and 9). In the straight collecting tubules bacteria seem always to lie in the lumina of tubules. In the pelvis staphylococci and bacilli are found. The pelvic mucosa looks normal. Some few bacteria are to be found in the interstitial tissue, most of them lying in the lymph spaces.

NOTE.—This kidney seems to indicate that there has been a general infection. In the first there was considerable abscess formation resulting, which had begun to heal. There seems in addition to have been severe septicemia, many bacteria from which are seen in the process of excretion through undamaged glomeruli.

CASE 13. Autopsy No. 3 West Medical 510-163. Male, age 69, September 20, 1898. *Present illness.* Has been sick for two weeks with dyspnea as chief complaint. *Physical exam.* Shows nothing of interest save high temperature and abscess back or neck. *White blood count* 83,000. *Urine* acid, cloudy albumin, slight trace sediment few hyaline casts, blood, leucocytes. Died fourth day. *Discharge diagnosis.* Septicemia. Abscess of neck.

Autopsy 6 hours post mortem. Anatomical diagnosis. Phlegmon right shoulder multiple abscesses lungs, suppurative nephritis with infarctions, acute hyperplasia spleen, decubitus.

Kidneys. Capsules free cortex of normal width, markings retained. Here and there in the pyramids and in the cortex are a few grey opaque pinhead sized points. In the kidney there is a large wedge-shaped area extending from the base of a pyramid upward to the capsule. The tissue is pale, and the outline is marked by a grey zone. Pelvis ureters, and bladder normal.

Microscopic examination. Micrococci seen in the abscesses. In one or two instances plugs of micrococci are found in the small vessels. Cultures from the carbuncle in the back show staphylococcus pyogenes aureus. Heart blood spleen, liver and kidney the same.

Sections stained for bacteria. One area of the small pyramidal area of suppuration apparently takes origin from a bacterial embolus in a small artery. In other instances the glomeruli are clearly the seat of abscess formation, while in still others plugs of bacteria are found in the lumina of tubules surrounding which there is a narrow area of necrosis of epithelium, outside of which is infiltration with polymorphous leucocytes. In still other areas staphylococci singly or in small groups are found in the arterioles entering glomeruli. In the glomeruli they are found within the capillaries and in the tubules, in many cases phagocytized within epithelial cells of the convoluted portion. In some instances bacteria are seen within epithelial cells in apparently normal tubules.

CASE 14. Autopsy No. 507 West Medical 76-47. Male, age 65 May 1900. *Present illness.* Eleven months painful and difficult urination brown, cloudy urine. Four months severe gastric symptoms suggestive of cancer. *Temperatures* normal entrance. *Urine* alkaline, albumin slight trace, occasional cast. No urine culture recorded.

Four days later without apparent reason patient began to have hematuria with small amount of pus, accompanied by rise of temperature to 98.5 and died the third day following.

Autopsy 8 hours post mortem.

Anatomical diagnosis. Adenocarcinoma of stomach, multiple carcinoma of small intestines, chronic nephritis, suppurative nephritis of right kidney renal and ureteral dilatation, arteriosclerosis, cholelithiasis, small fibroma of bladder wall.

Kidneys. Combined weight 200 grams. Left kidney capsule strips but is somewhat adherent. Cortex is 10 millimeters in width. Left ureter is slightly dilated along its entire course but opens freely into the bladder. The mucosa is negative. Right kidney capsule strips with some fine adhesions. The granular surface is dotted over in many places with minute yellow spots. On section the tissue is firm, cortex extremely narrowed. The yellow spots described as present on the surface project down into the kidney tissue as minute, small, reddish irregular areas. The pelvis is slightly dilated. The mucosa is smooth. The right ureter is dilated its mucosa is smooth and opens

Fig. A. Typical micro-pie held from the kidney of a patient known to have had chronic pyelonephritis of bacterial origin. It ended by a marked fall in phthalin output and subsequent return to normal function. The kidney is essentially normal. Photob. L. S. Brown. 45

Fig. B. Typical micro-pie held from rat kidney through which parenteral bacillus albus has been passed in large numbers on three occasions. Section on hanging glomerulus at () the kidney is normal. Photob. L. S. Brown. 45

freely into the bladder. The bladder mucosa is not remarkable save that in one area there is a round minute pedunculated mass springing from the mucosa. The prostate is negative.

Microscopic examination. There is marked fibroid atrophy of the renal tissue with much arteriosclerosis, extensive suppuration and destruction of renal tissue in the surrounding areas.

Bacteriological report. Cultures from spleen show question of bacilli. Sections stained for bacteria show only staphylococci. These are found in abscesses and a few in the tubules within the protoplasm of a clump of pus-cells.

CASE 15. Autopsy No. 2008 West Medical 814-201. Male, age 64, February 7, 1912. *Past history.* Boils on the shoulder three years ago. For six years has had diabetes. *Present illness.* Sore toe of two weeks duration. Coma. *Physical examination.* Shows diabetic gangrene. Temperature normal. Urine contains much free blood and pus, slight trace of albumin, sugar, acetone and diacetic present. Patient sent to ward where he promptly died. *Clinical diagnosis.* Diabetes, acidosis, coma.

Autopsy. 9 hours post mortem. Anatomical diagnosis: Diabetes, arteriosclerosis, abscess of prostate, amyloid kidneys, gangrene of toe, soft spleen, small abscess of kidney, staphylococcus septicæmia.

Kidneys. Combined weight 540 grams. Capsules strip leaving smooth surface save in one point on the right kidney where there is a collection of fibrinopurulent material which extends into the perinephric fat. The cortices are not narrowed. In the substance of the right kidney, a short distance below the collection of pus on the surface there is a

small dark red area the central portion of which is soft. The ureters are free. The bladder shows hypertrophy of the trabeculae and the mucosa of the trigonum shows swelling and dirty redish discoloration with here and there minute yellowish soft areas. The prostate is slightly enlarged and shows numerous small areas of pus throughout the organ. They are most numerous in the middle lobe and extend up beneath the trigonum. Cover glass preparations from the prostatic pus show staphylococcus.

Microscopic examination. Kidneys show amyloid infiltration of the small arteries and glomeruli, oedema with some areas of necrosis and pus-cell infiltration. Sections of the prostate show suppuration and abscess formation.

Bacteriological report. Cultures from the heart blood show many colonies of staphylococci. Sections stained for bacteria show staphylococci alone in the small abscess cavity.

CASE 16. Autopsy No. 2262 West Medical 712-95. Female, age 45, November 30, 1908. *Past history.* Negative save for polyuria five years ago at which time diagnosis of diabetes made. *Present illness.* Patient comes in for abnormal menstruation. Urine acid, no albumin, sugar, acetone or diacetic present, moderate amount of pus. Patient put on very strict diabetic diet. Patient continued comfortable except hungry for 15 days at which time she became brown, developed a slight cough and scattered rales in the lungs and died on the seventeenth day. *Clinical diagnosis.* Diabetes, acidosis, endometritis.

Autopsy. 14 hours post mortem. Anatomical diagnosis: Glycosuria, tuberculosis of left lung.

Fig. 2. Proximal convoluted tubule of the cortex filled with desquamated epithelium and containing bacteria.

soft spleen suppurative nephritis with milky abscesses of right kidney.

Kidneys. Combined weight 385 grams. Capsules strip easily save over an area of the right kidney where there is a reddened spot 5 millimeters in diameter. This area is dotted with minute abscesses. Cover glass preparation from pus is negative for tubercle bacilli. On section the remaining tissue of the kidney is firm, markings are visible cortex is not narrowed, the pyramids are brownish red and show indefinite minute yellow areas in places. Bladder, ureters and pelvis are not remarkable.

Microscopic examination. In two sections of the kidney there are abscesses with suppurative infiltration. There is no tuberculosis.

Bacteriological report. Cultures from the heart blood and spleen show growth. Sections stained for bacteria show some hemorrhagic glomeruli in which are cocci in very small numbers. An occasional group of cocci can be found in the lumen of tubules low down toward the tips of the pyramids and a few in the pelvis. The sections preserved from this kidney show no abscesses.

CASE 17. Autopsy No. 828 East Surgical 554-275. Male, 19. November 5, 1906. Present illness: Carbuncle upper lip five days duration. Intense odema, fever. No renal tenderness or masses. Temperature 104. Urine negative (but no sediment done). Patient died third day. Clinical diagnosis: Carbuncle of lip septicaemia.

Autopsy 6 hours post mortem. Anatomical diagnosis: Carbuncle of lip, multiple abscess of the lung with empyema, suppurative infiltration of the anterior and superior mediastinum, suppurative epiphitis, acute hyperplasia of spleen, staphylococcus pyogenes aureus septicaemia.

Kid vs. Combined weight 360 grams capsules slightly adherent. There are three or four minute suppurative foci in the kidneys. The cortices are normal in width and the markings retained. The bladder and ureters are not remarkable.

Microscopic examination. There is cloudy swelling of the epithelium of the tubules.

Bacteriological report. Cultures from the heart blood and spleen show staphylococcus pyogenes aureus. Sections stained for bacteria show large clumps of staphylococci within the abscesses, none in any other part of the section.

CASE 18. Autopsy No. 20 South Surgical 9055. Female, age 43, March 16, 1904. Present illness: Recent pneumonia followed by empyema with symptoms of brain abscess of two weeks duration. Urine examination negative thirteen days later slight trace of albumin, small amount of blood and pus. Operation: Exploration of old empyema. Following operation patient became unconscious and general paralysis developed. Patient died thirty-third day. Clinical diagnosis: Empyema, brain abscess.

Autopsy. Anatomical diagnosis: Abscess of brain, chronic empyema left with sinus communicating with the pleural flexure of the colon, subdiaphragmatic abscess, ulcer of stomach with secondary carcinoma, abscess of kidney operation wound.

Kidneys. The kidneys are of normal size capsule stripped. At one point in the surface of one of the kidneys is a small abscess which extends a short distance into the kidney tissue. The bladder and ureters show nothing abnormal.

Microscopic examination. Kidney sections show rather extensive degeneration of the renal elements.

Bacteriological report. Cover glass preparations from the pus of the brain abscess show leucocytes,

Fig. 3. Microphotograph of area of complete transverse lesion (—) base of pyramid. Below is shown necrotic pyramid. b—b Congested blood-vessels.

staphylococci streptococci and bacilli. Cultures from the heart blood show no growth liver shows many colonies of colon like bacilli and a few streptococci spleen shows slight growth of colon like bacilli. Sections stained for bacteria show clumps of staphylococci in abscesses none found in the tubules or pelvis.

CASE 19. Autopsy No 1093 West Surgical 441-45. Female age 3 June 1 1904. Past history negative as to genito-urinary tract. Present illness: Five years ago gall stone symptoms urine examination on admission negative. Operation: cholecystectomy with drainage of common duct. Slight sepsis of wound occurred. During convalescence swelling of right parotid gland which was later incised. Patient died on the thirty fourth day. Clinical diagnosis: Gall stones and pyæmia.

Autopsy 14 hours post mortem. Anatomical diagnosis: Cholecystectomy with open bile-duct subcutaneous abscess of the walls of the wound phlegmon of neck abscesses of kidneys septicæmia staphylococcus pyogenes aureus.

Kidneys. Weight is not mentioned capsules strip easily. In two or three places in each kidney the surface shows several small abscesses which extend a short distance into the kidney substance. Cover glass preparations from the pus of these abscesses show leucocytes and staphylococci. Ureters and bladder show nothing worthy of note.

Microscopic examination. Sections from the kidneys show abscesses.

Bacteriological report. Cultures from the heart liver spleen skin abscesses and kidney abscesses show growth of staphylococcus pyogenes aureus. Sections stained for bacteria. Abscess cavities show large clumps of staphylococci no other bacteria.

CASE 20. Autopsy No 1039 West Medical 384-40. Male age 38 March 15 1902. Present illness: Seven weeks ago began to feel poorly slight gastric symptoms restlessness at night. Two weeks later gave up work. Still later he began to develop pain and local areas of soreness in the left arm. Temperature at entrance 100 and continued as a high septic temperature. Physical examination: Large abscess of right shoulder another over sacrum. On back and extremities numerous small semi-furrow abscesses. Pus from abscesses showed staphylococcus pyogenes aureus. White blood count 26,000. Urine acid albumin slightest possible trace sediment rare casts but some with pus-cells adherent few pus-cells much epithelium. Patient continued with high fever until death on the fifth day. Clinical diagnosis: Pyæmia, multiple abscesses.

Autopsy 39 1/2 hours post mortem. Anatomical diagnosis: Multiple abscesses of the liver thrombosis of hepatic vein multiple abscesses of lungs kidneys and subcutaneous tissue of extremities and trunk hyperplasia of spleen purulent otitis media, septicæmia staphylococcus pyogenes aureus.

Kidneys. Combined weight 416 grams. Capsules free. Scattered throughout the substance of

Fig. 4. Drawing through area of kidney including cortex zone of suppuration and parts of renal papilla. Labels: a renal cortical tubules b congested area of transverse suppuration c lesion (purplish area of Fig. 1) marked by c empty blood vessels of anemic papilla.

each kidney are several small abscesses containing pus. Some of these are arranged in more or less confluent groups. Cortices of normal width with markings retained. Bladder prostate and ureters normal.

Microscopic examination. Aside from the abscesses, the renal tissue is not remarkable.

Bacteriological report. Cultures from the heart liver and spleen abscesses of the right kidney hip and left ankle show profuse growth of staphylococcus pyogenes aureus. Cover glass preparations from these abscesses show staphylococci but no other bacteria. Sections stained for bacteria. Abscess cavities contain clumps of staphylococci no other organisms.

Fig. 5 Microphotograph of necrotic renal papilla showing necrosis of interstitial tissue and epithelium of the tubules with fragmentation of nuclei and loss of cell outline. The lumen of one tubule is filled with large clumps of bacteria (almost entirely colon bacilli). Empty blood vessels seen (x400). Bacteria treated with 40 per cent formalin to cause them to retain the gram stain for photomicrographic purposes. Phot. by L. S. Brown, 500.

Fig. 6 Microphotograph showing destruction of a tubule by bacteria contained within its lumen. Remnant of tubule seen to the left. Bacteria are chiefly streptococci. Phot. by L. S. Brown, 500.

CASE 21: Autopsy No. 986 East Medical 573, 138 Female, age 5, December 2, 1900. *Past history* negative. *Present illness* Eight days ago symptoms of acute infection with vomiting, loss of appetite, shortness of breath and urinary incontinence. *Physical examination* Considerable fluid in abdomen, evidence of fluid in both chests. Question of tumor mass in abdomen. Temperature normal and remained so. White blood count 62,000. *Urine* acid, slight trace of albumin, moderate amount of pus. Abdominal fluid, exudate cells polymorphonuclear leucocytes. A few cocci in abdominal fluid. Patient died suddenly, third day. *Diagnosis* Ovaria cyst, septicemia and pyrexia.

Autopsy 6 hours post mortem. Anatomical diagnosis: Cystomata of the ovaries with suppuration and gangrene, compression and dilatation of the right ureter, suppurative nephritis of the right kidney.

Kidneys Left kidney somewhat larger than right. Capsule strips. Cortex narrow markings retained. On the surface of the right kidney are number of whitish slightly elevated areas which on section show purulent material. These areas are not sharply outlined from the surrounding renal tissue and show some tendency to extend in the form of streaks into the cortex.

Microscopic examination On section kidney shows an area of infected renal tissue infiltrated with polymorphous leucocytes. The renal tubules appear to be disintegrated.

Bacterial cultural report Cultures from the heart and spleen no growth from liver two colonies of bacillus coli communis. Peritoneal exudate also a

bacillus coli communis bacillus aerogenus capsulatus and staphylococci. Section stained for bacteria also few staphylococci. One of the tubules. There are bacteria in the section preserved.

CASE 22: Autopsy No. 83 South Surgical 60-64, Male age 3, January 6, 1902.

Past history Gonorrhea twice. *Present illness* Appendix symptoms three weeks duration with abscess at time of entrance to hospital. On entrance bowels slight trace of albumin sediment showed pus and very many casts, some with pus cells adherent. Septic temperature ranging from 100 to 104. White blood count 43,000. Free pus in the abdomen, culture from which showed staphylococcus pyogenes aureus. Patient died on the nineteenth day after admission. *Clinical diagnosis* Appendix abscess, septicemia.

Autopsy 34 hours post mortem. Anatomical diagnosis: Gangrenous appendicitis with abscess formation with perforation and gangrene of caecum, suppurative phlebitis ilioecolic and superior mesenteric veins, suppurative thrombophlebitis portal vein, multiple abscesses liver, abscesses right kidney, laparotomy wound, cut hyperplasia spleen, streptococcus septicemia.

Kidneys Combined eight 203 grams capsules strip. Cortical measurements 6 millimeters. The pyramids are dark reddish in color. The substance of the right kidney in the pyramidal portion discloses on section a small collection of pus. No areas of suppuration found in the left kidney. Ureters, bladder, prostate seminal vesicles, and testes are otherwise normal.

Microscopic examination A fairly large section of the kidney fails to show any lesion worthy of mention.

Fig. 1. Low magnification view of the slide showing the bacteria. The bacteria are small, dark, rod-shaped, and arranged in chains and clusters. The background is light and granular.

Fig. 2. High magnification view of the slide showing the bacteria. The bacteria are small, dark, rod-shaped, and arranged in chains and clusters. The background is light and granular.

Case 22. Autopsy No. 1463. East Surgical 1903. Male age 64. April 6, 1903. *Present illness.* Recent penetration of ankle and fracture of ribs. *On first examination* negative. *Second examination* two weeks later. albumin small trace. edema much pus. Admission temperature 101. rose to 103-104 maintained until death on twenty-fourth day. *Streptococci* in wound. *Clinical diagnosis.* Compound fracture of ankle streptococcus wound streptococcus septicemia.

Autopsy 15 hours post mortem. Anatomical diagnosis. Compound comminuted fracture of right ankle fracture of ribs purulent inflammation of deep tissues of the right leg slight suppurative nephritis streptococcus septicemia.

Kidney. Capsules strip revealing numerous small cortical cysts. The markings are obscured. The ureters are free. The bladder and prostate are not remarkable.

Miscellaneous examination. A small papillary adenoma of the kidney is present also occasional areas of atrophic atrophy with cyst formation. In two or three places are small suppurative areas.

Bacteriological report. Cultures from the heart blood and spleen show streptococcus pyogenes. Cultures from the liver show a few streptococci and many colon bacilli. *Sections stained by bacter.* A few chains of streptococci are found in the blood vessels of the kidney and in the areas of suppuration.

Case 23. Autopsy No. 984. West Medical 84-86. Female age 44. February 23, 1901.

Present illness. Recent penetration of ankle and fracture of ribs. *On first examination* negative. *Second examination* two weeks later. albumin small trace. edema much pus. Admission temperature 101. rose to 103-104 maintained until death on twenty-fourth day. *Streptococci* in wound. *Clinical diagnosis.* Compound fracture of ankle streptococcus wound streptococcus septicemia.

Autopsy 15 hours post mortem. Anatomical diagnosis. Compound comminuted fracture of right ankle fracture of ribs purulent inflammation of deep tissues of the right leg slight suppurative nephritis streptococcus septicemia.

Kidney. Capsules strip revealing numerous small cortical cysts. The markings are obscured. The ureters are free. The bladder and prostate are not remarkable.

Miscellaneous examination. A small papillary adenoma of the kidney is present also occasional areas of atrophic atrophy with cyst formation. In two or three places are small suppurative areas.

Bacteriological report. Cultures from the heart blood and spleen show streptococcus pyogenes. Cultures from the liver show a few streptococci and many colon bacilli. *Sections stained by bacter.* A few chains of streptococci are found in the blood vessels of the kidney and in the areas of suppuration.

Case 24. Autopsy No. 984. West Medical 84-86. Female age 44. February 23, 1901.

Present illness. Recent penetration of ankle and fracture of ribs. *On first examination* negative. *Second examination* two weeks later. albumin small trace. edema much pus. Admission temperature 101. rose to 103-104 maintained until death on twenty-fourth day. *Streptococci* in wound. *Clinical diagnosis.* Compound fracture of ankle streptococcus wound streptococcus septicemia.

Autopsy 15 hours post mortem. Anatomical diagnosis. Compound comminuted fracture of right ankle fracture of ribs purulent inflammation of deep tissues of the right leg slight suppurative nephritis streptococcus septicemia.

Kidney. Capsules strip revealing numerous small cortical cysts. The markings are obscured. The ureters are free. The bladder and prostate are not remarkable.

Miscellaneous examination. A small papillary adenoma of the kidney is present also occasional areas of atrophic atrophy with cyst formation. In two or three places are small suppurative areas.

Bacteriological report. Cultures from the heart blood and spleen show streptococcus pyogenes. Cultures from the liver show a few streptococci and many colon bacilli. *Sections stained by bacter.* A few chains of streptococci are found in the blood vessels of the kidney and in the areas of suppuration.

Fig. 9. Upper edge of small cortical abscess—1 millimeter below the capsule. Infecting agent pure staphylococcus albus. Note that tubules above the abscess contain no pus. There is extensive infiltration of the interstitial tissue extending from the abscess to the cortex. Neighboring tissue is normal. Phot. by L. S. Brown, 40.

Past history. Long standing anemia. **Present illness.** Still continues weak with a variety of symptoms chiefly of dyspnea and gastro-intestinal upset. **Physical examination.** Shows anemia and cardiac lesions. **Urine** at entrance negative save for unexplained small trace of albumin. **Temperature** continued as it had been before—slight evening increase to 99-100. Was given 6 gram 606 intramuscularly in left gluteal region, followed by vomiting and soreness in the buttocks and in duration with some increase of temperature. Twenty days later still some induration about site

Fig. 10. Small abscess found immediately below the abscess shown in Figs. 9 and 11 in column of Bertini. Note fine of tubules filled with pus cells and found to contain bacteria extending upward to connect with similar tubules shown in Fig. 9. The abscess shown here is situated in the bend of the loops of Henle. Photo by L. S. Brown, 40.

Fig. 11. Lower edge of abscess shown in Fig. 9. Note fine of tubules filled with pus—tending down into the kidney. There is some pus-cell infiltration of the interstitial tissue. Phot. by L. S. Brown, 40.

of pectus excavatum. One month after entrance to hospital urine began to show blood and pus in small amounts. Lungs show signs of edema. Condition thought to be arsenic poisoning and excision of reservoir of 606 done. Wound discharged freely and sloughed. Patient died at the end of four months. *Culture of pus.* Perforated gastric arsenic poisoning reaction.

Fig. 12. A third abscess underlying the tubules shown in Figs. 9, 10, and 11 situated in the straight tubules of the tip of the papilla. There here in the tubules of this pyramid tip are to be found small masses of staphylococci some with threads beginning bacteria formation. Phot. by L. S. Brown, 40.

Fig. 4. On a small tuft of cortical abscesses all of which seem to take origin from glomeruli. Phot. by L. S. Brown. 500.

Autopsy. 15 hours post mortem. Anatomical diagnosis: Arteriosclerosis nephritis with foci of suppuration, septicaemia streptococcus.

Kidneys. Right kidney weighs 116 grams. capsule adherent. The configuration of the organ is distorted by the presence of two large depressed areas corresponding to areas of extensive atrophy of the renal tissue. About one quarter of the volume of the kidney is involved in this area. The renal tissue outside of this area shows obscure markings, and the line of demarcation between cortex and pyramids cannot be made out. There is distortion of the pelvis due to area of atrophy. The left kidney weighs 51 grams. Its capsule is ex-

Fig. 5. Section through glomerulus at the point of entry of the capillary into the glomerulus to form the tuft. Portion of the capsule of Bowman is seen at —. Not large number of cocci entering the glomerulus in the blood stream. Phot. by L. S. Brown. 1500.

Fig. 14. Microphotograph showing thickening of the renal portion of the kidney. Phot. by L. S. Brown. 1500.

tremely adherent and thickened. Marking of the cortex cannot be made out and the line of demarcation between the cortex and kidneys is not clear. At one point the renal tissue over an area of 1 centimeter is extremely tough and fibrous in character. The pelvis, ureter and bladder are not remarkable.

Microscopic examination. Section from the non-atrophic portion of the kidneys shows large tubules and glomeruli. The failure to observe the usual cortical markings at autopsy was probably due to improper incising owing to obscuration of the parts. A second section shows a zone of extreme atrophy extending along beneath the capsule. There is ex-

Fig. 6. Edge of glomerulus showing phagocytosis in the lumen of the capillary and also free in the capsule of Bowman. There is no evidence of rupture of the capillary in this glomerulus. Phot. by L. S. Brown. 500.

Fig. 7 Microphotograph showing origin (first portion) of tubule. The glomerulus lies above and to the left. At this point to be seen streptococci in diplococcus form entering the first portion of the tubule. The remaining particles are refracts due to precipitated gram-stain. Photo by L. S. Brown, 500.

trreme sclerosis of the vessels in this area. At this point there is an area of suppuration in the cortical region. In the left kidney there are several areas of suppuration in the tissue.

Bacteriological report. Cultures from the heart blood show moderate growth of streptococci. Sections stained for bacteria show streptococci only. They are located in the tufts of the glomeruli and occasionally in the lymph-spaces. Glomeruli containing streptococci show mild glomerular changes.

CASE 26. Autopsy No. 544. Neurological. 1-10. Male, age 30. February 20, 1900. **Past history.** Two years ago right leg torn and crushed in an accident; an abscess formed which was later opened. **Present illness.** For past six weeks numbness of both feet which gradually extended upward involving the body from the lower half of the abdomen down. Diagnosis of myelitis. **Course.** At time of entrance, heavy, alkaline, slight trace of albumin and a few pus-cells. **Temperatures.** normal and remained so during the first thirty days of patient stay in the hospital at which time he developed bed sores, erysipelas, and septic foot. Died forty-second day. **Clinical diagnosis.** Myelitis, cystitis, erysipelas, bed sores, septic foot.

Fig. 8 A section of the proximal constricted tubule showing a tract of streptococci in the upper left hand portion of the tubule and a lump of cocci at the opposite side. Note the presence of these cocci in the protoplasm of epithelial cells. Photo by L. S. Brown, 500.

CASE 27. 5 hours post mortem. Anatomical diagnosis: Erysipelas, decubitus, hypertrophic bladder, and ureters, cystitis, ureteritis, pyonephrosis, early suppurative nephritis, chronic pericarditis, ulcer of right foot, embolized tract degeneration of the spinal cord, streptococcus septicemia.

Kidneys. Normal size, the papulae are slightly adherent. The surfaces are smooth and show few small depressions, some of which are pale in color. All kidneys are retained. Cortex is somewhat narrowed. The pelvis and calices are dilated and the papillae are slightly flattened. Pelvic mucosa is reddened. The ureters are markedly dilated and their walls thickened. The mucosa shows an injection. The bladder is thick and red.

Microscopic. In all the renal tissue is infiltrated with plasma cells, lymphocytes and leucocytes, and the renal tissue is disintegrated. The leucocytes are generally in the minority which may be regarded as indicating a beginning suppuration.

Bacteriological report. Cultures from the heart blood show a growth of streptococci. Sections stained for bacteria show few streptococci in the blood vessels and one or two of the glomeruli. The section preserved from the autopsy contained no abscesses.

CASE 27. Autopsy No. East Medical 6074. Female, age 5. April 20, 1904. **Present illness.** Three months ago for no apparent reason left leg became swollen and has remained so. Has had considerable abdominal and gastric distress with vomiting. Irregular septic temperature normal to 100 with premonitory rise. **Urine.** acid, albumin, slight trace, numerous epithelial cells, leucocytes,

Fig. 1. Pyogenic abscess in the kidney. The mass is surrounded by a thick, eosinophilic capsule. The mass is filled with numerous small, dark, granular particles, likely bacteria or debris. The surrounding tissue is highly cellular and inflamed.

in the left kidney. The left kidney was found to be normal. The right kidney was found to be enlarged and contained a large, pale, amorphous mass (pyogenic abscess) surrounded by a thick, eosinophilic capsule. The mass was filled with numerous small, dark, granular particles, likely bacteria or debris. The surrounding tissue was highly cellular and inflamed.

Autopsy.—A 48-year-old male. Autopsy performed 48 hours post mortem. Anatomical diagnosis: Syphilis of the aorta and kidneys. Both kidneys enlarged and contained a large, pale, amorphous mass (pyogenic abscess) surrounded by a thick, eosinophilic capsule. The mass was filled with numerous small, dark, granular particles, likely bacteria or debris. The surrounding tissue was highly cellular and inflamed.

Kidneys.—Right kidney weighs 145 grams. Left kidney weighs 140 grams. Both kidneys enlarged and contained a large, pale, amorphous mass (pyogenic abscess) surrounded by a thick, eosinophilic capsule. The mass was filled with numerous small, dark, granular particles, likely bacteria or debris. The surrounding tissue was highly cellular and inflamed.

Autopsy examination.—Kidneys show rather diffuse increase of interstitial connective tissue most marked in the left. In the right kidney there is a large, pale, amorphous mass (pyogenic abscess) surrounded by a thick, eosinophilic capsule. The mass was filled with numerous small, dark, granular particles, likely bacteria or debris. The surrounding tissue was highly cellular and inflamed.

Bacterial cultures.—Cultures from the heart blood and pleural space show profuse growth of streptococci.

Fig. 2. Pyogenic abscess in the kidney. The mass is surrounded by a thick, eosinophilic capsule. The mass is filled with numerous small, dark, granular particles, likely bacteria or debris. The surrounding tissue is highly cellular and inflamed.

in the right kidney. The right kidney was found to be enlarged and contained a large, pale, amorphous mass (pyogenic abscess) surrounded by a thick, eosinophilic capsule. The mass was filled with numerous small, dark, granular particles, likely bacteria or debris. The surrounding tissue was highly cellular and inflamed.

Clinical history.—The patient had a long history of syphilis, with aortic aneurysm and aortic regurgitation. He had been treated with mercury and arsenic. He had been ill for several weeks before death, with fever, chills, and weakness.

Autopsy.—A 48-year-old male. Autopsy performed 48 hours post mortem. Anatomical diagnosis: Syphilis of the aorta and kidneys. Both kidneys enlarged and contained a large, pale, amorphous mass (pyogenic abscess) surrounded by a thick, eosinophilic capsule. The mass was filled with numerous small, dark, granular particles, likely bacteria or debris. The surrounding tissue was highly cellular and inflamed.

Kidneys.—Right kidney weighs 140 grams. Left kidney weighs 145 grams. Both kidneys enlarged and contained a large, pale, amorphous mass (pyogenic abscess) surrounded by a thick, eosinophilic capsule. The mass was filled with numerous small, dark, granular particles, likely bacteria or debris. The surrounding tissue was highly cellular and inflamed.

Fig. Typical area from the kidney of child with chronic pyelonephritis which now presents the picture of pure pyelitis. The kidney tissue is normal throughout. Photo by L. S. Brown, 45.

seen to be the basal surface of small pyramidal masses extending into the tissue for a short distance and are marked off from the rest of the kidney substance by narrow, pale red margins. The largest infarct measures 5 millimeters at the base. The markings are retained and the cortex is not narrowed. The pelvis and ureter are negative; the bladder and prostate are negative.

Microscopic examination. The kidney shows acute degenerative changes in the epithelium in each of two sections, small infarcted areas.

Bacteriological report. Cultures from the spleen show no growth. *Sections stained for bacteria.* In the cortical region is situated a small pyramidal area with the base at the periphery and the tip extending down into the cortical substance to a point between the bases of the two pyramids. The center of this area shows homogeneous acutely degenerated kidney substance without cell infiltration. In the region of the capsule the blood vessels are tremendously engorged with some polymorphonuclear infiltration. This area of engorgement forms a border about one millimeter in thickness over the surface of the infarct. At the tip of the infarcted area two small arteries are found plugged with thrombi containing few organisms of the pneumococcus streptococcus group (Fig. 20). The periphery of the infarcted area consists of engorged blood vessels with rupture of some of these vessels and liberation of red cells into the tissue and moderate infiltration with polymorphonuclear leucocytes. No bacteria are found in any portion of normal kidney tissue or infarcted area except within the two arteries plugged with thrombi already mentioned.

The lesions above described are shown in these cases as follows: perinephritic abscess

Fig. Microphotograph of portion of pelvis (same case as Fig. 1) showing slight thickening mucosa without submucosa change and large numbers of colon bacilli growing in the mucosa. Photo by L. S. Brown, 500.

was demonstrated in Cases 4 and 9; capsular abscess and capsulitis appear in cases 6 and 9; cortical abscesses appear in cases 4, 5, 6, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 23, 24, 25, and 27. Septic infarct was demonstrated in Cases 10, 13, 21, 17, and 18, while diffuse suppuration appears in Cases 4, 7, 21, and 26.

THE LESIONS PRODUCED BY THE COLON TYPHOID GROUP OF BACTERIA

The lesions characteristic of this group of organisms are acute pyelitis, acute pyelonephritis, chronic pyelonephritis, and pyonephrosis. As evidence of this we submit Cases 29 to 33.

CASE 29. Autopsy No. 3503. Children's Medical vol. 33, p. 75. Female, age 13 months. September 6, 1905. *Present illness.* For one week before entrance child began to look sick but continued to eat well for past two days has been feverish. *Physical examination.* Negative. Since entering the hospital temperature has continued irregular and high, varying from 100 to 103 with a premortem rise to 107. Child unable to take food except in ounce amounts. Continued to lose strength and died thirteenth day. *Urine* at entrance showed small trace of albumin, many pus-cells and at four subsequent examinations findings continued the same. *Examination of stool* negative. *Culture of urine* bacillus coli. *Clinical diagnosis.* Pyelonephritis. Toxic absorption. Heat prostration.

Fig. 3. Typical appearance of the kidney in chronic pyelonephritis. The result of a long and extensive damage to the tubules and glomeruli. Phot. b. L. S. B. 45

Fig. 4. P4. Typical appearance of the kidney in chronic pyelonephritis. The result of a long and extensive damage to the tubules and glomeruli. Phot. b. L. S. B. 45

Intestine. Four hours post-mortem. Anatomical diagnosis: Bronchitis, emaciation, fatty metamorphosis of the liver, light infective focus in the colon.

Kidney. Combined weight 26 grams. Capsules stripped, leaving pale, moist surface. On section the tissue is of good consistency. Markings are made out and cortex measures 2 millimeters. In the pelvis of the kidney there are three or four minute, whitish, nodules. The rest is otherwise negative.

Bacterial culture. Culture from the heart at autopsy shows no growth.

Microscopic examination of the kidney. Some acute degeneration of the tubules, no glomerular change (Fig. 21). *Stain is stained for bacteria* with light pink and polychrome anilinization of the mucosa of the papilli and calices throughout the section with large number of bacilli scattered throughout the mucosa among the cells (Fig. 22). The glomeruli, tubules and interstitial tissue show no bacteria. There are no bacteria in the blood vessels or lymphatics. In one portion of the section a portion of a pyramid lying in contact with a recess of a calyx shows a clear area extending 2 to 3 millimeters into the tissue, a few isolated bacilli unattended by pathological change lying in the lymphatics of the interstitial tissue.

Case 30. Female, age 1, private patient of Dr. Hugh Cabot, January 15, 1905. **Diagnosis:** Infantile pyelonephritis. **Past history:** Since infancy has had more or less pyuria, the amount of pus in the urine having increased considerably during the last four years. During the past year or so years has had prolonged course of treatment with autogenus

vacines. The urine has always contained large amount of pus, albumin and macroorganisms which have been variously labeled as *Lactobacilli* and proteus by different observers.

Case 31. Shows some diffuseness of the bladder. Right ureteral orifice normal. Urine from the right ureter clear and lean. The left ureteral

Fig. 5. Section of ureter from case shown in Fig. 3 and 4, showing thickened mucosa and submucosa. The collecting cells in the submucosa. There are few pus cells in the submucosa. Bacteria along with pus cells are found in the mucosa. Phot. b. L. S. B. 45

Fig. 26. Typical picture of pyelonephritis due to the colon bacillus (in case in which the conditions requisite for ascending infection were present). Note normal glomeruli, dilated tubules filled with pus and desquamated epithelium and moderate interstitial infiltration with lymphocytes and few pus-cells. Phot. by L. S. Brown, 45x.

orifice is edematous and the urine from the left ureter is very dilute slightly turbid and flows freely. Phenolsulphonephthalein functional test. Intramuscular injection right kidney—appearance time, six minutes, amount in one hour 20 per cent left, 15 minutes, one hour amount 3-4 per cent. The capacity of the left pelvis is 50 cubic centimeters plus. Infected radiograph shows a very large dilated pelvis and ureter with widely dilated calices.

Fig. 28. Same case as shown in Figs. 26 and 27. Colon bacilli in the blood stream of the kidney. Phot. by L. S. Brown, 500x.

Fig. 29. Microphotograph of one of the dilated tubules filled with pus and desquamated epithelial cells. Note that the tubule is definitely the center of bacterial activity and pus production. A few bacilli are seen breaking through the tubules into neighboring tissue. They are unattended by pathological change. Bacilli treated with formalin. Phot. by L. S. Brown, 500x.

Right—as above only a few red blood-cells (traumatic) stained sediment box no bacteria. Left—shows albumin very slight trace sediment much pus many irregular sized motile bacilli considerable renal epithelium. Stained sediment shows on type of organism present gram negative bacillus. Cultures right—no growth left urine shows profuse growth of gram negative bacillus cultural characteristics and agglutination on test localizing it as bacillus coli communis. Oper. 11. Left nephrectomy with removal of ureter to the base of the pelvis. Rapid and eventful recovery.

Pathological report. The specimen consists of kidney and fragment of ureter—centimeters long. The kidney is slightly enlarged. The circumference of the ureter varies from 3 to 4 centimeters. The left kidney shows extensively dilated calices with very little kidney substance remaining. The kidney cortex measures from 1 to 4 millimeters in thickness. The kidney tissue remaining is rather pale mahogany color, is made out and the capsule strips easily in a few places. The pelvic mucosa is markedly thickened and has finely granular non-reflecting surface. The ureter shows the same thickening of mucosa as the pelvis. The infiltrative process in many places extends through the muscularis and is marked about the blood-vessels.

Microscopic section. shows somewhat thickened capsule. The glomeruli for the most part are undamaged. In other areas few show smooth hyaline appearance. There is some round-cell infiltration of the interstitial tissue generally distributed over the section. A portion of the con-

Fig. 6. Microphotograph of another typical pyelonephritic unit, that shown in Fig. 5, and shows that in this case there was no previous tubular dilatation. Addition of blood or red staining. An ascending infection would be impossible in this case. Phot. by L. S. Brown, X 45.

luted tubules show hyaline degeneration (Fig. 23). In a few of these the epithelium is desquamated and is found in the lumen of the tubules lower down. The lumina of the tubules are generally dilated particularly in the pyramids in which area there is also considerable interstitial thickening. The mucosa of the pelvis is much thickened and infiltrated with pus-cells (Fig. 24). Just beneath the pelvic mucosa is infiltration with round cells and a few polymuclear leucocytes extending into the pyramids for a distance of one centimeter. Sections of the ureter wall show some infiltration of the muscularis with some areas of polymuclear cells in the perireteral tissue. The mucous membrane is much thickened and infiltrated with pus-cells. The submucosa shows dense lymphocytic infiltration (Fig. 25) with a few pus-cells.

Sections stained for bacteria show no bacteria throughout the greater portion of the kidney. The area of submucosa infiltration in the pelvis, tips of pyramids and the ureter show a few scattered bacilli. The pelvic and ureteral mucosa and masses of debris within the pelvis and ureter show large numbers of colon bacilli. The groups of desquamated epithelial and pus-cells previously described in the lumina of the convoluted tubules show no bacilli. In some few areas single bacilli were found in the lymphatics of the interstitial tissue of the pyramids.

CASE 31. Autopsy No. 2035. West Medical 68 to 70. Male age 56. September 1, 1900. Present illness. Since childhood has had a complex group of symptoms, but none of a urinary nature, chiefly of gastric disturbance. The diagnosis of

Fig. 30. Destruction of tubules, colon bacilli. Same case. Fig. 29. Phot. by L. S. Brown, X 500.

hypertrophy and gastric neuritis has been frequently made at several Boston hospitals. Temperature at entrance normal. Urine negative. White blood count 6500. Patient remained in the hospital for 6 days, then she developed a temperature, symptoms of bronchopneumonia and died ten days later. Urine examination one week before death showed acid reaction, very slight trace of albumin, moderate number of pus-cells without casts. Clinical diagnosis: Hysteria, bronchopneumonia.

Autopsy 7 hours post mortem. Anatomical diagnosis: Extensive bronchopneumonia, suppurative nephritis, acute degeneration of the myocardium, soft spleen, fatty liver.

Kidneys. Combined weight 245 grams. In one kidney there are numerous large and small dark red blotches in the cortex. On section these blotches correspond to red bands and streaks of varying width extending from the cortex into the pyramids. The pelvis are not dilated, the ureters are negative.

Macroscopic examination of the kidneys shows supuration.

Bacteriological report. Cultures from the heart blood show a few colonies of bacilli. Sections stained for bacteria show an extensive suppurative nephritis of the pyelonephritic type. Bacilli are found only in the convoluted and collecting tubules and the pelvis. There are no cocci.

CASE 32. Autopsy No. 858. South Surgical vol. 61, p. 65. Male age 56. March 21, 1900. Diagnosis: Cancer stomach and liver. Past history negative as regards kidney symptoms. For 2 years loss of weight and strength associated with severe gastric symptoms. Physical examination shows tumor mass in epigastrium. Negative kidney examination and negative urine. Although no sediment was done. Operation. Exploratory laparotomy for adenocarcinoma of stomach and secondary carcinoma of liver with drainage of wound.

Fig. 5. Mixed colon bacillus and staphylococcus infection in kidney removed at operation. Cultures taken at operation were reported bacillus coli alone. Pathological examination shows multiple abscess formation. Error in diagnosis of the nature of the infection from dependence upon culture was due to overgrowth of staphylococci by the colon bacillus. Photo by L. S. Brown 500

Patient had to be etherized permanently from operation until death. Temperature remained subnormal throughout illness. Patient extremely weak and losing ground constantly. Wound showed a constant discharge of chylous fluid with some suppuration. Patient died quietly on twenty second day.

Autopsy 15 hours post-mortem. Anatomical diagnosis: Adenocarcinoma pancreas with metastases in the mesentery lesser and greater omentum walls of the intestine at stomach, peritoneum, liver and the left adrenal; ascites, fibrinous peritonitis, chronic adhesive pericarditis, arteriosclerosis of vessels of Willis, suppurative nephritis, slight dilatation of the pelvis of the right kidney, slight chronic interstitial nephritis, right kidney. Laparotomy wound healed, fracture left humerus.

Kidneys: Combined weight 300 grams. Left kidney capsule strips leaving smooth surface mottled in places with pinhead sized yellowish areas distinct and in small groups. In one place these areas show red mottling. On section they extend over a short distance into the cortical tubules. The markings are retained. The tissue of the upper portion of the pyramids and cortex shows some red marking and pinhead sized yellow and red areas. Pelvis and ureter of normal. Right kidney capsule strips leaving a smooth surface. On section the kidney tissue is firm the markings retained, and the section surface generally is pink colored. There is some slight dilatation of the ureter and pelvis. On section the mucosa of the ureter is not remarkable and entrance of ureter into bladder is free. The portion of the ureter which runs through the bladder wall is the smallest in caliber. Bladder not remarkable.

Microscopic examination: The sections show abscesses in small cortical tubules (Fig. 26). There is cloudy swelling of many of the convoluted tubules. There is also some arteriosclerosis. In other portions of the kidneys there is increase in the interstitial connective tissue with atrophy of many of the convoluted tubules and fibrous thickening of some of the glomerular capsules.

Bacteriological report: Cultures from heart blood no growth. Cultures from liver bacilli of the colon group, cultures from the spleen, few colonies of streptococci. Sections stained for bacteria. The picture is typical of a pyelonephritis (Fig. 26). Glomeruli are normal throughout the section save where they are secondarily invaded by suppurative processes within the neighboring tubules and are even then free from bacteria. Everywhere the tubules are dilated and filled with pus and desquamated epithelial cells. There is considerable lymphocytic and moderate pus-cell infiltration of the interstitial tissue. Bacteria are rarely seen in the interstitial tissues. Large numbers of gram-negative bacilli are found among the pus-cells of the dilated tubules (Fig. 27). As a rule no bacilli are to be found in glomeruli. In few of the larger veins and arteries an occasional bacillus is seen (Fig. 28).

In some of the tubules masses of bacilli are to be found apparently occupying what was once the lumen of a tubule. In some instances in what appears to be an abscess are to be seen the remnants of three or four tubules filled with bacilli serving as the centers of infection for the confluent mass which has resulted in small abscess formation. There are no cocci.

CASE 33. A topsy No. 570. South Surgical No. 34 pp. 94, 52-240. Female, age 56. November 5, 1890. Diagnosed fibroma uterus. Past history entirely negative as regards kidney symptoms. Entire complaint is vaginal discharge and hemorrhage. Physical examination negative save for the presence of a large fibroid uterus. Operation: Complete hysterectomy with drainage. Patient extremely poor condition from shock at the end of operation. After operation patient continued to run a swinging temperature varying from 100 to 102°. Developed tenderness in both costovertebral angles. Gradually failed and died on fourteenth day. No specimen reported on day of death was said to have shown no alb. min. sediment was done. Autopsy 29½ hours post-mortem. Anatomical diagnosis: Hysterectomy circumscript peritonitis with purulent infiltration and necrosis of tissues of the abdominal wall near wound, multiple old infarcts of spleen, chronic mitral endocarditis, leukithiasis, suppurative nephritis.

Kidney: Capsules strip easily and leave granular surface thickly dotted over with gray opaque mottling. On section cortex is increased in width 3 to 9 millimeters. Cortices present a mottled gray opaque appearance from the presence of numerous discreet and confluent pinhead sized opaque areas. Pyramids show gray lines. The

mucosa of the pelvis shows reddening and hemorrhagic areas. Bladder reddened.

Bacterial flora. Cultures from heart, liver, spleen and kidneys show colonies of a bacillus which was not classified but seemed from its growth on agar to belong to the colon group.

Microscopic examination. In both kidneys show some post mortem degeneration extensive infiltration of polynuclear leucocytes with disappearance of the renal epithelium over considerable areas of the kidney so that abscesses are formed some dilated tubules filled with polynuclear leucocytes and epithelial cells (Fig. 29).

Section stained for bacteria. The picture is typical of a pyelonephritis (Fig. 30). Glomeruli are as a rule free from bacteria and also free from pus save where invaded from neighboring tubular processes. The interstitial tissue shows considerable lymphocyte and some pus cell infiltration. Throughout the section the tubules are dilated and filled with clumps of bacteria and desquamated epithelium. Few bacteria are found outside the tubules. Where bacteria are found outside the lumina of tubules the renal epithelium is usually extensively destroyed with evidence of liberation of the contained bacteria (Fig. 30). Where dense abscess formations appear close observation shows the centers of upurulation to be remnants of tubules which have been extensively destroyed. The appearance of true abscess is due to influence of the destructive processes in several neighboring tubules. There are no cocci seen in the section. Large number of gram negative bacilli mostly in tubules are clearly the etiological factor in the process.

Note.—The striking similarity between the findings in this case and the preceding Case 3 is of interest because in the former the conditions for ascending infection exist while in this case no stretch of the imagination can the bladder be made red the origin of the renal condition. One might be an ascending infection the other clearly cannot be yet the pathological pictures presented are indistinguishable.

In this group of cases acute pyelitis and also chronic pyelitis are shown in Cases 29, 30, 31, 32 and 33. Acute pyelonephritis does not appear and its incidence is inferential as we shall later show. Chronic pyelonephritis is shown in Case 30 as is pyonephrosis.

INFECTION OF THE KIDNEY WITH BOTH PYOGENIC AND PYOGENIC ORGANISMS WILL PRODUCE A MIXTURE OF THE LESIONS CHARACTERISTIC OF BOTH GROUPS.

This fact we believe explains the not uncommon fallacy that the colon bacillus will produce abscess of the kidney. This has been freely stated and appears to have been supported by the evidence of cultures ob-

Fig. 31. Microphotograph (true blue) due to bacilli. One of the organisms is the colon bacillus the other a gram positive organism. Photo by L. Brown & Co.

tained from the kidney. The reasoning we have shown to be fallacious for two reasons. First cultures containing both colon bacilli and cocci will frequently be interpreted as showing only colon bacilli since this organism grows with great rapidity and readily obscures the colonies of cocci. Second it has been assumed that the cultures obtained from one part of a kidney represented the lesions produced in the whole kidney. This we have shown to be fallacious by the actual demonstration of bacilli in one portion of the kidney cocci in another and cocci and bacilli associated together in still other portions (Fig. 31). Our experience has led us to believe that in these mixed infections the colon bacillus probably precedes the coccus in point of time. Only in this way can be explained the appearances in certain kidneys which will be below described. These mixed lesions are rather likely to be found in cases occurring in Group II of our classification.

that is to say kidneys handicapped by previous disease. In support of these propositions we submit Cases 34 to 56 showing mixed infection with cocci and bacilli Cases 67 and 68 showing infection with two different kinds of cocci, and Cases 59 and 60 showing infection with two different kinds of bacilli.

CASE 34. Autopsy No. 84 West Medical, 564-88. Female age 51. Alth: 100. *Present illness.* Six days ago became dizzy (uræmia?) fell, and had a severe convulsion followed by mental aberrations. *Urin.* acid, 0.07 albumin 1/4 per cent. very small amount of pus and casts. *Temperature* varied about 100. *Hbts.* blood count 18,000 which later rose to 45,000. Patient gradually lost strength, became more irrational becoming comatose. Temperature became subnormal and death occurred sixth day. *Clinical diagnosis.* Chronic nephritis.

Autopsy. 8 hours post-mortem. Anatomical diagnosis. Chronic interstitial nephritis, suppurative nephritis, congenital malformation of the kidneys and anomaly of the right ureter, bronchiectasis with concretion, edema of the lungs, hydrothorax.

Kidneys. Small and of unequal size. Weight of left kidney 13 grams, right kidney weighs 5 grams. Left kidney shows focal lobulations and deformity. Capsule adherent. The markings are scarcely recognizable. In two areas are small cysts. Abnormal arrangement of the renal arteries. Right kidney is also deformed, its pelvis being nearer one pole than usual. Capsule adherent. The distinction between cortex and pyramids is obscured. The markings of the cortex are absent. At one point in the renal tissue is a cavity 6 millimeters in diameter full of pus. Ureter is of normal caliber until near the bladder when it becomes dilated. Its orifice in the bladder not found but in the situation of its orifice is a swollen area which on section exudes thin purulent fluid. A fibrous cord connects the pelvis with the lower portion of the ureter to which it is joined a few millimeters from the bladder. It has no lumen. *Bacteriological report.* Liver and spleen show bacillus coli communis. *Sections stained for bacteria.* show many staphylococci in plugs in a few of the tubules, a considerable number of gram-negative bacilli are found in the pelvis of the kidney. There are no abscesses in the sections preserved.

CASE 35. Autopsy No. 1076 West Surgical 43-63. Male age 40. June 24 1902. Patient brought to Accident Room unconscious with fracture of cervical vertebra. *Urin.* examination on admission negative. Six months later slight trace of albumin, hyaline casts much pus. Patient has been catheterized since July. *Irrregular temperature* with occasional chills for past four months. Death from exhaustion and sepsis on three hundred twentieth day. *Clinical diagnosis.* Cervical fracture.

Autopsy. 6 1/2 hours post mortem. Anatomical diagnosis. Calculus pyelitis and ureteritis with suppurative nephritis of the right kidney obstructing stone in ureter, cystitis, infarct right lung, scar of old fracture of cervical vertebra.

Kidneys. Combined weight 440 grams. Capsules strip easily leaving smooth surface, however some red mottling. Left kidney shows fairly firm tissue without narrowing of the cortex. In places the section surface is mottled with red areas. The right kidney tissue is somewhat soft, section surface generally pale with retained markings. The cortex is slightly narrow. In many places and especially in the cortex are numerous small red areas. The pelvis of the right kidney is dilated, its mucosa is grayish red and bathed in dirty yellowish purulent material. The calices are dilated and contain small yellowish secretions. The upper portion of the ureter for a distance of 2 centimeters is dilated, its mucosa roughened and grayish to red in color. Its lumen is occluded by small tissue. Below this situation the ureter is normal in size. Its mucosa is smooth showing here and there a few small ecchymoses. The left ureter is normal. Bladder shows dirty yellowish foul fluid and its mucosa presents numerous red patches.

Microscopic examination. Right kidney shows extensive infiltration with round cells. Places also infiltration with leucocytes. The left kidney shows renal tissue to be infiltrated in areas with pus cells, and the normal kidney structure is disintegrated at these points.

Bacteriology report. Cultures from the heart, liver and spleen show liquefying serum of growth of bacteria. *Sections stained for bacteria.* A considerable variety of bacteria some of which are staphylococci are found scattered throughout purulent areas in the kidney. Many bacilli.

CASE 36. Specimen number 92-6 South Surgical, 76- Male, age 53. February 9, 1900. *Present illness.* For two months has had a bundle on the back of the neck. For one month has had nausea, some vomiting and intestinal disturbance chiefly diarrhea.

Operation. Appendectomy. Chronic appendix found not removed. Following operation a patch of dullness located in left lower back. *Clinical course.* showed small amount of pus from the right ureter. A negative culture from the bladder urine showed colon bacilli with a few colonies of staphylococci. Cultures from the appendix wound which had become septic showed staphylococcus aureus and colon bacilli. Diagnosis of acute hematogenous kidney and operation determined upon. Small perinephritic abscess found and cultures from which showed staphylococcus aureus. The kidney was found and generously sprinkled with small abscesses. Nephrectomy done.

Pathological report. Kidney considerably enlarged, weight 300 grams. Capsules thickened. There is a large abscess at one pole of the kidney and numerous small abscesses scattered throughout.

the remainder of the kidney cortex. These are filled with thick tenacious pus showing small micrococci in clumps.

Microscopic examination showed multiple abscesses. Diffuse round-cell infiltration of remaining tissue with obliteration of tubules and glomeruli.

Pathological diagnosis Focal suppurative nephritis.

Sections stained for bacteria A large number of staphylococci and a moderate number of gram negative bacilli are found in the small abscess cavities and some of the tubules and occasionally in the lymph-spaces of the interstitial tissue.

CASE 37 Autopsy No 859 South Surgical LN 258 Male age 56 March 6 1902 *Past history* Gonorrhoea 36 years ago stricture developed six years later. Has frequently had retention *Present illness* Inability to pass water. *Urine* small trace of albumin large amount of pus.

Operation Internal and external urethrotomy for multiple stricture. Patient had uneventful convalescence for 10 days at which time he had a sudden rise of temperature to 103 nervousness and some vomiting. A few days later patient developed diarrhoea. He died on the thirty-third day.

Clinical diagnosis Multiple stricture of urethra.

Autopsy 19 hours post mortem. Anatomical diagnosis Chronic cystitis with extension through the bladder wall and through the perivesical tissue dilatation of the ureters double hydronephrosis ureteritis pyelitis suppurative nephritis suppurative focal pneumonia atheromatous endocarditis of the aortic valve healed perineal wound for stricture of urethra stricture of urethra at the penoscrotal angle.

Kidneys In each renal pelvis opaque purulent fluid. Kidneys are unequal in size weight not given. Capsules slightly adherent. At various points on the free surfaces are yellow slightly elevated areas which on section contain milky white pus. The kidney tissue covering the more dilated portion of the pelvis shows atrophy and the markings are obscured. The cortex is diminished in width.

Microscopic examination Kidneys show increase in the interstitial connective tissue atrophy of the tubules infiltration with small round cells some hyaline atrophy of the glomeruli. Some of the tubules show many pus-cells.

Bacteriological report Fluid expressed from the kidney shows a number of bacteria many of them gram negative bacilli staphylococci and streptococci. Cultures from the heart no growth liver and spleen, bacillus coli communis kidney many varieties of bacteria.

Sections stained for bacteria show staphylococci in the tubules colon like bacilli in the blood stream and staphylococci and bacilli in the pelvis.

CASE 38 Autopsy No 1817 West Surgical 545-107 Male age 79 October 1 1906 *Past history* For past 15 years has led catheter life on account of enlarged prostate. *Present illness* Four days ago broke his catheter leaving four inches in his bladder. Temperature normal on admission.

Urine alkaline slight trace of albumin sediment pus and blood-cells. *Operation* Perineal section for foreign body followed by partial suprapubic prostatectomy. Patient died as immediate result of this second operation on forty-sixth day after admission. *Clinical diagnosis* Enlarged prostate and senility.

Autopsy 6 hours post mortem. Anatomical diagnosis Diptheritic cystitis ureteritis and pyelitis suppurative nephritis right operation wound prostatectomy arteriosclerosis fibrocalcereous endocarditis focal tuberculosis of liver.

Kidneys Combined weight 240 grams. Capsule of left kidney strips leaving a firm smooth surface. Capsule of right kidney strips leaving a firm smooth surface showing here and there small abscesses. The pyramids in places show thin grayish yellow streaks. The mucosa of the pelvis is covered with a grayish yell w necrotic membrane. This material extends along the mucosa of the ureter over its entire length. The ureter moderately dilated. The mucosa of the bladder is covered with exudate and contains foul urine. The walls of the bladder are thickened and in several places there are small diverticula. In the situation of the prostate there is a grayish ragged necrotic cavity.

Bacteriological report Cultures from the heart blood yield no growth from the spleen profuse growth of bacilli. *Sections stained for bacteria* No blocks of kidney tissue were preserved. Sections from the prostate and liver show many staphylococci and a few bacilli. The prostate shows some glandular elements filled with pus in which the bacteria are located. The bacteria in the liver are found in the central veins.

CASE 39 Autopsy No 2220 West Surgical 600-53 Female age 40 September 22 1908 *Present illness* For one year definite symptoms of gall stones. Temperature normal. *Urine* negative. *Operation* cholecystostomy cholecystectomy Moderate sepsis of wound moderate temperature. Seventh day after operation patient became drowsy urine considerably decreased in amount bloody small trace of albumin some pus considerable number of cellular casts. Patient died eighteenth day.

Clinical diagnosis Cholelithiasis pyonephrosis.

Autopsy 6½ hours post mortem. Anatomical diagnosis cystitis ureteritis pyelitis suppurative nephritis arteriosclerosis slight fibrous endocarditis of the aorta and mitral valves ulceration of the intestines chronic peritonitis operation wound cholecystectomy and cholecystostomy.

Kidneys Combined weight 310 grams capsules strip. Surfaces are mottled with many small discreet and confluent yellowish areas which bulge in some places. Section surfaces are mottled with dirty yellowish areas which extend well down into the pyramids. The mucosa of the pelvis shows many minute ecchymoses and small areas of fibrin. The ureters are free and contain pus. The mucosa of the ureters shows ecchymoses bladder the same.

Microscopic examination Kidneys show many abscesses and extensive leucocytic infiltration.

Bacteriological report. Cultures from the heart blood and spleen show no growth from the kidney bacilli.

Sections stained for bacteria show mixed staphylococcus gram-negative bacillus abscesses of cortex.

CASE 40. Autopsy No. 21 West Medical, 710-33 Male, age 25, October 6 1908. **Present illness** Three weeks of pain in the right kidney region with fever and for four days severe vomiting. **Temperature** 102 to 105. **Urine** acid slightest possible trace albumin, rare cast with pus-cells adherent considerable pus. White blood count, 25,600. Guinea pig inoculated promptly died. Death too early for evidence of tubercle. Patient died fourth day. **Clinical diagnosis** Haematogenous kidney.

Autopsy 3½ hours post mortem. Anatomical diagnosis Septic infarcts and multiple abscesses of right kidney thrombosis right renal vein, acute localized peritonitis of the right side of the abdomen septic infarcts and multiple abscesses of lungs, soft spleen, staphylococcus pyogenes aureus septicemia.

Kidneys Left kidney weighs 7 grams, tissue is somewhat soft kidney not otherwise remarkable. The right kidney is enlarged. The cortex is mottled with minute yellow areas from some of which pus oozes when the capsule is removed. On section the markings are lost. Here and there are dark red areas in some of which the central portions show abscesses. The mucosa of the pelvis shows ecchymosis. Both ureters are free. The right renal vein is occluded by a large thrombus.

Microscopic examination of the kidney is not recorded.

Bacteriological report. Cultures from the heart blood, spleen and right kidney show profuse growth of staphylococcus pyogenes aureus and a slight growth of bacilli.

Sections stained for bacteria show staphylococci in the abscesses apparently in pure growth, staphylococci and bacilli in the pelvis.

CASE 41. Autopsy No. 83 West Surgical, 380-238. Male age 40 November 6 00. **Past history** Gonorrhoea 7 years ago. Now has evidence of stricture. **Present illness** Acute retention. This morning unsuccessful attempt made by his own doctor at catheterisation. **Temperature** normal. **Urine** albumin, trace, sediment much pus and blood. **Operation.** Dilatation of stricture. Three days later chill fever vomiting followed by suppression of urine.

Operation. Right nephrotomy for pyonephrosis. Kidney found to be dilated apparently recent infection. Operation did not improve patient's condition and he died fifteenth day. **Clinical diagnosis** Stricture of urethra, pyonephrosis.

Autopsy 10½ hours post mortem. Anatomical diagnosis Malformation of kidneys with extensive suppurative nephritis 1 tiny metamorphosis

liver hyperplasia spleen, hypertrophy and dilatation of heart inguinal operation wound.

Kidneys In the region of the operation wound is an irregular mass of tissue which extends into the abdomen. This is found to consist of kidney tissue and measures about 4 centimeters in length. Capsule strips leaving a fairly smooth yellowish brown surface showing in several places yellowish brown areas which on section contain pus. **Cover glass preparations** from this material show numerous leucocytes and a few bacilli. Two ureters are present. The left ureter leads to the pelvic mass of kidney tissue above described, the right opens into the shell of tissue in the right inguinal region.

Microscopic examination. In three sections of the kidney there is considerable post mortem change and much suppurative nephritis.

Sections stained for bacteria show in the centers of the suppurative areas many staphylococci. A section of the liver shows numerous gram-negative bacilli and staphylococci in the central vein. There are many gram-negative bacilli in the tubules and some suppurative areas surrounding dilated tubules filled with bacilli and cocci.

CASE 42. Autopsy No. 827 East Medical, 56-38 Male age 53 December 27 1900. **Present illness** Symptoms of cerebral embolism of sudden onset. Was put on constant drainage on account of incontinence. Developed urethritis. **Urine examination** at entrance and all through stay in hospital showed albumin and moderate quantities of pus. Fourteenth day in hospital developed carbuncle. Developed lung symptoms. Culture from carbuncle showed growth of staphylococcus aureus. Died forty-seventh day. **Clinical diagnosis** Cerebral embolism.

Autopsy 3½ hours post mortem. Anatomical diagnosis, chronic cystitis, pyelitis, slight dilatation renal pelvis and ureters suppurative nephritis, arteriosclerosis vessels of Willis, degeneration of posterior columns and crossed pyramidal tracts of the spinal cord.

Kidneys Capsules strip surfaces present here and there many brownish yellow spots and indurations. On section through these indurations yellowish mucous pus is obtained. On section kidney shows scattered brownish yellow spots and faint streaks. The pelvis of the kidneys show some dilatation with numerous areas of ecchymosis in the walls. Ureters are moderately dilated and filled with thin fluid pus. Ureteral openings are free. Bladder shows areas of ecchymosis and contains a moderate amount of thin pus. Two small abscesses of the prostate.

Cultures of the heart and liver show growth of bacillus coli communis.

Microscopic examination. Foci of suppuration and small abscesses are present. In these are many mononuclear and polynuclear leucocytes. There is a considerable increase in interstitial connective tissue but without lesions of the glomeruli characteristic of chronic glomerular nephritis.

Sections stained for bacteria. I redominant organism scattered throughout the tissue where there is evidence of suppuration is colon like bacillus. In some areas cocci are to be seen and in still others particularly the cortical abscesses the majority of bacteria are staphylococci.

CASE 43. Autopsy No 522 South Surgical 40-80 Male age 63 September 23 1899. *Present illness.* For three months has had bladder irritability nausea vomiting and hematuria has been catheterizing himself since onset of symptom. Patient entered hospital with symptoms of uræmia. Ure acid albumin 4 per cent sediment pus and blood. Died day of entrance. *Clinical diagnosis.* Enlarged prostate.

Autopsy 13 hours post mortem. Anatomical diagnosis. Adenocarcinoma of the bladder in olving both ureters. Orchitis cystitis and hydronephrosis with dilatation left ureter acute pyelitis right kidney abscesses of both kidneys chronic interstitial nephritis hypertrophy of heart.

Kidneys. Capsules strip easily. Here and there in both kidneys are small pinhead sized abscesses.

Miscoscopic examination. Sections of the kidneys show marked increase of interstitial tissue with some infiltration with round cells. Tubules of the cortex are greatly diminished in number. Some of those that are present are atrophied and contain hyaline casts. In one section there is moderate infiltration with polymorphous neutrophilic leucocytes. *Cultures from the heart and spleen in growth.* Cultures from the kidney bacillus of immunitis.

Sections stained for bacteria. Small abscesses previously described show many staphylococci. A few staphylococci are also found in tubule. Many gram negative bacilli are found in the pelvis of the kidney in one section. Gram negative bacilli and cocci are found in the other two sections one of which contains an abscess.

CASE 44. Autopsy No 304 East Surgical 340-83 Female age 58 August 1 1898. *Present illness.* For six weeks loss of appetite and vomiting frequent micturition. For one week pain in the angle of the right jaw. Examination shows alveolar abscess white blood count 8880. Urine acid albumin slight trace sugar sediment considerable pus. Transferred to Surgical Service. *Operation.* Alveolar abscess drained. Death of the patient from general septicæmia. *Clinical diagnosis.* General septicæmia alveolar abscess diabetes.

Autopsy 14 hours post mortem. Anatomical diagnosis. Abscess of kidneys bronchopneumonia with abscess of the lung arteriosclerosis wound of neck general infection staphylococcus pyogenes aureus.

Kidneys. Enlarged total weight 462 grams. Capsules adherent. On section several dark red areas are seen scattered through the kidney tissue some extending from the cortex well into the pyramids. These areas show softening and many of them have yellowish white areas within them which yield pus. Marking retained. In one area

there is a firm yellowish pyramidal area fibrous in character situated between the cortex and the pyramid. Pelvic mucosa slightly injected bladder shows nothing remarkable.

Bacteriological remarks. Abscess of neck heart spleen liver and kidneys show profuse growth of staphylococcus pyogenes aureus. Cover glass preparation of pus from kidney abscess shows staphylococci and numerous large irregularly stained bacilli.

Miscoscopic examination. Kidney abscesses show staphylococci in many areas phagocytosed.

Sections stained for bacteria. Many abscesses are found situated in the cortex. Small abscesses originating in the tubules sometimes in the convoluted portion at other times in the ascending and descending loops are to be found. These small secondary abscesses uniformly and like the apparently primary larger abscesses in the cortex. The abscesses frequently show large clumps of bacteria which may be seen macroscopically lying within the necrotic area. In most instances bacilli alone are to be found in the tubules while in still others the process is mixed. Bacilli and cocci are occasionally found in clumps arranged down the collecting tubules. There are both bacilli and cocci in the pelvis of the kidney.

CASE 45. Autopsy No 301 East Surgical 338-106 Male age 65 July 11 1898. *Past history.* Frequent micturition with flowing stream for six years. *Operation.* Stricture one year ago. *Present illness.* Recurrence of same symptoms. *Physical examination.* Shows stricture of bulb. *Operation.* Division of stricture. Urine at entrance alkaline albumin 10 per cent much pus few red blood-cells. Sixteen days after operation developed temperature and pain in the right kidney region. Temperature increased suppression of urine distention patient died seventeenth day. *Clinical diagnosis.* Stricture urethra.

Autopsy 18 hours post mortem. Anatomical diagnosis. Suppurative nephritis pyelitis ureteritis slight dilatation of renal pelvis and ureter on right side hypertrophic bladder with diverticula and cystitis arteriosclerosis cardiac hypertrophy edema and congestion of lungs hemorrhagic infarction of kidney.

Kidneys. Capsules strip leaving smooth surface. On section tissue mottled red and yellow. In the pole of the left kidney chestnut sized red spots scattered throughout tissue many pea sized abscesses. Some of these abscesses continue as dark red areas down into the pyramids. The papillary portion of the pyramids shows yellowish white streaks. *Cultures from kidneys.* show staphylococcus aureus and colon bacilli. *Sections stained for bacteria.* No abscesses in sections preserved. Gram negative bacilli clumps of staphylococci and some bacilli are found in the convoluted tubules.

CASE 46. Autopsy No 1164 South Surgical 87-55 Male age 63 November 5 1903

Present illness Eight years ago abscess of perineum, now has filliform stricture. **Urine** at entrance acid, trace of albumin, sediment clumps of pus, occasional red blood-cell. Patient ran an irregular temperature and died, after operation on the seventy-third day.

Clinical diagnosis Stricture of urethra, cystitis. **Autopsy** Anatomical diagnosis Pyonephrosis, cystitis, chronic urethritis, perineal fistula, dilatation of ureters and ureteritis, abscess of left kidney chronic interstitial nephritis, abscess of left epididymis and testicle, streptococcus septicemia.

Kidneys Somewhat smaller than normal capsule adherent. Pelvis, calices and ureters on the right are markedly dilated and filled with a thick yellow pus. The course of the right ureter is tortuous and at its lower extremity at the bladder wall forms somewhat of a cul-de-sac. The right pelvis is blackish in color and granular. The walls of the pelvis and ureter are thickened. The pyramids of the right kidney are flattened and the cortex narrowed. The markings are bared. The left renal pelvis, calices and ureter are also dilated. They do not yield pus. At two or three places there are cavities in the substance of the kidney filled with pus. The walls of the kidney pelvis and ureter are thickened. The bladder mucosa is dirty blackish in color and rough.

Microscopic examination. A section from one kidney shows fibroid atrophy of portions of the renal tissue and an abscess.

Bacteriological report. Cultures from the heart blood show a few streptococci. **Sections stained for bacteria** show staphylococci and gram-negative bacilli scattered throughout the kidney sections. It is impossible to differentiate the extent of post mortem invasion.

CASE 47. Surgical Case No. 934. South Surgical 172-5. Female, age 43. November 1908. **Past history** negative save for symptoms attributed to the appendix. **Present illness** For one week patient has had abdominal pain localizing in the right loin with chills and fever. **Temperature** at entrance 102. **White blood count** 5,400. **Urine** acid, small trace of albumin, considerable pus.

Rectal examination shows tenderness high up in the rectum with edema and fluctuating mass. **Operation** 1. Dissection and drainage of ischio-rectal abscess. **Second operation** appendectomy and nephrotomy with drainage of hematogenous kidney. Specimen excised for examination.

Pathological report. Two small pieces removed from surface of the kidney red, hemorrhagic with red cells and some leucocytes. **Section stained for bacteria** shows staphylococcus and large gram-positive bacilli in abscesses.

CASE 48. Autopsy No. 2635. South Surgical 266-85. Male, age 64. September 3, 1902. **Past history** Frequent catheterization for past ten years on account of bladder inflammation. **Present illness.** Complaint frequency **Urine** acid, trace of albumin, leucocytes and many bacteria. **Operation** Exploratory laparotomy for

tumor of the bladder. Bladder palpated but not opened. Operation wound remained clean. After operation patient failed without apparent cause and died thirteenth day. **Clinical diagnosis** Multiple diverticula enlarged prostatic cardiac insufficiency.

Autopsy 8 hours post mortem. Anatomical diagnosis Suppurative nephritis, acute pyelitis, arteriosclerosis degeneration of kidneys, hypertrophy of prostate, hypertrophy of bladder wall with diverticula, operation wound.

Kidneys Combined weight 20 grams. Capsules strip leaving granular surfaces the tissue is quite firm. The cortex measures 3 to 6 millimeters. Here and there the section surfaces are streaked and mottled with small yellow areas. The pelvis and calices are moderately dilated. The mucosa is generally reddened. The walls of the bladder are thickened. A few diverticula and one large one are present. The prostate is considerably enlarged.

Microscopic examination. There is extensive infiltration with polymorphous leucocytes, in one or two places abscess formation.

Bacteriological report. Cultures from the heart blood show growth.

Sections also sent for bacteria. Sections from the kidney tissue which were preserved show but little suppurative process. Staphylococci and bacilli are found, few in number in the pelvis.

CASE 49. Autopsy No. 32. South Surgical 9-4. Male, age 66. August 1893. **Present illness** Prostatic symptoms seven years. Catheterized one month ago and apparently infected at that time. **Operation** Prostatectomy. **Urine** smoky acid, large amount of pus some blood large trace of albumin. Died twenty-eighth day. **Clinical diagnosis** Hypertrophy of prostate, pneumonia.

Autopsy 6 hours post mortem. Anatomical diagnosis Suprapubic cystotomy and partial prostatectomy. Abscess of region of Scarpa's triangle with sinus formation, thrombosis right femoral vein, abscess of lungs, acute pyelitis with abscesses of kidney ulcerative prostatitis.

Kidneys In both renal pelvis marked induration of mucosa with some patches of exudate. Cortex 5 millimeters. Tissue slightly pale and in some of the pyramids grayish yellow streaks in the papilla. In one kidney there are two or three pinhead sized abscesses. Sections of the small abscesses of the kidney show micrococci with cloudy swelling of the epithelium of the cortical tubules.

Section stained for bacteria show staphylococci in abscesses, bacilli in the yellowish streaks in the papilla lying within the tubules, bacilli and cocci in the pelvis.

CASE 50. Autopsy No. 2030. West Medical 502-5. Female, age 47. October 6, 1911. **Present illness** Two years of abdominal symptoms, one week of diarrhea followed by distention of the abdomen and abdominal pain with much vomiting.

Temperature at admission normal. Later a somewhat irregular fever reaching 100. Urine at admission no albumin, rare leucocytes. White blood count 8500. *Clinical diagnosis* Cancer of the stomach disseminated abdominal cancer.

Autopsy 28 1/2 hours post mortem. *Anatomical diagnosis* Diffuse carcinoma of the stomach with extensive metastasis including the right kidney, carcinomatous strictures of the large intestine, left bronchopneumonia, chronic endocarditis of the mitral valve with stenosis, suppurative nephritis, hydronephrosis right due to constriction of the ureter by neoplasm, small infarct of lung.

Kidneys Combined weight 284 grams, right kidney is small. There is much perinephric induration and thickening marked about the ureter, especially in its upper portion. The pelvis and calices of the right kidney are dilated and contain a cloudy fluid. The surface of the right kidney is fairly smooth with a few ill-defined gray white areas both discrete and confluent. On section these areas extend for a variable distance into the renal tissue beneath. The markings of the cut surfaces are obscured. The renal cortex is narrowed. The cortex of the left kidney shows numerous small abscesses. The tissue about these in many instances is dark red. These areas are seen to extend into the cortical substance in the form of yellowish gray streaks. The ureter is not dilated. The bladder is negative.

Microscopic examination One section from the right kidney shows an area of carcinoma. There are numerous areas of suppurative nephritis.

Bacteriological report Cultures from the heart blood show scum of growth (several types of bacilli).

Sections stained for bacteria Abscesses show only cocci, some gram negative bacilli are found in the lymphatics and the blood stream. In the pyramidal portion of the kidney, large plugs of bacteria, both cocci and bacilli are found in the tubules.

CASE 51 Autopsy No 1352. Genito urinary 10-155. Male, age 28. April 15, 1914. *Past history* Stricture of urethra for five years, in terminal urethrotomy three years ago. *Present illness* For one year has had recurrent pains in right kidney without fever. For two weeks has had increased frequency followed by severe pain in region of right kidney and vomiting. His urine has been much more cloudy than previously. *Urine* acid, cloudy, large amount of albumin, much pus and a few red blood-cells. *White blood count* 19000. *Cystoscopy* showed cloudy urine from the right side with markedly decreased function, left kidney moderate amount of pus, 10 per cent function. *Cultures* from both kidney urines showed colon like bacillus. *X-ray* showed right renal calculus. *Operation* Right kidney full of small calculi removed by pyelotomy and nephrotomy. Left kidney showed perinephric abscess with many multiple abscesses in cortex. Patient died fourteenth day. *Clinical diagnosis* Calculus pyelonephritis, right acute suppurative nephritis, left uræmia and pneumonia.

Autopsy 13 1/4 hours post mortem. *Anatomical diagnosis* Nephrothiasis, diphtheritic pyelitis and pyonephrosis, perinephritis with abscess formation, chronic interstitial nephritis, right with chronic ureteritis, double nephrotomy with purulent infiltration of perinephric tissue, tuberculosis of the lungs, bronchopneumonia, focal necrosis of the bladder, absence of left testicle, scar of old cystotomy, fatty liver, streptococcus septicæmia.

Kidneys Combined weight 330 grams. Abscess of perinephric tissue about each kidney. Right kidney shows adherent capsule. Surface is marked with occasional irregular depressions. In the substance of the kidney extending from the convexity to the pelvis is an irregular excavation bounded by ragged necrotic kidney tissue bathed in pus (Nephrotomy wound). The pelvis is moderately dilated, its mucosa covered with a dirty white layer. All the calices are dilated and contain irregular granular concretions and pus. The cortex is markedly narrowed. The left ureter is adherent to the surrounding tissue. Its mucosa is smooth. The right kidney has an adherent capsule on removal of which several cavities filled with yellow pus are exposed. There are numerous pinhead sized abscesses on the surface. In the substance of the kidney extending into the pelvis is an irregular cavity bounded by necrotic tissue (Nephrotomy wound). The renal pelvis is moderately dilated and filled with pus, two concretions. The mucosa of the pelvis shows an adherent dirty layer. The left ureter is not remarkable. The bladder and prostate are normal.

Microscopic examination One section of the kidneys shows suppurative nephritis, another section shows atrophy and a round cell infiltration. At the tip of the pyramids in one section is necrosis and purulent infiltration.

Bacteriological report Cultures from the heart blood show profuse growth of colon like bacilli and cocci. *Sections stained for bacteria* In the section preserved there were no abscesses and small evidence of suppuration. Many staphylococci and a few gram negative bacilli were found in the pelvis.

CASE 52 Surgical Case No 8127. East Surgical 506-207. Female, age 25. January 9, 1908. *Past history* Painful micturition since childhood. *Present illness* Four days of right-sided abdominal pain with vomiting, later pain localized in right kidney region, urine became cloudy. *Urine* at admission alkaline, slight trace of albumin, much pus. *Temperature* 103. *White blood-cell count* 15,600. *Physical examination* showed a mass similar to appendix abscess and thought to be that. *Operation* Exploratory laparotomy and nephrectomy for acute infected kidney. Uneventful recovery. *Cultures* peritoneal fluid, no growth, pus from kidney abscess shows few cocci and bacilli. *Clinical diagnosis* Acute infected kidney.

Pathological report Kidney very much enlarged. On the surface multiple small purulent foci, on section the same are seen in the cortex of the kidney more rarely in the papilla.

Microscopic examination. Infiltration with round and pus-cells and destruction of the tubules especially in small foci.

Sections stained for bacteria. No true cortical abscesses found in tissue. The picture is more that of a colon bacillus pyelonephritis with tubules the center of suppuration. Bacteria found in these areas show mixed infection of staphylococci and gram-negative bacilli, the latter predominating.

CASE 53. Surgical Case No. 710-17 South Surgical, 541 Female, age 34, October 9, 1907. **Present illness.** Eight days ago onset of abdominal pain in region of appendix with fever which quickly subsided leaving soreness in region of kidney. **Physical examination.** Right kidney palpable and tender. X-ray negative. **Urine** 1 entrance acid, slight trace of albumin, some pus. **White count** 7,300. Guinea-pig inoculation negative for tuberculosis. **Operation.** Nephrectomy. Kidney slightly enlarged, pale, few areas of discoloration. It was thought to be the cause of the trouble and removed. **Clinical diagnosis.** Coli-pyelonephritis. **Recovery.**

Pathological report. Enlarged soft kidney with opaque yellow stripes and dots in the pyramids surrounded by reddened zones.

Microscopic examination. Foci of round-cell infiltration in many places with intense congestion of surrounding vessels. Epithelium of the tubules swollen, disquamated and the lumen filled with hyaline and granular casts. **Cultures** from the kidney tissue at operation, colon bacilli.

Sections stained for bacteria. Considerable number of gram-negative bacilli in the tubules and pelvis with a typical picture of colon pyelonephritis. Here and there in the cortical region are small abscesses with a mixed infection of gram-negative bacilli and large numbers of staphylococci.

NOTE.—A colon pyelonephritis with superimposed staphylococcus abscess.

CASE 54. Autopsy No. 364. West Surgical, 595-561 Female, age 54, May 28, 1908. **Past history.** Marked constipation for four months. **Present illness.** For five days acute abdominal left-sided pain with chills and fever, temperature of 102-104, with pusy urine.

Two days ago acute tender red mass appeared in the left kidney region. **Urine** acid, very slight trace of albumin, small amount of pus, microscopic blood. **White blood count**, 22,000. Culture from the urine shows colon-like bacilli. **Operation.** Nephrotomy for septic kidney. Kidney considerably and symmetrically enlarged, soft and pulpy with scattered small abscesses of the cortex. Pelvis not dilated. Patient died 10 days after admission, fourth day after operation. **Clinical diagnosis.** Septic kidney.

Autopsy 7 1/4 hours post-mortem. Anatomical diagnosis. Carcinoma of vagina with obstruction and dilatation of left ureter; left ureteritis, pyelitis and suppurative nephritis, nephrotomy wound, streptococcus septicemia.

Kidneys. Right kidney weighs 171 grams. Capsules strip with some difficulty leaving a granular surface. Cortex measures 6 millimeters. Markings are fairly distinct. There are no abscesses in the right kidney. Right ureter is not remarkable. Left kidney weighs 208 grams, perinephric fat separated from the kidney and the space is filled with bloody purulent material. On the convexity of the kidney there is an irregular opening 6 centimeters in length leading into the pelvis. The walls of this cavity are composed of soft necrotic kidney tissue. At various places in the cortex and extending into the pyramid the kidney tissue is transformed into soft yellowish black, semi-fluid material. These areas are wedge-shaped with free pus at the surface. Generally they are sharply outlined from the surrounding renal tissue. The surface of the cortex where not involved in the above-mentioned necrotic area about the wound shows indistinct markings. There are no abscesses of the kidney. The mucosa of the pelvis and ureter are reddened and the lumen contains purulent areas. The lower half of the ureter is dilated and its lower end is pressed upon by tumor mass.

Microscopical examination. Shows acute degenerative change with suppuration.

Bacteriological report. Cultures of the heart blood and spleen show streptococcus and colon like bacilli.

Sections stained for bacteria. There are clumps of streptococci in small arteries and in the capillaries of the glomeruli. There are a few clumps of streptococci and gram-negative bacilli in the straight collecting tubules. There are also a few bacilli in the blood stream.

CASE 55. Autopsy No. 880. West Medical, 570-6 Male, age 5, May 28, 1902. **Present illness.** Six months weakness, some nausea, occasional vomiting, restlessness at night, loss of appetite, nocturia three or four times, slight frequency. Has a history of hematuria once within that period. **Physical examination.** Redness and tenderness with some edema of outer and under side of both thighs and buttocks. **Temperatures** normal at entrance. **White blood cell count** 48,000. **Urine** bloody acid, small trace of albumin, sediment much blood, few cell-casts, moderate number of leucocytes. Patient began to run, septic temperature which reached 102 became unconscious and died fifth day. **Clinical diagnosis.** Erysipelas.

Autopsy 19 1/4 hours post-mortem. Anatomical diagnosis. Suppurative nephritis with infarcts of the kidney; subcutaneous glomerular and chronic interstitial nephritis, suppurative prostatitis, septicurulent peritonitis, soft pleural mural thrombi in the right auricle and the right ventricle, thrombi in the right common iliac and right femoral veins, arteriosclerosis with small secondary aneurysm of the left coronary artery, hemorrhagic edema of the inferior lobe of the left lung, streptococcus infection.

Kidneys. Capsules free. Surfaces show numerous minute yellow points. The glomeruli do not

appear to be abnormal. On section, the areas above described are found to extend through the cortex and into the pyramid in some cases as grayish yellow lines. Bladder and ureters not remarkable. Prostate shows numerous small abscesses.

Microscopic examination In many places the interstitial tissue of the kidneys is increased in amount over small areas and there is atrophy of the renal element and round-cell infiltration. In a good many tubules pus cells and necrotic desquamated epithelial cells are present. In one section two abscesses are observed. The capillaries of some of the glomeruli contain leucocytes. In a minority of the glomeruli there are vesicular nucleated cells closely packed together which are proliferated epithelium of the glomerular capsules. There is considerable oedema of the interstitial tissue.

Bacteriological report Cultures from the heart blood no growth. Cultures from the liver and spleen profuse growth of bacteria mostly staphylococcus.

Sections stained for bacteria Staphylococci among which are some chains of streptococci are found in the small areas of suppuration. There are also a few bacilli.

CASE 56 Autopsy No 1505, East Surgical 522-119 Male age 60 September 19 1905 *Past history* Gonorrhoea 47 years ago. Stricture 16 years later operation division of stricture at that time. *Present illness* Admitted with retention. Urine acid slight trace of albumin, much pus. *Temperature* normal. *Operation* Perineal section. Twenty days after operation developed temperature and symptoms thought to be right pleurisy; patient refused nourishment began to vomit had partial suppression of urine and died on the forty-sixth day. *Clinical diagnosis* Stricture of urethra.

Autopsy 33 hours post mortem Anatomical diagnosis Stricture of urethra penile sinus, slight hypertrophy of prostate hypertrophy of bladder with diverticula and cystitis diphtheritic ureteritis pyonephrosis diphtheritic pyelitis and suppurative nephritis on the left senile atrophy of right kidney hypostatic pneumonia.

Kidneys Left renal pelvis and calices dilated and filled with foul thick fluid. Adherent to the walls of the calices and pelvis is a grayish pink membrane. The capsule of the left kidney is adherent surface is extremely granular. Here and there on the surface are whitish slightly elevated areas 2 to 3 millimeters in diameter containing pus. The cortex is thinned. The right kidney shows slightly adherent capsule. The pelvis of this kidney is slightly enlarged otherwise negative. The right ureter is negative.

No microscopic examination of the kidney is recorded no autopsy cultures.

Sections stained for bacteria No kidney tissue was preserved, section of prostate used. The millary abscesses in the prostate show staphylococci a few chains of streptococci and many bacilli.

CASE 57 Autopsy No 119, West Surgical 465-67 Male age 40 March 15 1904 *Present illness* Fracture of vertebra of twenty four hours standing. Urine on entrance small trace of albumin, a few finely granular and epithelioid cell-casts leucocytes. *Operation* Laminectomy. No other urinary examination recorded. From entrance patient ran an increasingly high temperature and died twentieth day. *Clinical diagnosis* Fracture of dorsal vertebra.

Autopsy 2 hours post mortem Anatomical diagnosis Fracture first lumbar vertebra crushed cord operation wound — laminectomy, septic wound meningitis abscess of right lung double empyema abscesses of kidney and prostate cystitis Pott's fracture of left leg streptococcus septicaemia.

Kidneys Combined weight 365 grams. Capsules easily removed revealing small abscesses on the surfaces of both kidneys. In places these abscesses extend a distance into the cortex and in a few instances as streaks as far as the tips of the pyramids. The kidneys are not dilated ureters are free. The bladder presents an ecchymotic gray red mucosa. The prostate shows an abscess 3 centimeters in diameter of the right lobe.

Microscopic examination Sections of the kidney show abscesses.

Bacteriological report Cultures from the heart liver and spleen show staphylococci and streptococci. Cover glass preparations from the pus in the wound show streptococci. *Sections stained for bacteria* Abscesses in the kidney tissue show clumps of streptococci and staphylococci. In one abscess there are two large masses of bacteria one of which seems entirely a streptococcus infection the other entirely a staphylococcus infection.

CASE 58 Autopsy No 1731, West Medical 644-161 Female age 32 June 30 1906 *Past history* Four years ago post-puerperal sepsis. *Present illness* One week ago began to have recurrent attacks of chills without other symptoms. Patient came to hospital in prostrated condition high temperature pulse and respiration. Urine very slight trace of albumin moderate number of red blood and pus-cells. *White count* 13 000. Patient continued to grow worse and died fourth day. *Clinical diagnosis* Septicæmia origin unknown.

Autopsy 19 hours post mortem Anatomical diagnosis Malignant endocarditis of mitral valve bronchopneumonia, purpura hemorrhagica in facets of spleen and kidneys suppurative nephritis septicæmia staphylococcus pyogenicus aureus early pregnancy and abortion.

Kidneys Combined weight 339 grams. The capsules strip easily leaving a dark reddish surface dotted over with minute yellow points, dark red spots and here and there small irregular confluent abscesses. The small yellow areas mentioned are seen to be the outer surface of fairly firm homogeneous masses surrounded by blackish red kidney tissue from which they are sharply marked off. In

some places these infarcts are situated in the cortex, while in others a few extend from the bases of pyramids to the cortex. In the pyramids are to be found numerous yellow streaks and spots. The cortex measures 5 to 6 millimeters. The m. cosa of the pelvis shows minute blackish red spots. Ureters and bladder normal save a few ecchymotic areas.

Microscopic examination. The kidneys show necrosis with abscesses and hemorrhage.

Bacteriological report. Cultures from the heart blood and spleen show pure growth of staphylococcus pyogenes aureus. Sections stained for bacteria show in the discrete abscesses mixed infection of streptococci and staphylococci. In many places the vessels are found plugged with bacteria most of which are streptococci, although all were found to contain considerable numbers of staphylococci.

CASE 50. Autopsy No. 108. South Surgical 70-97. Female, age 61, June 26, 1903. *Present illness.* One week of acute abdominal pain with high fever finally localizing in the gall-bladder region. *Urine* neutral reaction trace of albumin occasional blood and pus-cells, no casts. *White blood count* 80,000 *temperature* varied from 100 to 104. Patient was not operated on and died of sepsis on seventh day. *Clinical diagnosis.* Cholelithiasis, cholecystitis, suppurative epiphritis.

Autopsy 44 hours post-mortem. Anatomical diagnosis. Pyonephrosis, pyelonephritis, cholelithiasis, icterus, fibromyoma of the uterus.

Kidneys. Left kidney is apparently normal right kidney is enlarged, and its capsules strip leaving smooth surface dotted here and there with minute yellowish abscesses. On section the tissue is soft and section surface shows numerous milky purulent areas. The cortex is of good width the pelvis is dilated and contains yellowish brown, foul, purulent material. Ureters and bladder show nothing remarkable.

Microscopic examination. Sections of the kidney show the usual appearance of pyelonephritis. Sections of the left kidney show only edema.

Bacteriological report. Cultures from liver and spleen show accumulation of growth of bacilli.

Sections stained for bacteria show considerable numbers of gram-negative colon-like bacilli in the arteries and in some of the tubules while a considerable number of a smaller gram-positive bacilli are to be found in abscess areas.

CASE 60. Autopsy No. 185. East Surgical, 338-6. Male, age 80, June 14, 1903. *Present illness.* Patient admitted for retention. Could give no information about himself. *Temperature* 100 vomiting, died soon after entrance. *Clinical diagnosis.* Enlarged prostate.

Autopsy 9 hours post-mortem. Anatomical diagnosis. Adenoma prostate, diverticulum bladder slight dilatation ureters, suppurative nephritis arteriosclerosis, senile emphysema lungs, papillary adenoma kidneys.

Kidneys. Capsules somewhat adherent. Cortex of each kidney somewhat narrowed. Kidney tissue

pale opaque and soft. A few small abscesses beneath the cortex (Fig. 32). Cultures of the heart blood show no growth. Cultures from the kidney show several varieties of cocci and bacilli which are not differentiated.

Microscopic examination. Kidney shows in the cortex extensive areas of infiltration of leucocytes with some disintegration of the renal epithelium. Glomeruli are not remarkable. Arteriosclerosis of the vessels, some areas of fibroid atrophy and round cell infiltration.

Sections stained for bacteria. The predominating organisms in the abscess cavities are two types of bacilli one gram negative bacillus probably bacillus coli, the other long barred gram positive bacillus.

NOTE.—These two bacilli clearly seem the etiological factors in the production of suppuration although occasionally cocci are found. This case shows considerable post-mortem sepsis which may explain the presence of the variety of organisms found yet the occurrence of the two bacilli described above in large numbers and confined to abscess cavities seems to indicate that they are the etiological factors.

THE LESIONS OF SO CALLED ASCENDING INFECTION ARE HISTOLOGICALLY INDISTINGUISHABLE FROM THE EXCRETORY TYPE OF LESION

It has been customary to assume that there was a definite lesion produced in the kidney by ascending infection. This is referred to again and again in the literature and is often spoken of as the typical lesion of ascending infection. That this distinction cannot be maintained appears to us to be conclusively shown by the two following cases (32 and 33). Without reproducing here the whole evidence printed above we may note that Case 32 was that of a man whose urine was normal at the time of entrance to the hospital. Following operation for cancer of the stomach retention of urine took place and he was catheterized regularly until the day of his death three weeks later. During the process of catheterization pus appeared in the urine and the case is typical of those generally credited with being ascending infection. Case 33 was that of a woman interestingly enough of exactly the same age who died two weeks after an operation for fibroma of the uterus followed by infection of the wound. This patient had no urinary infection at the time of entrance was not catheterized during her stay in the hospital and at autopsy showed a normal bladder. Nevertheless the lesions of the

kidneys in these two cases are indistinguishable as a glance at the illustrating figures will show. These cases are typical of several occurring in our experience and we think they are sufficient to require an abandonment of the belief that there is any lesion of the kidney typical of ascending infection.

THE BEARING OF THE ABOVE OBSERVATIONS UPON THE DIAGNOSIS OF RENAL INFECTION

If we have succeeded in establishing the fact that the pyogenic organisms produce lesions of the kidney essentially different from those produced by nonpyogenic organisms it follows that this fact has an important bearing upon diagnosis. In the first place it has, we think, been abundantly demonstrated by the testimony of many observers that organisms concerned in renal infection appear promptly in the urine though they may not long continue to so appear. That organisms not concerned in renal infections may also appear in the urine is to be remembered. The evidence above referred to of the appearance of tubercle bacilli and lepra bacilli after the administration of salvarsan, the recent observations of William H. Smith in regard to the appearance of organisms in the urine of patients with fever probably caused by a septicaemia and a mass of extremely careful evidence all bear upon this point.

On the other hand with clinical evidence suggesting a renal infection the diagnostic importance of a careful examination of the urine can hardly be overestimated. Thus the lesions characteristic of pyogenic organisms will show the bacteria in the urine perhaps only during the early stages. Since however these lesions are comparatively shut off from the lower portions of the kidney and as they do not involve the pelvic mucous membrane pus in any considerable amount will be found rarely if at all. By the same token since the lesions of the nonpyogenic group are produced chiefly in the renal pelvis evidence of this fact is abundantly clear in the urine by the early production of pus accompanying the appearance of the microorganisms.

A very striking difference is also to be ob-

served in the effect on kidney function as measured by phthalein in these two types of infection. Since the suppurative infections involve chiefly the cortex and comparatively little the convoluted tubules they would be expected to produce comparatively little effect upon kidney function thus measured and such is in fact the case. On the contrary the chief lesion of acute renal infections with the colon bacillus group is not upon the convoluted tubules the pelvic lesion though appearing early being we think secondary to the tubular lesion. This should and in fact does produce sudden and profound changes in kidney function the case described on p. 498 being but one of a considerable series of observation which we have previously discussed in a paper on "Ilelo-nephritis." Briefly and somewhat dogmatically stated therefore the diagnostic evidence is as follows. If with clinical evidence suggesting a renal infection freshly drawn urine studied as suggested by Crabtree shows cocci in abundance with a small amount of albumin a few red blood corpuscles and many leukocytes or a little pus together with a renal function at or near normal limit a diagnosis of coccus infection of the kidney is justified. If on the other hand a similar examination shows many bacilli a little albumin and much pus coupled with a markedly diminished kidney function a diagnosis of colon bacillus infection of the kidney is unavoidable.

Though it is foreign to the title of this paper it may not be improper to suggest the bearing of these observations upon treatment. Clearly the suppurative lesions concern those portions of the kidney which are relatively inaccessible to drug and if these lesions are such as to require treatment that treatment must be operative. On the other hand the lesions produced by the colon bacillus group concern those portions of the kidney relatively accessible to formaldehyde containing drug and the surgeon is therefore justified in persisting in treatment by this method on the assumption that if it be properly planned and efficiently carried out

it will succeed in controlling the infection. This statement must not be assumed to mean that we believe that the formaldehyde containing drugs act upon the cells of the convoluted tubules. Thus we have no reason to assert, but the lesion of this portion of the kidney is a very transient one and such damage as is done by the acute process is rapidly overcome by the restorative action of the cells themselves. This particular lesion does not require treatment. It is the lesion of the pelvis and to some extent of the lower urinary tract that is the persistent and dangerous lesion, and this can be reached by formaldehyde.

NOTE.—W. wish to express appreciation of the valued services of Dr. James Homer Wright director of the laboratory for lively interest in the work and for aid in collecting material. W. have appreciated the privilege of appealing to his judgment on difficult questions arising during the progress of the work.

Dr. Oscar Richardson has kindly supplied from the autopsy room much valuable material.

Dr. William H. Smith has offered many helpful suggestions on the staining of bacteria in tissue.

Whatever of unusual merit our microphotographs may show is due to the painstaking thorough work of M. L. S. Brown.

CABOT AND CRABTREE NON-TUBERCULOUS RENAL INFECTIONS

- [illegible]

THE BASTEDO SIGN IN CHRONIC APPENDICITIS

B. JACOB ROSENBLUM M.D. PH.D. PITTSBURGH

IN 1911 Bastedo (1) described a new test for chronic appendicitis. It consists in passing a colon tube eleven to twelve inches into the rectum and injecting air by means of an atomizer bulb. He found that as the colon distends, pain and tenderness to finger point pressure becomes apparent at McBurney's point, if appendicitis is present. Dreyer (2) Rost (3) Slawinski (4) Hertz (5) Goodman and Lueders (6) and Bischoff (7) have described their experiences with this test.

Bastedo, Hertz, Dreyer and Bischoff consider colonic inflation of great value as a diagnostic sign of chronic appendicitis. Rost, however, claims that Bastedo's sign is positive not only with diseases of the appendix but also in pathologic conditions in the colon. Rost also says that the pain appears only if there are changes in the mesenterium which brings the appendix into a certain abnormal relation to the cecum, however. Bischoff on the contrary has found the test positive when the mesenterium was entirely normal and the appendix alone was diseased. In the cases that he examined after operation, there was no longer the slightest pain in the appendix region when the colon was distended.

Goodman and Lueders however claim that there is no constancy in the results obtained with this test, and it is in no sense pathognomonic of chronic appendicitis. They have seen no positive reactions in normal individuals.

I have personally been using this test, ever since its description by Bastedo and have found it of great service in the diagnosis of chronic appendicitis as may be readily noted by the accompanying tabulation of cases studied.

SOME OBSERVATIONS CONCERNING POST-OPERATIVE COMPLICATIONS OF THE LANE SHORT CIRCUIT AND COLECTOMY

BY R. L. SMITH, M.D. LOS ANGELES, CALIFORNIA

THE intestinal work of Sir Arbuthnot Lane has been widely criticized in this country with varying degrees of justice depending upon the knowledge of the writer or speaker upon the subject and his experience in dealing with these cases.

If it be possible to summarize the opinion of surgeons on the subject of relief of intestinal stasis by surgery, I would say that it can be expressed in this: There is no doubt that certain cases are greatly relieved of their symptoms of intoxication by one of the Lane procedures but the result of the operation is too often spoiled by complications which arise from the surgery itself.

In this paper I shall take up separately the complications that seem to be peculiar to this particular type of surgery and attempt to point out the reasons for their occurrence and the logical way to avoid them.

In ileocolostomy the one great fear of American surgeons has been the backing up of feces into the blind pouch of the cecum necessitating secondary colectomy. Lane's records in 1912 showed that this complication happened in 20 per cent of his own cases and that he was unable to foretell in which case it might be expected. A more careful consideration of the *physiology* of the colon will show that the remedy for this the greatest bugbear of the short circuit lies not in finding some method to prevent the ileal content from going back into the cecum but in assuring this content a free outlet after it has backed up. The ileal content in all successful short-circuit cases backs up into the blind pocket and the only ones that become impacted are those with a partially obstructed colon from which the solid residue cannot return.

It has been repeatedly shown by the X-ray that any fluid thrown into the terminal segment of the large bowel will be carried immediately into the cecum by reverse peristaltic waves. Here the fluid is absorbed and the

so-called normal peristaltic waves carry the more solid content back to the lower segment or container. This is precisely what happens after a short circuiting operation and there will be no difficulty with fecal impaction as long as the colon is unobstructed. A simple short circuiting operation in the obstructed case will not only be of no service but is distinctly contraindicated. Either the obstruction must be relieved or the colon removed to the point of obstruction at the time of anastomosis or an impacted cecum will result.

To my mind the most serious complication is that of unusual post-operative adhesions which by contraction cause obstruction varying from slight narrowing to complete cutting off of the bowel. Symptoms from these adhesions are usually not apparent for several months after operation although I have lost one case from acute obstruction in the third week of an apparently smooth convalescence. These adhesions are peculiar in that they are usually in patches and are the result of local peritonitis in widely separated parts of the abdomen. These constant patches of peritonitis are due to direct infection at the time of operation because of technical error in the arrangement of the steps of the Lane operation used almost universally by American surgeons. In making the anastomosis the infected thread which sews through and through the colon wall is handled by the surgeon touches the gauze packs and renders the whole field unsterile after which the patient is eviscerated and the split in the mesentery stitched. In spite of the most scrupulous care on the part of the surgeon it is impossible to prevent some infection at this time and the handling of the whole abdominal contents in moving the small intestine to the upper abdomen is accountable for the wide distribution of the infection. As Lynch has suggested it is a safer, urged procedure to sew the mesenteric

before the anastomosis is done and it is also safer to make the opening and sewing of the colon the last step in the operation, at which time the field must be considered infected, and the same care exercised to prevent the distribution of infection as is customary in operating in a recognized infected field.

The technique of intestinal anastomosis has been largely influenced by the development of the technique of gastro-enterostomy where it has reached its highest point of perfection. This technique however efficient in the comparatively uninfected upper abdomen, cannot be used in anastomosis of the colon or terminal ileum, where the contents are highly infected. The wide application to all parts of the intestinal tract of this simple and effective method of sewing is responsible for the great preponderance of post-operative adhesions which are prone to follow all operations entailing the opening and sewing of the lower bowel.

Experience has shown that late in the convalescence alarming symptoms develop in the cases in which a partial or complete colectomy accompanies the intestinal anastomosis. This occurred in my work until I properly appreciated the importance of the *physiology* of the parts removed and adopted a very simple routine of supplying fluid to the patient before it became evident that it was necessary. In six consecutive partial colectomies since that time I have not seen any untoward symptoms develop. Lane gives a large quantity of saline solution under the skin while the patient is on the table and repeats it later if the patient shows signs of needing fluid. Although I followed Lane's rule, my early colectomy cases all became dehydrated, developed rapid pulse, nausea, vomiting and in most cases acute dilatation of the stomach. Their condition was more alarming from the fourth to the eighth day than immediately following operation—the reason is obvious. About 65 per cent of all the fluid intake of the body

is absorbed by the cecum and ascending colon. The sudden removal of this filter leaves the patient unable to pick up water until the left side of the colon has taken up the work—usually from six to ten days. If the patient during this time be given salt solution under the skin *daily* the convalescence will lose all its terrors and become that of any major abdominal operation.

The importance of the choice of cases to be operated upon and the choice of operation in each individual case cannot be overestimated. Improper selection of either is sure to be followed by defeat in obtaining the desired symptomatic results, as well as by post-operative complication, which would be attributed to the surgery itself. Ileocolostomy is designed to relieve a stasis in the ileum—the result of an obstruction preventing the free passage of its contents to the cecum. This has nothing to do with colon stasis or constipation and if a simple short circuit be done on a patient with constipation, a secondary colectomy will probably have to be done for impacted cecum. We should not expect to cure a mechanical difficulty in the large bowel with an operation designed only to relieve a mechanical difficulty in the small bowel. If a patient suffering from toxemia from the *small bowel only* becomes a surgical case I believe that the simple Lane short circuit is the operation of choice and I am sure it can be done with safety if the simple precautions against adhesions mentioned above are followed. If as is usually the case, the obstructed ileum is accompanied by a dilated cecum, which has lost the power to empty itself normally the Mayo right-sided colectomy is, to my mind the operation of choice. The technique as developed in the Mayo clinic is free from the criticism of the Lane technique in that the intestines are not handled after the colon has been opened, and thus the possibility of infection is greatly lessened.

CIRCULAR CONSTRICTION IN THE TREATMENT OF FRACTURES OF THE LONG BONES

By F W PARHAM MD FACS NEW ORLEANS

AT the meeting in December 1912 of the Southern Surgical and Gynecological Association Mr Milne of the London Hospital showed a device for the fixation of fractures of the long bones. This consisted of a metal band with a screw thread its whole length along which a nut was made to move by means of a spanner as shown in Fig 1 *a b d and e*. The band is thrown about the bone the one end passed through a loop at the other end and the band tightened by the spanner until the fragments of bone are held in place when the nut is fixed and the band cut off.

I was so much struck with this device that after getting back home I began to experiment to see if the apparatus could not be somewhat simplified. My aims were two first to find the best and simplest material to place about the bone and second to make as simple as possible the device for tightening the constrictor band. The second part of the apparatus was first elaborated on the principle of the *écraseur* or the wire snare. The constricting material was not so easily settled upon. I first tried silver wire doubled so as to form a loop at one end. The loop end was to be passed about the bone the free end

carried through the loop and a perforated shot slipped over the wire. This being attached to the tractor was easily drawn up and tightened by turning the traction screw and made as snug as desired about the bone. As the wire was tightened the shot was of course driven against the bone immediately over the loop and there mashed against it. This appeared extremely simple and theoretically seemed likely to answer all expectations. However in practice something always went wrong. We afterward twisted the wire which seemed especially to adapt it to holding

Fig 1 *a b c d e* Mil Instrument

Fig 2 Putt's Apparatus.

Fig 3. Putti instrument showing band tightened and about to be carried over and caught between the lateral ends.

Fig 4. Putti instrument showing tightening of band. Upper band tightened and in place.

itself in place about the bone but it was found that when sufficient force was put upon the wire to tighten it either the wire broke or cut through the shot, so that the constriction was lost. We experimented with different kinds of wire—copper, aluminum, and bronze—but found none answered the purpose. Dr. Martin suggested a steel band with a slit in one end expanded so as to make room for the other end to be slipped through. A hole in the other end made it easy to attach it to a pin near the end of the screw rod which was drawn up by turning the wheel at the other end.

After various modifications in the perfecting of which we were cheerfully assisted by our instrument makers, the apparatus as finally elaborated and sold to the profession is represented in Fig. 8.

I showed the apparatus before the American Society of Clinical Surgeons which met in New Orleans in March, 1914 and presented a femoral fracture treated with two bands. Dr. Martin shortly afterward applied two bands to a fracture of the tibia, holding the fragments so firmly in place that they were not displaced when in a delirium the following night the man got out of bed and walked about the ward (Figs. 10 and 11).

Dr. Lund, of Boston asked me to send him one of the instruments shortly after this meeting and was able to report at the recent meeting in Washington of the American

Surgical Association 30 cases thus treated. He applied the bands in Boston last October before the Clinical Congress of Surgeons of North America, taking X-ray pictures of the cases immediately afterward showing the fractures reduced and the bands in place.

Dr. Matas recently called my attention to an article on a new method of osteosynthesis by Professor v. Putti published in *La Clinica Chirurgica*. In this article Professor Putti gives a history of metallic ligatures in the treatment of bone fractures and describes an apparatus of his own which he had employed with success. Cuts explain the apparatus fully. It will be observed that there is a striking similarity between this apparatus and the Parham and Martin device.

I did not know of his work until May 1, 1916 when Dr. Matas called my attention to it as above stated. The suggestion of the Parham and Martin apparatus was derived as mentioned in the beginning of this paper from Mr. Robert Milne of London. He subsequently showed his instrument and made

Fig 5. Putti bands applied.
Clin. Chir. Milano 14, 1122 June 30.

Fig. 6. Fracture of humerus (Putti).

some remarks upon its use at Murphy clinic in Chicago. The remarks and cut are published in *Murphy's Clinics* for April 1913 to which I am indebted for the illustrations of the Milne apparatus here given.

The Parham and Martin bands are intended for oblique fractures. If it is desired to apply them for a transverse fracture a plate or the girder of Mr. Souttar shown in Fig. 1 c and two bands would have to be employed. This girder is a metal plate about a half inch wide bent along the middle parallel to its length to a little less than a right angle. A longitudinal slit is made in the fragments while held in apposition and one edge of the plate driven in until the other lies flat on the bare surface. The band or two bands are then applied or the plate may be held in place by two or more screws.

The article of Putti is so interesting that I shall give here an abstract of it prepared from a translation kindly made for me by Dr. Graffagnino of New Orleans.

The metallic ligature, one of the oldest methods of uniting bones, should not be confused with the metallic suture which is limited in its application and should be definitely abandoned. The metallic ligature is based, he thinks, on correct principles and should be considered the method of election for

Fig. 7. Band applied to the patient's arm.

all fractures of the extremities, oblique and overlapping.

It has been cut many times, the use of various positions and is which is held about the bone by twisting together the ends.

The result depends on two factors:

1. Quality of material.

Manner of employing it.

Silver has been most used but is not as strong well because it breaks easily. Bronze aluminum is better because of its tenacity and resistance to oxidation but it is not very malleable. In Putti's opinion that advocated by Lambotte is best. This is a gold or silver plated copper wire.

The objection to wire is:

1. The wire being cylindrical does not adhere well to the bone.

Fixation by twisting the ends together results in breaking the wire at the critical moment.

Putti was unable to overcome this objection so he finally turned to the metallic band, tightening it about the bone somewhat after the manner of a slip-knot. The tightening is done by a band lever which is illustrated in the accompanying illustration (Figs. 2 to 5).

The band is composed of an alloy with a bronze base. It varies in width and thickness according to need. The 2.5 and 6 millimeter width has been most used.

From the cut it appears that the inner cut lies the band which is drawn up gradually by the long screw worked by the wheel at the other end. The required tension being obtained the handle is carried forward bending the band through an arc of about 90° when it is cut off and the instrument removed. To avoid irritation of the tissues the band is armed between the two metallic ears just beyond the bridge of reflection through which the band has been passed (Figs. 2, 3, 4, 5, 6 and 7).

It will be observed that Putti's instrument is more complicated and cumbersome than the Parham and Martin apparatus requiring, as it does a loop for making the slip knot and

Fig. 8. Parham and Martin instrument and band.

Fig. 13.

two lateral ears just beyond to hold the band in situ.

In our instrument there is nothing but a slit in the expanded end through which the other end is passed. The tension of the band when tightened is sufficient to hold it in place.

The band is of steel with a sufficient percentage of carbon to give it just the right degree of rigidity. The width varies from 3 to 5 millimeters.

It will be seen from a comparison of the two instruments that ours is decidedly simpler, being a simple band passed through a slit and clamped by simply holding it down flat. To cut it off requires only that it should be held fast by a chisel while the tractor is wiggled to and fro a few times, when the band breaks readily. It is then driven down flat by a few taps of the mallet on the chisel pressed against it. The instrument is so simple that the whole operation may be completed without once touching the wound (Figs. 8, 10, 11, 12 and 13).

Dr. Lund has devised a simple instrument for passing the band and we have used a needle like a large aneurism needle which answers well. The band itself is easily passed

Fig. 12. Parham's case of oblique compound fracture, May 3, 1906.

Fig. 13. Band applied June 3, 1906. The band was subsequently removed owing to some irritations, though slight occurred. Healing has been satisfactory.

without any aid in some cases, but generally speaking it is difficult to do this as the band is not well adapted to moving about a cylindrical bone surrounded by dense fibrous tissues, such as those attached to the linea aspera of the femur or the interosseous membrane of the tibia.

Mechanically this band method is extremely simple and effective. I have not intended to discuss the question whether as W. P. Carr of Washington, asserts it really violates an essential principle in the treatment of fractures and actually interferes with callus formation. A most elaborate investigation published in the *British Journal of Surgery* has led Mr. Hey Groves to conclude that in dogs and cats it does inhibit the development of external callus under and over the circular band, but the work of Dr. Lund which has been more extensive than Dr. Martin's and mine, seems to show that practically the objection does not hold.

THE PARHAM AND MARTIN BAND IN OBLIQUE FRACTURES

WITH REMARKS UPON MECHANICAL APPLIANCE VERSUS BONE CRAFTS

BY F. B. LUND, M.D., FACS, BOSTON

AS we gain further experience and skill in the operative treatment of fractures we are more and more able to make an intelligent choice of the cases which should be operated upon early to operate more skilfully and take better after care, thus avoiding the painful necessity of operating late upon the bad results of those fractures which have received the so-called conservative treatment.

In fractures of the femur—particularly those cases in which the old Buck's extension treatment entailed for the patient so much discomfort and so long confinement in bed (three to six months) and for the surgeon so much care and constant adjustment of the apparatus—have our results been more satisfactory and the method of obtaining them more easy and comfortable both for the patient and the surgeon.

In cases of transverse fracture of the femur, especially those where repeated attempts fail to bring the ends into apposition and in which X-rays show the ends overlapping or perhaps actually separated by a clear space, interposition of soft tissue, is the operation indicated. We gain by operation with firm internal fixation: (1) the knowledge that the ends of the femur are in perfect position; (2) the ability to hold them there by fixation in a plaster-of-Paris dressing; (3) the power to bid farewell to the cumbersome unsatisfactory and trying extension methods. We can also practically ensure for our patient a perfect anatomical result without shortening.

The long plates with six or eight screws offer very good fixation in femur fractures, but the length of the limb and the power of the muscles are so great in proportion to the strength of the plate that without firm long continued external fixation a slight springing of the ends may take place, the screws gradually loosen and pull out and marked bowing or actual displacement of the ends occur resulting in failure. Of course, experience has

by this time brought us to use wood-screw and to fit them tightly in the screw hole, but even with adequate technique fixation by plate and screw is not absolutely satisfactory and long and careful immobilization is necessary.

Even though in plating our results are better than with the old method and our deformities less, union is not much more rapid and in fact some (Martin) have claimed that it takes place more slowly and I think he is right.

In oblique and comminuted fractures we have a method of fixation which is simple, rapid, mechanically effective and get union in a comparatively short time. I refer to the steel band devised by Parham and Martin of New Orleans.

Oblique and spiral (or uncomminuted) fractures are perhaps more frequent than transverse. Transverse fractures are produced when the fracturing force is applied at right angles to the bone, as when a man in an automobile accident is thrown sideways against a telegraph pole. Oblique and spiral fractures occur when the force is applied nearly in the longitudinal axis of the bone, as in falls from heights striking upon the feet, especially if the body be twisted so as to produce rotation. Sheerness of the application of force tends against transverse and for spiral fracture. If we wish to break a stick transversely we pull it sharply across the knee. If we wish to splinter it we stand it on end and hit it with a mallet or twist it holding one end in each hand. It seems possible that a majority of fractures of the shafts of the long bones are more or less spiral or oblique, at least we use the bands nowadays full as often if not oftener than the plates. An obliquely fractured bone may be compared to a broken fishing rod; the rod always breaks obliquely with a splintered fracture and the effective way to mend it is to wind it with waxed thread, thus bringing the fractured surfaces in apposition and holding

Fig. An oblique fracture of the femur, banded 1 year ago, in child, aged four years. A (left), anterior view showing band embedded in the femur and entirely covered by new periosteal bone. B, lateral view showing that here the bone has not entirely embedded the band.

them firmly. The same principle is applied to bone by the Parham band. The bone if outside the body might be wound with copper wire as a fishrod is with thread and the result would be excellent. But this would take much time and cause much trauma in operating through a deep incision in the muscles of the thigh. A single wire passed once around the bone would not give firm enough apposition and would be likely to cut its way quickly into the cortex so as to be too rapidly loosened.

The bond of Parham and Martin is wide enough so that one or at most two of them passed around an oblique fracture give effective support and they can by means of the band placer be carried quickly around the bone and fixed as quickly as a wire can be twisted. The rough oblique-fractured sur-

faces are firmly held together and the fragments evidently much more firmly supported than are the transverse fractures by a bone plate. The strain on the plate is transverse and sometimes breaks it. The strain on the band is longitudinal; it never is broken after it is once in place. The firm apposition of the rough surfaces of bone prevents slipping, twisting and springing. Union takes place quite rapidly and motion may be allowed several weeks earlier than with the bone plate. The band is wide enough so that it does not cut in and thus become loosened. It is simpler of application than the plates and screws as it requires no drilling of the bone, accurate fitting of screws or careful use of screwdrivers and drills. The one advantage in the plate and screws is that one does not always have to clear the soft tissues off clear around the bone but can grasp the ends with heavy forceps and drill and put the plate in without clearing the soft tissues off the posterior surface of the bone. This is an advantage in the femur because the *linea aspera* is difficult to clear and it is there if anywhere that we get hemorrhage while in the tibia we must avoid the *interosseous* membrane and the occasional injury of the posterior tibial which may take place if we carry instruments carelessly around behind the bone. This slight disadvantage is not to be weighed for an instant in the oblique cases however against the other advantages of the bands. A very clever instrument has been devised by Dr. Duff of Boston which may be passed around the bone while hugging its posterior surface and with the minimum of trauma and separation of soft parts which in my hands has greatly facilitated the passing of the bands. They may thus be quickly and simply applied. In spiral fractures with comminution the band holds the separated piece firmly in its position between the main fragments of the shaft or if one band (as is rarely the case) does not accomplish this effectively two will certainly do so. For these cases before I knew about the bands I formerly used a plate and wires.

In our hospital we have a good many oblique fractures of the femur in children and three years ago I began to use the band on those

FIG. 1. Ankle fracture with hip in. (Ht. 41)

After banding and plaster-of-Paris fixation the patient have been surprisingly comfortable and the great advantage has been that no adjustment of apparatus has been required. After four weeks the plaster can be taken off and after living in bed a week the little patient get up on crutches and very soon are running about. The result in these cases have usually been perfect. When we first began to use the bands we were warned by various surgical wiseacres that in these children as the bones grew the bands would cut in and girdle the bone and that fracture would result or that the band would cut off the nourishment from the distal portion of the bone and prevent its growth, comparison being made to girdling a growing tree by a wire tight enough to cut off the flow of sap and kill it. But the blood and lymph which nourish a bone do not flow straight up between the periosteum and bone as does the sap between the bark and wood of a tree from bottom to the top or the root to the branches. The periosteum from which the surface of the bone is regenerated is nourished by blood vessels from all side which are not cut off by the band and the marrow is nourished by the branches of the nutrient artery which as it is protected by bony wall is not compressed or cut off by the band. None of my children who have had their femur encircled by bands has suffered sub-

FIG. 2. Oblique fracture of femur with ankle in. (Ht. 41). Same fracture treated by the band. This fracture would have been tremendously difficult to treat by extension with the ankle with the bone well fixed. The boy was walking on the leg in seven weeks.

sequent fracture and I am fortunate enough in one case to be able to present an X-ray photograph (Fig. 3) of a femur in a child aged four years about which a band was placed two years ago. The picture shows the femur slightly widened at this point and the band included in the shaft of the bone which has grown over it. In time it must happen that the band is shut up or enclosed in the bone and how it can cause irritation when firmly fixed in rigid tissue is difficult to see.

The question may fairly be asked why we have not undertaken the intravascular bone graft method in these fractures in order to do away with foreign bodies and employ nothing but normal bone tissue for fixation.

The answer is that we have felt that in fractured femurs the muscle wound is necessarily so deep that it would be a difficult job to saw out the graft and that the use of the band is so simple and easy a comparison with the other that in fresh fractures one would

Fig. 3. A (left). Oblique fracture of lower end of femur in woman aged about three years. The difficulty of adequate treatment by skeleton in this case is evident. B same case treated by band. There is rapid and successful recovery and good function.

hardly be justified in employing the latter method. The inlay bone graft also is obviously much better adapted to transverse than oblique fractures.

Fresh cases of fracture of the tibia of transverse can usually be brought into apposition without operation in fact they are usually the result of direct violence applied in a transverse direction and the tibia keeps them in place. In the much commoner spiral fracture the line of the fracture does not favor the inlay graft while the band holds the surfaces in perfect apposition and must give a firmer support than would the inlay graft. An inlay graft would obviously be much easier to saw out in the subcutaneous surface of the tibia than in the femur.

The non-operative treatment in spiral fracture of the tibia never adequately gets the ends in apposition and there is always at least an inch of shortening. The results of the band treatment it seems to me leave little to be desired as the bone is restored practically to its normal contour.

When plates are applied to the subcutaneous surface of the tibia, they usually have to be removed, as they are placed so superficially

Fig. 4. A (left). Spiral fracture of the tibia in an adult. B same case after application of band.

beneath the skin that they ulcerate through by pressure. However band on the tibia hardly ever have to be removed practically never if the operation is aseptic.

The bands are applied as follows: a longitudinal incision through the skin, fascia lata and muscle exposes the fracture which is cleared of periosteum, reduced by extension and manipulation with the heavy Lane forceps in the usual way. Then the periosteum is cleaned from the bone around the central point of the line of fracture the Duff instrument passed around the bone and the band caught by the hook in the end and drawn around. The end is then threaded through the slot the hole caught in the pin and the screw turned until the band tightly encircles the bone. The band is then bent sharply back by depressing the handle of the instrument and the instrument freed and removed. The band is then cut off close to the slot with wire cutters and the end hammered down. The fascia lata is closed with a continuous catgut suture and the skin with silk worm gut without drainage. Smoothly applied sterile gauze and wadding and bandage plaster-of-

Fig 5 A Oblique comminuted fracture of upper end of femur

Fig 5 B Same fracture application of band

Paris sprica to thigh. The bandage should extend from the toes to above the knee in case of fractured tibia.

Six weeks in plaster is the time required for an adult thigh and four weeks for a tibia. Stitches are removed in ten days through a window cut in the plaster. On removal of the plaster of Paris union is usually complete. In femur cases the patient is kept in bed one week with the plaster off and then gets up on crutches. There is usually some temporary oedema on removal of the plaster of Paris.

Sepsis ought never to occur and may of course be insured against by adequate technique. If it does occur the wound must be opened, washed out and drained, but it may not be necessary to remove the band for four to six weeks, by which time bony union is complete. Infection may result in bad ad-

hesion of the muscles to the bone and in stiffness of the knee. It is a very serious matter and a reproach to the surgeon or hospital where it occurs. With a competent and a well trained staff we can count on avoiding it, but unfortunately, we cannot always be certain where constant changes in assistants are made and an occasional incompetent slips by, as in many of our large hospitals.

Since January 1, 1914 I have used the bands in 14 cases and the Lane plates in 7, showing that in 66 per cent of our operative femurs the bands can be used. Since January, 1911 I have plated 30 femurs. I have used the bands 9 times in oblique fractures of the tibia and have not used the plates at all for the tibia since we had the bands. I had previously used the plates for 13 tibias. I

have never used the bands for the forearm bones, fractures of which 16 in number I have subjected to open operation since 1911 11 were plated 1 wired 1 sutured (ole cranon) 2 open reductions, and 1 bone graft

The figures which follow have been chosen to illustrate cases suitable for treatment by the bands cases in which it would be difficult to get good and quick results by so-called conservative treatment Note especially Fig 3 A and B and Fig 4 A and B in both

of which a good and quick result was attained

As a result of this experience and the observation of the cases of my colleagues, I believe that the Parham and Martin band is of very valuable assistance in the treatment of many difficult fractures, and I wish to express my debt to the distinguished inventors and to say that it is not the only one of their contributions to surgery which has been of great value

NAILS AND SCREWS IN JOINT SURFACES

By ARTHUR T. MANN, M.D., F.A.C.S., MARY POLIS
Associate Professor of Surgery, University of Minnesota Medical School

THIS series of experiments was undertaken after nailing a fractured and misplaced external condyle in the elbow of a boy of seven through the joint surface in order to determine the behavior of nails and screws so placed and the joint changes in response to their presence

This boy was referred to me six weeks after the fracture with the fragment still out of place, though the usual methods had been faithfully used to replace it I was unable to replace it by any of the ordinary methods and determined upon an open operation After opening the joint we found the fragment rotated nearly one hundred and eighty degrees about a slight attachment to the external lateral ligament of the elbow and standing straight out from the joint Little or no callus had formed and it was fairly easy to reduce it but it would not stay in place It could not be made to stay in place either with the elbow at cut angle flexion, at right angles, or with the arm straight The head of the radius forced it out of place We decided to nail it through the joint surface This was easily done Firm adhesions developed to the tissues about the joint which later had to be broken up forcibly under ether This loosened the fragment somewhat from its bed but the final result was good serviceable arm with moderate limitation at the extremes of motion

The method described was suggested to me by an admirable article on joint fractures by Sherman and Tait in the course of which they detailed some experiments with Lane's plates, bone pegs, screws and staples and in

the course of which they stated that after a painstaking search they could find no case in the literature in which nails and screws had been used through the joint surfaces

I think my series of experiments bring out some further points of interest

In the whole series no joint became infected and no specimen was lost In most of them rubber gloves were used a few were done with the bare hands to see if the technique would stand this amount of exposure No dressings were used after painting the suture line with tincture of iodine and the dogs were allowed to run about without fixation of the joints Most of them favored the leg operated on for a time but as a rule they soon lost their limp and all of them were running about actively without a limp at the time the specimens were recovered

Dog No 600 Right knee Two nails were driven into the inner condylar and countersunk less than the thickness of the cartilage Moderate trauma was added to the cartilage about them Four months 6 days after operation (Fig 1) The nails are entirely covered with a thin layer of tissue apparently of the same color as the rest of the cartilage The cartilage is nearly smooth but not quite in the very close about the nails The semilunars and the joint cartilages are otherwise apparently smooth and normal, opposite the nails as elsewhere There is no staining of the heads of the crucial ligaments

Dog No 600 Left knee A five-eighths inch silver plated screw was countersunk into the inner

Fig. 1. Periment 690 right knee 4 months 6 days after operation. Two nail heads sunk less than the thickness of the ligament. The entire area covered with connective tissue.

Fig. 2. Periment 690 left knee 3 months 12 days after operation. Five eighth inch silver plated screw sunk well below cartilage surface. Screw entirely covered. Condyle appears slightly built up over screw.

condyle of the femur well below the thickness of the cartilage. Three months less 2 days after operation (Fig. 2). A slight amount of blood was in the joint. The screw is entirely covered and the condyle apparently *slightly built up about the screw area*. The covering is not yet quite smooth and does not show quite as clear a translucent gray as the rest of the cartilage.

The cartilage on the outer posterior quarter of the other condyle shows some thinning, is a pale pink and the surface is not quite so smooth as the normal cartilage, possibly from overuse due to a faulty position of holding the leg during the stages of convalescence. This was the only case in which changes suggestive of osteo-arthritis were present. The cartilage of the tibial head suggests a very slight similar change while the semilunar seems normal. This was an old poorly nourished dog and we came to the conclusion that this was probably present at the time of the experiment and not the result of the experiment.

The surfaces opposite the screw seem normal. Though some blood was left in this joint the roots of the crucial ligaments are not as stained as in most of the other specimens, practically none at the femoral ends.

Dog No. 69. *Right knee*. Two nails were driven into the internal condyle of the right femur and countersunk well below the depth of the cartilage. Three months 24 days after operation (Figs. 3 and 4). The nails are completely covered and the tissue is almost level with the joint cartilage, slightly pitted but nearly smooth. The semilunar cartilage and the bearing surface of the tibia opposite the nails is perfectly smooth and normal. The cut surface shows no apparent overbuilding of

bone or cartilage above the normal level. Both nail heads are covered across with bone which is lined with tissue about the same thickness as the joint cartilage.

Dog No. 697. *Left knee*. One half inch silver plated screw was countersunk, not quite the thickness of the cartilage, into the condyle of the left femur. A second larger drill was used to take care of the flare of the screw head. Two months 20 days after operation (Figs. 5 and 6). There has evidently been a *slight upbuilding of the condyle* about the screw. The screw head is entirely covered by a thin plate of tissue at a lower level than the joint surface and with the lower edge growing over the edge of the screw with almost the joint level. The opposing joint surface on tibial and semilunar cartilages is smooth and normal. The cut surface shows bone beginning to grow inward over the top of the screw and is covered in turn by a thin cartilaginous or connective tissue.

Dog No. 726. *Left knee*. A silver plated screw was countersunk into the inner condyle of the left femur so that one edge was flush with the surface and the other edge buried one and one half millimeters below the surface. Six months less 2 days after operation (Figs. 7 and 8). The surface of the condyle has built up so that the free edge is buried. The edges of the tissue have grown over the screw head burying all but one-fourth of its area and has grown way across in the groove of the screw. The joint surface is glossy and smooth at all other places in the joint. There is no roughness or inflammation of the head of the tibia or semilunar cartilage opposite. The joint is apparently normal in every other way except possibly the slight atrophy of the head of the inner crucial ligament. The cut surface

Fig. 3 Experiment 607 right knee, 3 months 24 days after operation. T nails below depth of cartilage. Nails completely covered.

Fig. 4 Experiment 607 right knee. Cut section, 3 months 24 days after operation. N apparent building up of condyle. Nails covered with bone and connective tissue.

Fig. 5 Experiment 607 left knee, 3 months 20 days after operation. One-half inch silver-plated screw sunk not quite the thickness of the cartilage. Screw entirely covered by this plate of connective tissue.

Fig. 6 Experiment 607 left knee. Cut section, 3 months 20 days after operation. Evidently slight up-building of the condyle about area of screw.

shows bone as well as connective tissue in the tissue growing over the edge of the screw head and the advancing tissue is not quite as thick as the normal cartilage of the joint.

Dog No. 76 *Right knee*. A steel screw was inserted as before so that its upper edge projected over 5 millimeter the lower edge being buried about 1 millimeter the inner edge flush with the cartilage and the outer edge about 0.75 millimeter below the free surface. Five months after operation (Fig. 9) *The surface of the condyle* is 1/2 p enough to more than make up for the projection of the screw. The edge of the screw is covered with

very slight extent three fourths of its circumference. Although the unexposed part is still free and uncovered. The joint is otherwise smooth and apparently normal, with no stretching of the tibial cartilage on the semilunar over which it swung and got its bearing except that a little gloss is lost on the surface. There is slight staining at the roots of the crucial ligaments at the femoral end. (The condyle was not sawed open.)

Dog No. 576 *Right knee*. Two nails were driven into the same condyle of right femur on anterior and other. The anterior one, a small head nail was driven in flush with the cartilage surface. The

new tissue is nearly smooth and apparently of the same character as the normal cartilage but in reality shows a connective-tissue structure. The groove which had been cut deeply through the semilunar cartilage, the cartilage of the tibia head, and into the bone has smoothed up and partially refilled in the six weeks. The surface is covered smoothly with cartilage looking like the normal cartilage of the joint surface. The joint cartilages are otherwise smooth and normal. There is no staining of the heads of the crucial ligaments. *The cut surface* The new increase in tissue seems directly due to new bone. The new cartilage which covers this elevated area is no thicker than the thin cartilage of the joint surface.

CONCLUSIONS

1 Nails and screws are tolerated in joint surfaces in the human as well as in the experimental cases and with surprisingly little reaction.

2 They have remained firmly imbedded in every specimen recovered.

3 In every case where the nails and screws projected above the joint surface, there was a distinct upbuilding of the condyle as Nature's reply to a rigid metal body projecting into the joint.

4 It is exceedingly interesting to find that the increase in joint level seems always due to the growth of bone and not to the increase in the thickness of the cartilage.

5 In each case where tissue grew across over the head of a nail or screw or across in the groove of the screw the new tissue showed a reversion to the connective tissue type.

6 Even when the nails and screws have remained more or less uncovered the dogs have run about normally after a short convalescence.

7 In each case the scratch or groove on the opposing surfaces was filled in as the projection of the nail or screw lessened by the upbuilding of the condyle. The defect was apparently entirely filled in all but one specimen and this was closing in nicely at the end of six weeks.

8 As a point in technique it seems better to swing a hinge joint freely at time of operation to scratch the groove made necessary by a badly placed nail or screw and thus save the time and pain which would be required in scratching the groove little by little later.

NEW MECHANICALLY AND SURGICALLY CORRECT METHOD OF BONE GRAFTING

COMPARISON OF VARIOUS METHODS OF OPEN TREATMENT OF FRACTURES

By PAUL B. MAGNUSON, M.D., CHICAGO

LANE PLATE

SINCE Mr Lane stimulated world wide interest in the open treatment of fractures with the introduction and use of the steel plate screwed onto the outside of the shaft of long bones, there have appeared many and devious ways of holding fractured fragments of long bones in apposition by many forms of mechanical appliances.

From a surgical standpoint, the Lane plate is deficient in the following ways:

1 In most individuals steel acts as an irritant both to soft tissues and to bone with which it comes in contact, favoring infection by producing a collection of serum around

the plate and lowering the resistance of the tissues immediately in contact with it, if not actually killing them.

2 The necessary length of the plate in order to secure proper leverage necessitates the loosening of the muscles from their attachment to the bone for a considerable distance on either side of the fracture, thereby producing unnecessary trauma and favoring infection.

3 The screws used in Lane plate operations are of the wood screw type and it is necessary to use at least four in each plate to prevent the fragments from angulating. The pressure of these screws on the bone gradually

Fig. 1. Magnuson lateral bone lamp in position holding fragment in position. Outline of ant. d. d. graft shows g. w. dth of med. lary. t. t. s. t. f. f. t. u. r. e. one eighth inch wider at p. p. o. s. i. t. i. o. n.

produces necrosis of the bone cells immediately surrounding them allowing the plate and screws to loosen in a comparatively short time. This allows the plate to move and further irritate the tissues both bony and soft which further produces a favorable field for infection.

These are in brief the main objections to the use of the Lane plate from a surgical standpoint.

From a mechanical standpoint the only bearing surface which the Lane plate affords in holding the bone in line is that which is provided by the small wood screws driven through the plate and into the bone. This is a very weak form of mechanical union and when taken in conjunction with the fact that pressure of the screws produces necrosis of the bone immediately in contact with them we have double reason for not wishing to trust entirely to the support of a contrivance of this kind.

In spite of these objections there are some cases in which it is impossible to use anything but the Lane plate in repairing a fracture and one should always be at hand to suit the occasion no matter what plan is made before the operation.

THE BONE PLATE¹

The bone plate of Brougham and Ecker has the advantage of being non irritating and easy of application but has the disadvantage of the Lane plate in that the muscles must be disturbed from their connection with the bone over a relatively large area. It is

¹Brougham and Ecker. A preliminary report on the treatment of fractures by the use of bone plates and bone screws. Surg. Gynec. & Obst.

Fig. 2. A thor's circular saw cutting side of bone graft. F. d. of graft is cut with thin bladed hovel or smaller saw with single handle. Note distance between j. w. of clamp and wing free room to work.

claimed that this plate is absorbable. In the author's experimental work however with both dead bone and ivory it has been shown that neither dead bone nor ivory are absorbed except where they are closely surrounded by bone. The screws driven through these bone plates and into the bone cortex will eventually be absorbed only in such part as lies within the bone leaving the plates without any attachment except an incapsulating fibrous tissue which forms around them. The mechanical application of the plate to the outside of the bone throws an undue strain on a substance which is brittle and which is not braced on all sides and consequently subject to easy breakage.

Brougham and Ecker have used the screw principle introduced by the author of tapping a thread in the bone and bone plate and using bone screws which undoubtedly hold much better than steel screws. The plate however is weak at the points where the screws are driven through it. The objections then to this form of apparatus are from a surgical standpoint the loosening of the muscles and production of extra traumatism in the application from a mechanical standpoint its weakness at the points where the screws penetrate the plate.

These plates however are improvements over the Lane plate and should constitute a

Fig. 3. Clamp removed and fragments slightly angulated to allow insertion of graft into medullary cavity of opposite fragment. The socket wrench, such is used in driving the screw is also used as an instrument to drive the graft in. Dotted line shows the final position of the graft inside medullary cavity.

part of the equipment of the surgeon doing any amount of open treatment of fractures.

IVORY SCREWS

In 1908 the author introduced the method of retaining fragments of bone in correct apposition by the use of ivory or bone screws. The channel for these screws was first cut out by drilling a hole smaller than the screw to be used and tapping a thread within the bone with an ordinary mechanic's tap. This method has proved highly satisfactory in the treatment of oblique fractures of all kinds since it does away with the necessity of dissecting loose to any extent, the muscles attached to the fractured bone. The field of operation can be made small and traumatism to the bone and soft tissues reduced to a minimum. The screw holds the rough ends of the fragment in close apposition not only in one plane but in all planes. It fits snugly into the hole made for it, but not so snugly that it produces necrosis of the cells surrounding the screw. The retention apparatus is small as compared with the size of the bone

Fig. 4. Fragments brought back into line. Graft in place. Drilling hole through graft and opposite side of cortex preparatory to cutting thread for ivory screw.

but on account of its mechanical construction which follows the lines of a machine screw rather than a wood screw it has a long bearing surface. This screw is cut off flush with the cortex on both sides allowing nothing to project into the soft tissues to irritate them. Neither the ivory nor bone screw will irritate the tissues with which it comes in contact. This operation is simple and is easily and quickly performed. If the oblique surfaces of the fracture are long a screw at each end of the obliquity will hold against any pull of any group of muscles in the body not allowing angulation or displacement of the fragments and allowing early motion of the joints above and below the fracture.

One ivory screw has been used in the treatment of a slightly oblique fracture of the femur on a number of occasions, with perfect results. An article to follow reporting a series of cases of open treatment of fractures with the use of ivory plates and screws will contain the X-ray pictures and photographs of these cases.

From both a mechanical and a surgical standpoint the screw used in this way is an ideal method of treating oblique fractures.

IVORY PLATES

In transverse fractures it is impossible to use screws alone. It was therefore necessary

Memorandum Lengthening shortened bones of leg. Univ. Penn. M. Sch. 1908, May. Ivory plates and screws in the open treatment of fractures. J. Am. M. Ass. 1911, Dec. Lengthening short and bones of the leg by operation. Surg. Gynec. & Obst. 19, 1, 1910, 64.

to devise some method which would meet the following requirements:

1. Minimum traumatism in application.
2. The substance must be non irritating to the bone and soft tissue.
3. It must remain *in situ* without loosening.
4. It must be strong enough to hold against strains in any direction and the constant pull of any group of muscles without allowing angulation or shortening.

In order to meet the first requirement the apparatus must necessarily be small. It had been proved that ivory was non irritating to bone and soft tissues. It had also been proved that ivory did not loosen, which was also true of dead bone. The fourth requirement — strength — gave ivory the preference over dead bone and it was therefore used instead of the latter.

The method used consisted in the cutting of a slot or as mechanics term it a keyway into the bone by parallel circular saws the slot being exactly the width and length of the plate to be used and extending across the fracture in the long axis of the bone the length of the largest plate being one and three fourths inches long and three sixteenths inch thick by one inch wide. A keyway and key is the strongest form of mechanical union known so far as a shaft is concerned the key

being braced on all sides but one by the material into which it is driven. As long as this key remains in the keyway and is fixed by pegs driven through the key and shaft at an angle to the key holding it down into the slot it is impossible for any motion to take place between the fragments of the shaft. This operation eliminates the necessity of loosening the muscles from the shaft for more than an inch on each side of the fracture reducing the amount of traumatism to a minimum. The retention apparatus is very small and is as previously stated non irritating. The plate is driven snugly into the slot cut through the proximal side of the cortex only its lower edge being driven tightly against the medullary side of the opposite cortex. As in the case of the screws the application is snug but not tight enough to produce necrosis of the bone-cells immediately in contact with it. The ivory being braced on all sides by the bone cortex has sufficient strength to resist all strain which is exerted on the fragments by the muscles and in the very nature of its application will not allow the slightest angulation.

This operation has proved very satisfactory not only in the hands of the author but at this writing in the hands of many surgeons. Special instruments are needed to perform it but this is true of every operation as it is in other mechanical lines of work.

Fig 7 Cross section of graft through plane of screw showing slot out of which graft was taken. Position occupied by graft in medullary cavity and screw through graft and cortex of opposite side holding graft firmly in place.

THE INTRAMEDULLARY BONE GRAFT

The intramedullary autogenous bone graft as used and advocated by Murphy was one of the first forms of autogenous graft used in the open treatment of fractures. This necessitates cutting down on the tibia and removing the crest, reaming out the medullary cavity of the fragments above and below the fracture. This destroys at least part of the endosteum, delays union to some extent, and produces considerable hemorrhage. The graft is then inserted into the medullary cavity of one fragment to almost its full length, the fragments being slightly angulated out of the wound and the graft being worked into the medullary cavity of the fragment not already occupied by it. This, of necessity makes a weak and loose mechanical union. It will hold the fractured pieces from moving past each other but will not prevent angulation to a certain extent. The bone graft strikes the inside of the cortex at three points namely at each end and at the fracture. This gives a lever of the first class permitting any jolt or jar to break the graft, or the pull of the muscles to gradually bend it, unless the external dressing is firmly fixed which is almost impossible in cases of fracture of the femur just below the trochanters.

This operation necessitates opening up not only the bone which has been fractured, but making a wound in the lower leg necessitating two operations instead of one.

THE BONE INLAY

The bone inlay as advocated by Albee follows the same principles as the ivory plate the advantage of it over the ivory plate being

ASC

Fig 8 Longitudinal section through bone graft and screw showing position of graft in medullary cavity. Slot left by extension of graft and screw holding graft in place.

that it possesses bone regenerating power. The objections to it are that it necessitates cutting down on the tibia to secure the graft, producing extra traumatism of this bone and necessitates extensive cutting operations on each side of the seat of the fracture loosening up considerable distances of muscle from the bone and cutting a considerable trough of bone out on both sides of the fracture.

As first described by Albee this bone graft was tied in with kangaroo tendon run through small drill holes at the edge of the slot, and through the edge of the graft. Sutures have never been a strong form of mechanical union in bone either in the shape of wire or kangaroo tendon or the like and it should be borne in mind that a severe strain by muscle pull is put on every fracture retention apparatus, whether it be external or internal. Albee has recognized this fact in his recent work by introducing the use of an autogenous bone screw put in in the way described by the author and already referred to. The use of the autogenous screw is unnecessary takes a considerable amount of special equipment, lengthens the time of operation, and has no advantage over the ivory or dead bone screw since it is the bone graft which is depended upon to regenerate bone at the seat of fracture. This procedure then is superfluous. It is impossible without producing tremendous traumatism and hemorrhage to cut out a key of bone and fit it into a full length slot as described by Albee in the case of a femur or humerus and these are the bones most frequently necessary to treat by open operation.

It is also practically impossible without producing tremendous traumatism to cut a long slot on one side of the fracture and a short one on the other moving the long piece of bone down across the fracture and using

the short piece for the purpose of making bone screws as described by Albee without freeing the muscles from the bone for a considerable distance on each side of the fracture producing a great deal of hæmorrhage both from the muscle and bone and lengthening the time of operation and shock thereof to an unwonted extent. This operation can be done very nicely on the tibia where the bone lies immediately under the skin and where there is no muscle to contend with. Consequently favorable reports of this sort of graft in the tibia mean comparatively little.

It was to correct the defects mechanically and surgically in the bone grafting operation that the procedure next to be described was devised. The requirements were (1) To secure an autogenous graft as small as possible to assure firm retention of the fragments. (2) to eliminate the necessity of traumatizing other fields than that of the fractured bone. (3) to shorten the time of operation and (4) to place the graft in the bone in such a way that it would prohibit motion in any direction and hold against any pull exerted on it by the muscles attached to the shaft.

This was done by cutting a short graft from the fractured end of the most convenient fragment either proximal or distal. This graft was cut in the shape of an extremely long sided truncated cone. The end of the graft which formed part of the fractured surface is exactly the width of the medullary cavity and the end farthest from the fracture not over an eighth of an inch wider than the medullary cavity the graft being from one and one half to two inches long and covered by periosteum. The sides of the graft being cut out with the circular motor-driven saw the end of the graft is freed with a thin bladed chisel. The opposite fragment is then angulated slightly out of the wound and the graft driven in to the end of the medullary cavity to half its length. On account of its wedge shape it fits snugly. The fragment

is then brought back into line with its fellow and the protruding end of the graft is driven down into the slot out of which it came. This being the wider end allows for the thickness of the saw blade on each side and yet allows the graft to come closely in contact with the walls of the cortex on each side and sink down into the medullary cavity. The result now is that one end of the graft is firmly driven into the end of the medullary cavity of one fragment the other end being driven into the lower end of the slot out of which it came. There is no way of angulating these fragments except by one end of the graft slipping out of the slot or keyway. This was provided against by drilling through the graft and the opposite cortex tapping a thread in the bone and putting through an ivory screw which holds the key firmly down in the keyway. The screw is then cut off flush with the graft leaving nothing protruding beyond the cortex on one side or the graft on the other and leaving a one inch trough above the graft to be filled in with new bone.

This operation has been extremely satisfactory in the hands of the author and a few other surgeons who have seen fit to use it. It does away with the necessity of cutting into any other bone to procure the graft and meets all the mechanical requirements of a strong union. There is not as much loosening of the muscles as there would be in a Lane plate operation but somewhat more than in the ivory plate operation. In cases of ununited fracture the bone graft is preferable to any dead bone substance.

The technique described shortens the time of operation lessens the shock and does away with a large amount of the hæmorrhage which occurs when the graft is taken from the tibia. Therefore we believe it meets all the mechanical and surgical requirements of the internal splint and that it will be found to be much more satisfactory than the methods heretofore advocated.

A CONTRIBUTION TO THE ETIOLOGICAL STUDY OF OVARITIS¹

B. CARL HENRY DAVIS, M.D. CHICAGO

From the Memorial Institute for Infectious Diseases and the Department of Obstetrics and Gynecology, Rush Medical College

ELABORATE studies have been recorded giving the histological changes which occur in acute and chronic ovaritis. The bacteriology of acute ovaritis has been studied extensively but heretofore little has been accomplished in the cultural studies of the chronic inflammations associated with sclerosis and cystic degeneration. The newer bacteriological methods as emphasized especially by Dr. Rosenow have made this study possible. That some of the acute infections of the ovary may be of hematogenous origin and not a direct extension from the lower genital tract was suggested by Lawson Tait many years ago and is supported by many recent clinical observations. Rosenow has demonstrated that bacteria from foci of infection and the involved tissues in various diseases from which the streptococcus is recovered, such as appendicitis, ulcer of the stomach, cholecystitis, erythema nodosum and herpes zoster tend to infect electively the corresponding organs in animals, when injected intravenously and recently he has shown that some of the streptococci which we recovered in chronic inflammation of the ovary showed elective affinity for these structures in animals.

Using a technique which has been described in other papers, Dr. Rosenow and I have cultured 65 ovaries. In three of the patients the condition was rather acute and in these the streptococcus viridans was recovered twice and the gonococcus once. The other patients had chronic pelvic disorders. In ten cases the cultures remained sterile after a week's incubation. In the remaining 52 cases in which the ovaries showed fibrous and cystic degeneration, streptococci were isolated 30 times, the number of colonies ranging from one or relatively few usually in the depths of the ascites-dextrose agar to countless numbers. They were present in pure culture in 8 and associated in the others with the Welch bacillus, a few staphylococci or colon bacilli. Welch bacilli were found in small numbers in

21 diphtheroid bacilli in 10, a few colonies of staphylococcus albus in 9, the gonococcus in 2, the colon bacillus in 3 and an anaerobic streptothrix in 1.

The associated abdominal conditions were carefully recorded in 56 of the histories. Fibromyoma of the uterus was found in 18 patients, and the ovaries from 15 patients gave positive cultures—the streptococcus viridans being isolated from 11 and the Welch bacillus from 8. Salpingitis was reported eleven times, and the ovarian cultures were positive from 9 streptococcus viridans in 8, Welch bacillus in 3 and gonococcus in 2. Chronic appendicitis occurred 11 times and the streptococcus was recovered from 8 of the ovaries. Eight patients had a chronic cholecystitis and 6 of the ovaries cultured contained the streptococcus viridans.

Only a few of the women with chronic ovaritis gave a history of a preceding acute pelvic infection. In a number it seemed evident that the pelvic symptoms were the result of contracting a cold during the menstrual period or followed definite attacks of tonsillitis. In others the pelvic symptoms were subsequent to some one of the acute infectious diseases of childhood. While many of the women were married and more exposed to the conditions producing ascending infections, a number were undoubtedly virgins and in at least one patient, in which the ovarian cultures showed the streptococcus, the possibility of an ascending infection can be definitely eliminated.

MICROSCOPIC ANATOMY OF THE HUMAN TISSUES

The microscopic changes were such as have been described in the extensive studies on fibrocystic degeneration of the ovary and do not call for detailed description. With the help of W. L. Brown, 16 additional ovaries have been studied since the joint report with Dr. Rosenow making a total of 39 ovaries which have been carefully examined. In a

number these were remnants of follicles which were largely replaced by connective tissue and surrounded by round-cell infiltration. The stroma in all showed marked fibrosis and frequently small islets of the interstitial cells. The blood vessel walls were thickened. The walls of the small cysts were infiltrated with numerous round cells while the walls of the larger ones were made up of old connective tissue. Nests of round-cell infiltration were found in many chiefly surrounding the blood vessels and in the walls of the graafian follicles. In a number aggregations of leucocytes were found within and around small blood vessels especially in those in which the portion cultured showed a relatively large number of streptococci.

To demonstrate the bacteria in the tissues was extremely difficult but in sections from eleven ovaries including the eight previously reported where the cultures showed a large number of the streptococci Gram Weigert and methylene blue stains showed diplococci. They were found usually in the areas of infiltration and in at least one case in the wall of a corpus luteum.

Discussion Lawson Tait in his monograph on *Diseases of the Ovaries* says "So far as I know acute ovaritis is the result of four diseases only

- 1 Injury
- 2 Gonorrhœal infection
- 3 Septic poisoning in the parturient condition

4 Exanthematic fevers and acute rheumatism

Thus it is evident that Tait recognized non-ascending acute infections of the ovary dependent upon the exanthematic fevers and acute rheumatism even though he had no knowledge of the bacteriology of these conditions. He says "In 1870 and 1871 and still more in 1874 my attention was drawn to the occurrence of acute pelvic peritonitis in women after attacks of scarlet fever and small pox these attacks leaving indications which showed clearly that the mischief began in the ovaries. Accident enabled me to trace the subsequent history of two such cases and I found that in both the menstruation became greatly diminished in amount

and that it was accompanied by severe dysmenorrhœal symptoms and that in one of the cases it entirely disappeared. From these cases I began to suspect that the attacks were primarily due to inflammations of the uterine appendages and that this had some kind of relation to the zymotic disease which preceded it. Later he writes "I have only once had an opportunity of dissecting a case where I had recognized chronic ovaritis in life and then it certainly was the result of acute rheumatism. It occurred in the case of a girl seventeen years old who had suffered from eight or nine attacks of rheumatic fever. In two of them she was under my care as a dispensary patient and after the recession of the particular infection an attack of pelvic pain came on which was increased by pressure and the attack was accompanied by an irregular menstrual flow. The whole passed off in a few days after the application of a blister but ever afterward her menstruation was irregular profuse and painful and she suffered from the symptoms which I shall describe immediately. I regarded the attack as one of mild acute or subacute ovaritis followed by a chronic stage. She died subsequently of embolism of a cerebral artery and I found her ovaries large soft covered with lymph and dotted with enlarged follicles and the peritoneum was thickened around them. The left ovary was adherent to the rectum and it had nearly the whole of the fimbriae of the corresponding tube glued to it.

It has long been recognized that mumps are apt to cause orchitis in men and ovaritis in women. But Joel in 1886 called attention to the occurrence of orchitis in boys and ovaritis in girls following tonsillitis. For generations women have recognized that to take cold during a menstrual period was apt to result in a suppression of the menses with subsequent dysmenorrhœa and often pelvic pain. Our textbooks all recognize this fact but I have never seen a satisfactory explanation.

The recent writers of books on gynecology all recognize the possibility of non-ascending infections of the ovary but they apparently believe that most of the infections are ascending. Dr Webster writes (p. 365) on the

etiology of acute ovaritis. Various infective conditions e.g. especially infection following abortion or labors gonorrhoea, pneumonia, mumps, the acute exanthemata, tuberculosis actinomycosis etc. And (p 366) Chronic inflammations of the ovary may be the sequel of an acute attack such as has been described or it may develop slowly with no definite onset.

Active congestion displacements and twistings are favoring conditions. It is frequently secondary to infectious processes in the uterus and tubes. It is very frequently associated with fibromyomata of the uterus and large ovarian tumors of the opposite side. Of all the causes gonorrhoea is one of the commonest. It may be secondary to appendicitis. Findley says. Chronic ovaritis may be the terminal stage of an acute infection of the ovary. Any condition causing prolonged congestion of the ovary will result in chronic ovaritis such for example as sexual excesses, menstrual congestion, subinvolution malpositions of the uterus, habitual constipation incompetency of the cardiovascular system, pelvic and abdominal tumors, and the disorders of the organs of digestion. Findley made a careful study of 180 cases operated on for cystic ovaries by Dr Webster and himself. He found that. The usual infectious diseases of childhood were experienced in 65 per cent of the 180 cases and there was a history of puerperal post abortive, or gonorrhoeal infection in 63 per cent. He believes from this study and a review of the literature that. Cystic degeneration of the ovaries is almost invariably the result of chronic ovaritis. This is the consensus of opinion of Virchow Gebhard, Abel Kolb Ruge Pfannenstiel Amann, Martin and Frankel (Findley).

Wilder in a recent paper presents strong evidence that acute streptococcic ovaritis may follow the streptococcic sore throats. He quotes three typical cases reported by Leyden, Kunzel, and Schwern, and adds a fourth personal observation. In these four cases there can be little doubt but that the acute infection of the ovary was blood borne and in each case secondary to the infection in the throat. Yet with the normal genital

tract it is almost impossible to prove from the study of the cases that the infection could not have been ascending. But this clinical evidence is proved by the case in our series in which chronic salpingo-ovaritis had developed in an eighteen year-old girl in whom there was no passage between the vagina and uterus. It is further strengthened by a case in which there was a congenital stenosis of the uterus with a double cavity. The cultivation of streptococcus viridans from the ovarian tissue in these cases, the demonstration of the organisms in sections of these ovaries, the experimental production of ovaritis in animals, and the finding of the organisms in their ovaries explain clearly how a patient may contract chronic ovaritis without a preceding infection of the lower genital tract. While allowance must be made for the possibility of direct extension of infection from some other infected organ such as the appendix, the finding of the colon bacillus in only 3 cases is good evidence that chronic ovaritis can be but extremely rarely if ever due to organisms which have passed through the normal bowel wall.

While the experimental work explains the importance of the streptococcus in ovarian degeneration, the significance of the Welch bacillus in one-third of our cases is not so clear. Since this organism is found so frequently in the cultures of tissues of carnivorous animals it has been thought that it is as the rule, a rather harmless invader. But Williams states that the bacillus aerogenes capsulatus is occasionally concerned in puerperal infection and several cases have been reported from his service at the Johns Hopkins Hospital. In our series a pure culture of the Welch bacillus was obtained from the ovary of a woman who had suffered with puerperal sepsis but while the ovarian trouble dates from the sepsis it may not follow that this organism was responsible for either the degeneration or the preceding sepsis.

From our cultural studies of 65 ovaries it would appear that the streptococcus viridans is the most common organism associated with the chronic degeneration of the ovaries, being found in approximately 50 per cent of the cases. The Welch bacillus was found

Fig. 1. Drawing of specimen Case 960.

in 33 per cent but is probably of little importance. Other organisms are apparently found rarely in the usual chronic degenerative changes of the ovary. While the gonococcus is undoubtedly a common cause of acute infections of the ovary it is not found in the more chronic conditions and our results suggest that some of the chronic pelvic conditions which were formerly credited to the gonococcus may have resulted from nonascending infections with the streptococcus viridans.

The fact that ovaritis is so much more common than is orchitis is of considerable significance. Wilder in his review collected 56 cases of primary peritonitis probably all of the streptococcal type of which 44 or nearly 80 per cent were in females. He believes that in most of these that the primary infection was in the ovary and the peritonitis secondary. It has been suggested that the corpus luteum is often the point of inoculation. Certainly the fact that women are so prone to infection of the ovary at the time of menstruation is a strong argument in favor of this suggestion. That the tube may become infected from the ovary or the ovary from the tube is generally accepted and it is also probable that both are infected simultaneously from the blood stream in some cases of bacteræmia.

The following two cases which were reported in the joint paper with Dr. Rosenow are of so much importance in the discussion of this subject that they must be included in our case histories.

Fig. 2. Drawing of specimen Case 960.

CASE 960. A girl of 18 years entered the Presbyterian Hospital complaining of a dull heavy aching pain in the right inguinal region which recurred each month during the past year lasts three days and then disappears. She has never menstruated. At the operation Dr. Webster found an imperforate vagina one inch long the uterus was retroverted the cervix lay posterior to the vaginal wall and was only attached to the corpus by means of a fibrous band there was considerable thickening of both tubes with closure of the right fibrous and cystic degeneration of both ovaries especially the left and adhesions about the rectum and appendix. He did a modified panhysterectomy and appendectomy.

A drawing of this specimen is seen in Figs. 1 and 2. Twelve colonies of streptococcus viridans were grown from a portion of the left ovary and a diplococcus was demonstrated in the sections.

CASE 33. A single woman age 30 entered the Presbyterian Hospital on the service of Dr. Billings July 30, 1914, complaining of multiple enlarged swollen tender painful joints and muscles particularly the jaw elbows hands and feet with marked limitation of motion and fixation. The arthritis began three years before some weeks after a severe attack of tonsillitis. There had been recurring exacerbations and remissions of the symptoms but on the whole they had steadily progressed. She had lost 30 pounds in weight during the past year and a half and in the past year had developed a severe dysmenorrhea. Cramps and nausea had lasted throughout the period and often for eight or ten days following. Except for frequent attacks of tonsillitis and a chronic rhinitis the patient had been in fairly good health until three years before when she had the attack of tonsillitis with an abscess of the tonsil. The tonsils were removed

nine weeks after the arthritis began and she improved greatly. She had measles and whooping cough in childhood. During the past year she had been curetted twice for the dysmenorrhea without relief. The patient had good appetite and slept well. The bowels were regular there was no urinary disturbance no leucorrhea at the time of examination, no cough, no dyspnea, no night sweats, no edema of the feet no cardiac or gastric disturbance no jaundice no diarrhea, no chills or fever. The examination was negative except for the condition of the joints, the finding of small remnant of the left tonsil, and some bad teeth. X-ray of her hands showed that there was complete ankylosis of some of the fingers, with marked destruction of the cartilage in the balance of the joints. The remnant of the tonsil was removed and the condition of her teeth rectified. The patient left the hospital and returned again in January 1905. The symptoms of the arthritis had greatly improved but she complained of excessive menstrual flow for which she was curetted by Dr Webster but without relief.

On March 23, 1905, Dr Webster removed the left ovary ligated the uterine arteries, removed the appendix and a small fibroid from the back of the uterus. Cultures of the ovary were made by Dr B. O. Raulston and the streptococcus viridans obtained in large numbers. Dr Rosenow injected sub-cultures into three female dogs and four female rabbits in doses ranging from 4 to 95 cubic centimeters of the broth culture suspended in salt solution. All but one rabbit recovered. The animals were chloroformed on the second and third days after injection. All of the animals injected showed lesions of one or both ovaries. Five showed in addition distinct arthritis on myositis one cholecystitis and two hemorrhages and edema of the thymus. Three showed lesions in the uterus, and one hemorrhage in the fallopian tubes. Filtrates of this broth-culture, on the other hand, injected into two rabbits in equivalent and repeated doses failed entirely to produce lesions in the ovary or otherwise.

Following the operation in March, the patient a general symptoms were much better but the menorrhagia soon returned and on October 5, 1905, Dr J. C. Webster removed the uterus and remaining ovary. Cultures of this ovary were made by Drs. F. Garde and G. Coleman and the same organism was again isolated. This injected into rabbits produced arthritis, but unfortunately their ovaries were not examined for lesions.

When seen on March 5, 1906 the patient stated that she had gained twenty pounds in weight and that she feels much better in every way. She still has joint pains but less severe.

The following histories are chosen from the cases cultured because of the large numbers of organisms found in the cultures and the variety of associated conditions.

No. 90380, Mrs. D. age 24 entered the Presbyterian Hospital, November 1905 complaining of weakness, a constant feeling of tiredness, headaches, backache, pain in the lower right quadrant of the abdomen, leucorrhea and constipation.

During the past year she had felt tired and weak all of the time especially on arising in the morning. During the past four months she had been unable to work. She has had severe headaches during the past few months, frontal in character dull aching in type, present nearly all of the time. They are especially severe in the morning and are gradually growing worse. During the same period she has had a dragging backache. For over a year she has had some pain in the right lower quadrant of the abdomen. Four months ago it was very severe but of late it has been causing less trouble. She says that there is a feeling of soreness which comes

whenever she is tired and is always worse during the menstrual period. During the past four years she has had marked leucorrhea. Two years ago it was most severe but is better now. During the past three years she has had marked constipation. The patient says that she has had no sickness other than the diseases of childhood.

She was married 5 years ago but has been separated from her husband for years. She had one pregnancy 3 months after marriage and aborted.

The writer dictated the following findings at the operation. Numerous adhesions between the uterus and the rectum holding the uterus in retroversion. The left ovary is about the size of a small English walnut and is buried in a film of adhesions. The left tube is somewhat thickened. The right ovary and tube are buried in adhesions and fastened to the brim of the pelvis. The ovary is moderately enlarged and markedly cystic. The appendix is 4 inches long slightly thickened, but free from adhesions.

Operation. Freeing of pelvic adhesions. Right salpingo-oophorectomy. Webster round ligament operation. Covering of the raw surfaces in the pelvis. Appendectomy. Cultures of the right ovary showed many colonies of streptococci. Mrs. D. reports March 26, 1906 that she is free from pain, has no headaches or backaches, no constipation. She is at work in an office and while she still tires easily feels perfectly well.

No. 90236 Mrs. R. C. age 49 married ten pregnancies, no miscarriages or abortions.

The patient complains that during the past year she has had considerable pain in her back, intermittent in character present during the day but not at night. The aching is worse when she is on her feet, is relieved by massage and by lying down. It has steadily been growing worse. The menstrual flow has steadily increased in amount during the past 4 or 5 years but has not increased in duration. The abdomen has been increasing in size during the past 4 years until now it has the appearance of a 5 or 6 month pregnancy. There has been some loss in weight. During the last

3 years she has had a severe leucorrhœa. Her past history is negative. Her family history is negative. Habits are negative.

Dr Webster dictated the following findings at the operation. The uterus is enlarged by tumor mass 8 inches in diameter. Both ovaries are cystic. There is a hydrosalpinx condition of both tubes. There is a simple cyst of the left ovary 2 inches in diameter. Gall bladder is free and normal. Right kidney is scarcely movable. Left kidney is scarcely movable. Stomach is normal. No nodules or enlarged glands are found in the upper abdomen.

Operation. Supravaginal panhysterectomy. The tumor was found to be an interstitial throid of the uterus which had undergone a myxomatous degeneration. The sections showed no evidence of malignancy. Cultures of the ovaries showed many colonies of streptococci.

CASE 5248. Miss S., age 34, entered the Presbyterian Hospital June 1910 complaining of constant backache, constant tenderness in the lower abdomen, leucorrhœa, and general weakness having been in bed most of the time during the past three years. Bowels are regular. Menstruation is of the regular 29-day type preceded by soreness in the breast for ten days, slight dysmenorrhœa. Has cold chilly sensation most of the time. Has no urinary disturbances. No history of sickness other than the diseases of childhood.

Operation June 22, 1910. Dr Webster dictated the following findings. Uterus is retroposed 3 inches deep and dilates with difficulty. Prolapsed in flamed degenerated ovaries. Marked adhesions in the pelvis. The appendix is thickened.

Operation. Dilation and curettage, removal of the left tube and ovary, ligation of the right ovary, removal of the right tube, Webster round ligament operation, appendectomy. The patient had a normal temperature when she entered the hospital but following the operation her temperature went to 101.4 and remained 100 or over most of the time during the following week. Her pulse varied from 120 to 100. She was discharged in good condition July 12, 1910.

Miss S. entered the hospital again June 14, 1914, complaining of pain in the right lower quadrant of the abdomen, nervousness and general weakness. She stated that the pain is worse during the menstrual period. She has not been very much better since her operation four years ago.

Operation June 15, 1915. Dr Webster dictated the following findings. There are adhesions of the omentum along the anterior abdominal wall. The right ovary is enlarged cystic and fastened with a lhesion. The uterus is adherent to the rectum and bladder. The gall bladder is normal.

Operation. Hysterectomy and right oophorectomy. Her temperature went to 100.5 the second day after the operation and varied between 99 and 100 during the first ten days after the operation.

November 1915. Miss S. reports that she is free from pelvic and abdominal pain. Physically she

Fig. 3. Somewhat schematic diagram. Case 85742. Mrs. M., aged 9. Since her fifteenth year she has had subjective symptoms of menstruation every 8 days. Had a laparotomy when fifteen. Both tubes and one ovary removed. Had abdominal drainage for four days. During past year she has had little potting with pelvic cramps on two occasions but has never menstruated.

Operation by D. Webster revealed dense pelvic adhesions with loops of bowel attached to the uterus and remnant of the left ovary. Section of the uterus revealed the congenital malformation as shown in the above diagram. She was operated during an attack of so called menstrual pain and fresh blood was found in both cavities of the uterus. The endometrium was very thin and showed no evidence of inflammatory changes.

is perfectly well but states that she suffers from attacks of melancholia and that she often has severe headaches in the top of her head. She feels particularly bad in the morning but as the day passes she gradually loses her depressed feeling provided she is with cheerful company and usually feels good in the evening. She does not suffer from hot flashes and never has had them.

She states that as a girl she was subject to tonsillitis but that the tonsils have not bothered her for many years. The pelvic trouble started with a severe cold contracted during the menstrual period.

and gradually became worse. She was a chronic invalid for about twelve years.

Miss J. W. age 24, entered the Hospital May 9, 5 complaining of swellings on each side of the lower abdomen, pain in both lower quadrants of the abdomen, tenderness of the right breast. The patient states that she was perfectly well until about fourteen months ago when she noticed a marked increase in the pain during the menstrual periods about the same time there appeared swelling in the left side of the lower abdomen which was tender to the touch and to the pressure of her clothing. A little later a smaller lump appeared in a corresponding position on the right side. These swellings have persisted and are still tender to the touch.

The pain is bilateral but more marked on the right side. It is usually of a dull aching type but occasionally she has attacks of sharp sticking pain. These occur at intervals of four to six days. These attacks are very brief, lasting but a minute or two and they do not radiate. About six months ago her symptoms were so marked that she was confined to her bed for three weeks. Recently she has been much worse again. The right breast has been tender and painful for seven weeks but has not been red or swollen.

Her past history is negative except for measles and whooping cough as a small child and some kind of a fever at the age of nine. Menstruation began at 3 years, regular 28-day type of 3 days duration until one year ago when she began to flow for two days skipping a day with return for two days.

The pain is increased during the periods.

Dr. Webster dictated the following: Gall-bladder normal, kidneys each have a 28-inch range stomach normal, appendix 7 inches long and fastened with adhesions, uterus enlarged by a tumor mass (fibromyoma) 4 inches in diameter right tube thickened in the middle part, right ovary shows chronic cystic degeneration but is not much enlarged, left ovary has the same condition.

Operation. Appendectomy, supravaginal hysterectomy. The patient's temperature went to 100 a few hours after the operation but never went over 101.5 and returned to normal after four days.

SUMMARY AND GENERAL CONCLUSIONS

From a cultural study of 62 ovaries showing the changes found in fibrocystic degeneration and three in which the process was more acute the findings of the streptococcus viridans in 50 per cent of the cultures suggests that the streptococcus viridans is the most common organism associated with chronic ovaritis. Since the cultures from ten ovaries remained sterile, it would appear that chronic degeneration may result without the presence of bacteria or that the bacteria are gradually killed and the ovary rendered

sterile. The findings of the gonococcus in only one acute and one chronic ovary would seem to indicate that this organism may not be responsible for as much of the chronic ovarian disease as was formerly supposed. Although the Welch bacillus was found in small numbers in 33 per cent of the cases yet in the absence of any definite animal experiments it may be considered a more or less harmless invader still it must be remembered that this organism has been the cause of puerperal sepsis. The staphylococcus albus and the diphtheroid bacillus are regarded as accidental or harmless invaders since intravenous injections of each do not produce lesions in animals.

It has long been recognized that the chronic ovarian degeneration may follow acute infections of the ovary and this study shows that bacteria must also be regarded as the etiological factor in chronic ovaritis though it has developed without a definite history of an acute infection. The various conditions which cause passive congestion in the pelvis are to be considered as predisposing and not as etiological factors.

The not uncommon history of pelvic trouble following anginal attacks during the menstrual period, the occurrence of pelvic infection following immediately after tonsillitis, the discovery of chronic tubo-ovarian inflammation in a young woman with a congenital stenosis of the cervix and the uterus, with an imperforated vagina and the isolation of the streptococcus viridans from her left ovary together with the experimental production of ovaritis in animals seems conclusive proof that hæmatogenous infection of the ovaries occurs and that it may be responsible for much of the chronic ovaritis in which there is not a definite history of gonorrhœa or puerperal sepsis.

The find of bacteria, especially the streptococcus viridans in the greater portion of the ovaries cultured offers a logical explanation for the not infrequent recurrence of cystic swellings after resection of the ovary. It also suggests that the ligature or drainage through a single opening with Paquelin's cautery as practiced by Dr. Webster may be the method of choice since

the heat may kill the bacteria. This study also shows a probable reason why transplanted ovaries degenerate.

A study of the tissues together with a careful review of the histories gives no new or definite mean for choosing between a conservative and a radical operative procedure. Since some ovaries are sterile and many others contain only a few organisms, the writer believes that this study favors conservation of the ovaries whenever the operative findings will permit. In this series it was usual to find rather large numbers of streptococci in the ovaries of patients who came to a second operation. With a young woman it is better that she come to a second operation than to lose both ovaries the first time even if there is an equal chance that conserved tissue may degenerate.

The findings of bacteria in fifteen (eleven of which showed streptococcus viridans) of the eighteen degenerated ovaries associated with fibroids of the uterus suggests strongly that bacteria are likewise responsible for the chronic ovaritis so commonly associated with fibromyomata.

Since there appears to be very frequently some rather definite connection between the

more common form of chronic infection and ovaritis, it is evident that in treating a patient with ovarian trouble that any such foci should be located and removed. It would seem logical to believe that by the early detection and elimination of these primary infection it might be possible to lessen the occurrence of ovaritis.

I wish to acknowledge my indebtedness to Dr. J. Clarence Webster for his suggestions and the privilege of reporting his cases, and to Dr. E. C. Rosenow for his co-operation in this study.

THE LEUCOCYTES IN PREGNANCY LABOR AND THE PUERPERIUM¹

By JOSEPH L. BAER, SM, MD, FACS, CHICAGO

AFTER Nasse had called attention to the existence of a true leucocytosis of pregnancy, numerous workers began checking his results at first with widely varying outcome but finally with sufficient unanimity to warrant the statement that there is a leucocytosis of late pregnancy, especially in primiparae.

The physiological leucocytosis of labor and the puerperium is generally accepted without debate but in clinical practice the question constantly arises: Is the leucocytosis in the given case physiological or pathological? To supply a working answer to this question and to establish a standard of

comparison for the leucocytosis and differential analysis of pregnancy labor and the puerperium the following study was undertaken at the suggestion of Dr. L. E. Frankenthal utilizing the material afforded by the Michael Reese Maternity.

The literature abounds with investigations of this kind and each worker has laid stress on the errors of his predecessor. For example, it is pointed out that counts should start on the pregnant woman and be carried through on the same woman in labor and the puerperium; that comparisons on different women at different periods introduce an avoidable error; that the figure of interest is the in-

crease in the leucocyte count over the normal for that woman not the actual count itself that the figures are complicated by the introduction of abnormal cases into the series that the influence of digestion was ignored etc.

Among the earliest views is that found in Virchow's *Cellular Pathology*. He states that there is a monthly increase in the leucocytes in pregnancy which is proportional to an increase in the lymphatics of the uterus, and an increase in the lymph nodes of the inguinal and lumbar regions.

Madame Mochatcheff did a novel piece of research in that she made comparisons between blood obtained from the portio vaginalls and the finger and found that there is a leucocytosis in pregnancy that blood from the portio contains fewer leucocytes than from the finger in pregnancy and that the reverse is true in labor.

Payr stated that there is an adenoid character to the whole endometrium, and hence in labor the leucocytes are squeezed into the circulation, thus raising the count.

Rieder examined 31 pregnant women from fourteen to sixteen hours after eating and found a range of leucocytes from 10,200 to 16,500 with an average of 13,000. In 50 per cent in multiparæ (18 cases) there was an increase among 13 primiparæ all but one showed an increase and during digestion in 6 cases there was a decrease.

Hofbauer constructed curves from 20 cases. The curve starts just above the normal goes up during and past labor dropping down soon after labor and reaches a level ten to twelve hours post partum which it maintains until the second to the third day of the puerperium, when there is a secondary rise associated with the incoming of the milk. He considered that the leucocytosis of pregnancy was due to the painless, rhythmical contractions that the first curve in labor was due to the work of the uterus, and the second curve to the activity of the breasts.

Willd examining 30 cases found an increase in the leucocytes in labor and explains the same by means of a comparison between the uterine surface and a wound surface. He states that the increase which continues into

the puerperium is due to the resorption of the uterine material.

Hilbard and White present the following conclusions: (1) Leucocytosis exists in three-fourths of all cases more often in primiparæ in labor. (2) In the puerperium the curve drops first rapidly then slowly to normal, rising a little on the seventh day. (3) Leucocytosis is greater in young women and less with each labor. (4) Prolonged labor causes an increase. (5) Breast infections produce a rapid increase. (6) Leucocytosis of labor is an increase essentially in the polymorphonuclear neutrophiles.

Bégoune thinks there is an increase in the last of pregnancy which involves only the ripe forms of the leucocytes the young forms are decreased. The first day post partum there is a marked increase in all forms. In the puerperium the polymorphonuclear neutrophils show a relative and absolute decrease. The eosinophiles are increased at the beginning of pregnancy decreased post partum and then increased steadily after the second day.

Nannicini found that there is no increase in multiparæ. The count stays within the physiological upper limit. There is a true leucocytosis of pregnancy in primiparæ. There is an absence of leucocytosis of digestion. The count is actually less during digestion.

Carstanjen says the neutrophils are increased in pregnancy and decreased during the puerperium. The lymphocytes are decreased in pregnancy and increased during the puerperium. The large mononuclears are always decreased. The eosinophiles are decreased post partum and then on the seventh day of the puerperium they are increased beyond the percentage found in pregnancy.

C. Hahl examined 36 normal cases in pregnancy labor and the puerperium. The leucocytes were slightly increased in the last days of pregnancy. With labor there was a considerable increase due to the neutrophils. Post-partum there was a gradual decrease reaching the normal in one to seven days. His comparisons showed with no contractions, no increase in leucocytosis with contractions, a marked leucocytosis. His explana-

Chart Leucocytosis in labor and puerperium. (Michael Reese Hospital.)

In the last three classes there is a secondary division into round parts and loops. Arneth examined 10 pregnant women 5 primiparæ and 5 multiparæ. In the primiparæ he found a count ranging from 7,800 to 11,000 in the multiparæ from 3,000 to 8,600. He found the neutrophile changes to be a displacement toward the left in other words, toward the first class of neutrophils, or so-called young cells. The smaller the total count, the more the displacement toward the left and he found the neutrophils to belong chiefly to classes two and three. In labor he examined six primiparæ and two multiparæ. All the total counts but one exceeded 10,000—as high as 18,100. The displacement of the neutrophils was still more to the left. In the puerperium there was a total decrease with the displacement back toward the right of the scale. On the third day post-partum

in the presence of lactation, no influence on the leucocytes was noted the count remaining unchanged, and the neutrophils remaining toward the left.

His explanation was that as in infections, there is a more rapid destruction of the leucocytes, resulting in an increase in the total and an increase in the young forms that is classes two and three but the destruction is not so severe as to cause the appearance of chiefly class one cells.

Hans A. Dietrich laid special emphasis on the fact that he used the Turk counter and the May-Gruenwald stain for differentiations. He analyzed 20 cases, carrying the same women through pregnancy labor and the puerperium, examining them every two weeks ante-partum, and he made analyses of the labor counts at various stages such as the rupture of the membranes, the beginning of

Chart Effect of multiparity (M had Reese Hospital)

pains the height of pains the birth of the head and daily post partum counts for eight days. All of this was done under identical external conditions the patients being in the clinic and all examinations being made three hours after the meal time. Dietrich maintained that there can be no fixed normal maximum in pregnancy such as the arbitrary figure of 10,000. Each individual has her own normal count. Hence he determined to state his figures in terms of increase or decrease in the individual case based on the low counts of pregnancy. On this basis he determined that at the end of pregnancy there is an increase over the normal in primiparae of 3,068 and in multiparae of 1,234. The increase is in the neutrophiles. The eosinophiles were decreased in 17 out of the 20 cases and there were no appreciable changes in the lymphocytes. In labor among primiparae there was an increase of 8,506 over the normal and in multiparae of 9,453 a maximum count of 34,200 — an increase of 18,500 and a minimum count of 16,400 — an increase of 2,600. The maximum point is reached just post partum. The contractions seem to increase the count. On differential examination it proved to be purely a polymorphonuclear neutrophilic increase. In 13 normal cases post partum there was a rapid fall reaching normal on the third day. The eosinophiles absent in labor reappeared on the first day of the puerperium and then

became more numerous than during the normal pregnancy. There was no relation to lactation or after pains that he could determine.

Dietrich offered as an explanation of the leucocytosis a comparison to the theory of eclampsia on the basis of toxins from the fetus and placenta. These toxins in normal cases call forth as neutralizers the neutrophils especially. Therefore primiparae have a greater number and multiparae have a certain immunity. Uterine contractions throw more toxins into the circulation hence more neutrophils appear from the bone marrow.

Possibly the work theory of Schultz offered by Hofbauer namely that increase in intra abdominal pressure results in a compression of the veins and an increase in the circulation time hence an increase in the leucocytes in the peripheral parts — in other words an apparent leucocytosis may be a part of the explanation.

S. Adachi studied the blood changes in pregnancy and labor. He pointed out that variations in healthy non pregnant women are marked. The figures given by various observers are: Moleschott 12,605 to 14,000; Mallasz 6,923 to 7,692; Duperie 4,090 to 4,545 and Senator 3,000 to 6,000. If there be such variations in the normal non pregnant counts the variations in the pregnant woman or in any unusual condition would

Chart 3. Effect of duration of labor (Michael Reese Hospital)

therefore be proportionately greater. He considered as important factors the apparatus and technique condition of the subject, and the external factors. For apparatus, he used the Thoma-Zeiss counting chamber but preferably the Turck. Hemorrhage, fever, meal digestion exertion, were factors to be considered in the condition of the patient. Room temperature was a factor in that cooling seemed to increase the leucocytes, and vice versa. Adachi counted ten non-pregnant cases, in whom he found an average of 5,500 to 8,400 19 nine months pregnancies, in whom with the Thoma he found 6,800 to 12,600 and with the Turck, 4,960 to 10,530 and 14 cases in active labor from one half to five hours antepartum usually the second stage, in whom he found a range of 11,000 to 25,600 — in one case a 9,800 count. He found no increase in the ninth month of pregnancy over the non-pregnant state in this agreeing with Zangemeister and Wagner. He found a marked increase in labor proportional to the severity of the contractions. He counted 98 cases in all, omitting 30 for various causes making his total in all groups 68 cases. However he saw almost all his cases only once or

at most twice. His explanations are that in the ninth month of pregnancy there is no change in the leucocytes, erythrocytes or hemoglobin that in labor the leucocytes are increased proportionally to the contractions and he found no difference between primiparae and multiparae all of which conclusions are at variance with the findings of most other reliable observers.

W. Sieben analyzed 10 cases in labor and the puerperium. He was unable to make comparative counts on the same women through pregnancy labor and the puerperium. He found an increase in the ninth month of pregnancy and approved strongly of Dietrich's method of following the individual case through her pregnancy labor and puerperium, rather than the Adachi method of numerous totals from all possible sources. In labor he found a leucocytosis maximum of 21,000, minimum of 11,000 average of 17,000 with a constant decrease in the puerperium of all cases but two reaching the normal at the end of the second week. His differential analysis showed the neutrophils to decrease throughout the puerperium, and determine the general curve. The lympho-

cytes increased a little on the first or third day possibly in relation to infection. The eosinophiles were present in 50 per cent of the cases just post partum in which Sieben differs from most other authors who have found them absent—an increase throughout the puerperium or reaching a maximum on the third day. The neutrophils and the lymphocytes were found to be reciprocal the one increasing as the other decreased. In the mononuclear lymphocytes the transitional cells and mast cells no rule applies. His conclusions were (1) In labor there is an increase averaging 17,000. (2) There is a return to the normal in the second week. (3) In the differential analysis the polymorphonuclear neutrophils decrease steadily throughout the puerperium. The lymphocytes like the polynuclears decrease but may rise in a week to a figure greater than the labor total. This change occurs chiefly in the small lymphocytes.

As the small lymphocytes increase the large lymphocytes decrease. The eosinophiles were present in 50 per cent post partum and their curve was parallel to that of the neutrophils.

No single worker analyzed a sufficiently large series to establish a standard scale and the discrepancies between various investigators together with the varying conditions under which their results were attained made it seem impracticable to combine their figures even from only the more recent sources.

In this investigation single counts and differential analyses were made in 25 pregnant women (11 primiparae and 14 multiparae) one to four weeks before delivery and counts were made in a consecutive series of 100 ward cases in labor afterwards eliminating 13 because of fever (11 with one temperature of 100.2 or over and 2 with fever of several days duration). In each of these women a leucocyte count was made during active labor and once daily thereafter for ten consecutive days. Whenever possible the blood was taken in late forenoon late afternoon or at night i. e. when well removed from meal time. At the same time spreads were prepared for differential counts and the polymorphonuclear neutrophils were subjected to the Arneith analysis in an attempt to confirm his findings.

(Chart 4. Effect of appearance of milk (Michael Reese Hospital))

In the last month of pregnancy the average count in eleven primiparae showed 10,909 or 2,909 above the mean normal of 8,000 (if we accept the normal range as 6,000-10,000). The multiparae (14 cases average 8,886) showed no change and the differential counts come very close to normal figures (Chart O).

Very early it was found that there is a striking difference between primiparae and multiparae a point little emphasized in the literature. In this series it is very noticeable (Chart 1). Among 30 primiparae the average labor leucocytosis was 18,255 and the average high point 19,883 was reached on the first day of the puerperium with a steady tapering off from that to the tenth day 10,840.

Among 57 multiparae (II para to VII para) the labor figure was 13,467 and the average high point, 15,062 again was reached on the first day of the puerperium then tapering to 10,467 on the tenth day.

With each successive childbirth there seems to be a decreased reaction on the part of the leucocytes a kind of immunity if you please and in this respect the single VII para was striking (Chart II).

The duration of labor proved less of a factor than had been anticipated a noticeable increase beyond the average leucocytosis

Chart 5. Effect of age. (Michael Reese Hospital.)

occurring only in the primiparae in labor over twenty four hours (Chart 3)

The incoming of the milk seemed not to affect the leucocytosis, except possibly in the group of fourth day primiparae in which a secondary rise occurred on the third day and the single fifth day primipara, who reached her maximum count on third day (Chart 4)

Cases grouped on the basis of age, each group covering a five year period showed the most marked elevation in the leucocyte count among the eight primiparae aged 18 to 20. Among the multiparae there was nothing noteworthy except the group aged 36 to 40 seven in number in which there was the least reaction, explainable, however on the basis of multiparity rather than age (Chart 5)

The differential analyses are in accord with the findings of the more recent workers notably Dietrich and Sieben. The leucocytosis is of the polymorphonuclear type these elements reaching their maximum at the end of labor and on the first day post partum, then rapidly and steadily decreasing reaching normal proportions after five days in primiparae and three days in multiparae. The eosinophiles were absent in half the labor cases, reappeared in normal proportions on

the first day post-partum and at no time were noticeably increased.

The small lymphocytes were diminished as the polymorphonuclear leucocytes increased and the large mononuclear transitional forms and mast cells maintained normal percentages (Chart 6)

Classification of the polymorphonuclear leucocytes on the Arnet plan was carried out systematically and showed the displacement toward the left, i.e. classes 2 and 3 of which he speaks but this was not a constant finding

SUMMARY

There is a leucocytosis of pregnancy appearing in the ninth month slight in amount, and especially noticeable in primiparae

The leucocytosis of labor is marked in primiparae averaging 18,255 and is increased by a duration of labor beyond twenty four hours. It is less marked in II parae and is slight in III plus parae.

The height of the curve in primiparae and multiparae is reached on the first day of the puerperium, after which there is a rapid and constant decline to the tenth day at which time the curve is about at the normal level

Chart 6 Differential analyses in per cent. (Michael Reese Hospital)

The onset of lactation does not influence the leucocyte count except that in the fourth day primiparæ there is a slight secondary elevation on the preceding day — about 1,500 to 2,000.

Age is not a factor except in primiparæ aged 20 years and under in whom the leucocytosis is higher than in any other group.

Differential analysis showed the increase in leucocytes to be chiefly in the polymorpho-nuclear neutrophils with a return to normal proportions by the third day of the puerperium an absence of eosinophiles in about half the cases in labor and their reappearance in normal proportions on the first day of the puerperium. The lymphocytes large and small mast cells and transitional types showed nothing unusual.

The Arnet analysis showed a displacement toward the left i.e. toward classes 2 and 3 but this was not constant and no pertinent deductions could be drawn.

To my chief Dr Lester E. Frankenthal I wish to express my deep appreciation of the privileges afforded me in the Michael Reese

Maternity Wards and for his helpful suggestions and invaluable criticisms in the carrying out of this work.

PERITHELIOMA AND ENDOTHELIOMA OF THE UTERUS¹

By W. A. NEWMAN DORLAND, A.M., M.D., F.A.C.S., CHICAGO

Professor of Gynecology, Post-Graduate Medical School of Chicago, F. & L. Loomis, Medical Reserve Corps, U. S. Army

A CASE OF PERITHELIOMA OF THE UTERUS

IN October 1907 a tumor of unusual scientific interest fell into my hands. The clinical and pathological findings were these (33)

The patient a fragile, single woman, 65 years of age had been complaining of pain in the pelvic region for little over two months. She had visited many physicians of considerable ability who had made vaginal examination and had pronounced the condition "neuralgia of the pelvis." The patient was placed on a suitable course of treatment but without any amelioration of the symptoms. On the contrary the pain grew more severe and the patient was referred to me.

External. I found the woman anemic and thin almost to gauntness. Her skin was shrivelled and on the abdominal surface could be picked up in thin folds. It was sallow or paler yellowish in color. After considerable difficulty due to the extreme modesty of the patient I succeeded in making vaginal exploration when the following points were elicited. The vagina was small and undergoing senile changes. The vulvar mucosa showed the characteristic smooth, yellow appearance of senility. The uterus lay anteriorly was small although larger than would be expected from the age of the patient and was distinctly sensitive to the touch. There was very slight discharge from the os sanguineous, but without odor or any decided appearance of hemorrhage. At no time had the patient suffered from bleeding nor had she at any time noticed any odor or the small amount of leucorrhoea of which she complained. The history of the patient her age the condition of anemia, and the local signs impressed on me the importance of making microscopic examination of the intra-uterine curettings, and after considerable opposition this was finally agreed to. Under ether anesthesia the uterus was scraped at the patient's home and considerable quantity of debris obtained. The examination at this time confirmed the findings of the previous exploration, and also demonstrated the abnormality of the uterus and the healthy condition of the ovaries and tubes. The scrapings were sent to the distinguished pathologist, Dr. A. O. J. Kelly since deceased who reported that they showed an unusual condition of great malignancy which warranted the immediate removal of the uterus. He at this time pronounced the growth a perithelial sarcoma, the small tumor-cells showing an unusual degree of grouping around the vessel walls.

Operative. Two days later notwithstanding the general unfavorable condition of the patient, I removed the uterus and tubes, performing a pan-hysterectomy. This, at the urgent insistence of the patient was done at her home. I was ably assisted by Drs. H. A. Stocum, G. A. Kowles, and F. A. Faught and two skilled nurses. The operation was simple and uncomplicated taking not more than thirty minutes for its completion. The patient made an uninterrupted recovery for three days. Then symptoms of bowel-obstruction supervened, and despite the use of castor oil and other remedies and measures generally employed in this condition the patient sank steadily and died of adynamic ileus on the evening of the fifth day. Lavage was not resorted to on account of the age and feeble condition of the patient.

Pathologic part. Dr. Kelly's report of the pathological examination of the specimen follows. The scrapings consist of a new-growth made up of a framework of fibrous connective tissue supporting large cylindrical cells, with clear vesicular nuclei. The connective-tissue stroma is quite scanty and in some places altogether wanting. The tumor-cells, for the most part, are arranged radially about and attached directly to capillary blood vessels—whence morphologically the term perithelial sarcoma seems justified. In other places there is diffuse infiltration of the tissue—endometrium and musculature—by the tumor-cells. The uterus is rather small and reveals at the fundus a rough excrescence about centimeters in diameter projecting into the cavity and infiltrating the wall of the uterus to a depth of seven to ten millimeters. Microscopically the growth consists of a connective-tissue stroma enclosing epithelial cells arranged about the manner of the glands of the endometrium. In general this glandular arrangement is more or less well preserved, but in many places it is altogether wanting and the epithelial cells infiltrate the tissues irregularly as is common in this type of tumor.

This case is established therefore as one of the earliest recorded instances of perithelioma of the uterus—one of the rarer group of endothelial tumors.

THE ENDOTHELIUM AND THE PERITHELIOMA

In order to comprehend the difference and yet the very intimate relationship existing between the two groups of endothelial tumors about to be analyzed it becomes imperative to appreciate the exact anatomical variation

between the structures known as the endothelium and the perithelium

It was His (70) who invented the term *endothelium* for the flat cells composing the inner lining of serous cavities as well as of the blood vessels and the lymph vessels. These cells have a definite origin from the mesenchyma—a layer of the primitive mesoblast—as Courtauld (24) established by his investigations of the newly forming blood-capillaries in very early placental tissue. Courtauld proved conclusively that the endothelial cells originate in the loose connective tissue of the chorionic villi and that the epiblastic layers have no share whatever in the process. It is obligatory therefore that neoplasms originating from these cells must be grouped with the mesoblastic growths side by side with the sarcomata whatever their histological appearances may be. They must be sharply differentiated from the carcinomata notwithstanding their many points of resemblance to that group of tumors. Because of their phylogenesis Lazarus Barlow (97) remarks that such tumors must be expected to show as they do a great variability of appearance ranging between that presented by a typical spheroidal cell carcinoma on the one hand and a typical sarcoma on the other. While both sarcoma and endothelioma therefore have their origin in the mesenchyma it is probable that the sarcomata arise at an earlier and more primitive stage of mesenchymal development as is proved by their earlier clinical appearance that is in children and patients of tenderer years.

In describing the endothelium Lazarus Barlow (96) states that normal endothelial cells are regularly arranged are flattened and round with a large round or oval nucleus and with a large amount of protoplasm to the cell. As a rule the chromatin is collected round the periphery of the nucleus and also in the center while strands of chromatin extend between the two. Hence in section the nucleus is remarkable by its clearness and its appearance of vacuolation. Mallory (112) adds that the endothelial cell is characterized by no production of fibrils hence it stands out in marked contrast to the neuroglia cell. These endothelial cells are found in

special regions notably in the blood vessels the lymphatics and the lymph spaces.

The *perithelium* on the other hand is the layer of endothelial cells which surrounds the capillaries and smaller blood vessels that is the external boundary or adventitia of the vessels running through the perivascular spaces but not the cells forming the external wall of these spaces. Eberth and Iwanoff (35) in 1870 first described the perithelium in the vessel of the pia mater and demonstrated them by staining with silver nitrate. Zeit (196) who in this country has probably most thoroughly studied these tissues emphasizes the fact that the perithelial membrane must be differentiated from the *perivascular lymph spaces* of His (70) which that anatomist described as surrounding the adventitia of arteries veins and capillaries of the central nervous system (which has no lymph vessels). The perithelium Zeit repeats is the outer lining of the adventitia of blood vessels outside of which is the perivascular lymph space. In 1871 von Ehner (36) described the perithelium in the vessels of the pineal gland the suprarenal capsules the thymus gland and the salivary glands. Waldeyer (192) and Sertoli (166) in 1868 described it in the vessels of the coccygeal gland and Palt auf (127) in 189 reported its presence in the carotid gland.

THE HISTOLOGIC FEATURES OF PERITHELIOMA AND ENDOTHELIOMA

As is true of all other tissues it is possible for neoplasms to develop from these delicate membranes. Stolz (146) calls attention to the fact that Golgi as early as 1869 first spoke of an *endothelioma* as a growth originating from endothelial cells while Kolaczek (84) in 1878 made the first great analytical study of endothelial tumors and recognized the condition as belonging to the group of angio-sarcomata. Marchand (113) and Weichselbaum in 1879 carried on these investigations both regarding the endotheliomata as tumors *sui generis*. Maurer (116) in 1890 gave the name *perithelioma* to the endothelial tumors arising from the adventitia of the blood vessels. Finally Ribbert (149) in 1901 stated that the endothelial tumor arises

ing from the blood vessels is a very rare growth—much more so than that arising from the lymph-channels and this observation is verified by the summary of all recorded endothelial tumors accompanying this paper.

It is unfortunate that there has been some confusion in the employment of these terms. The following résumé may aid in elucidating the matter. Under morbid stimulation endothelial cells wherever found will proliferate and this proliferation may take place inwardly or outwardly or in both directions at the same time. In the words of Lazarus Barlow (96) who with Bayon (11) the English pathologist has given this subject exhaustive attention. Outward proliferation will lead to the production of a central space lined with endothelial cells, and surrounded by two three or many layers of cells, more or less regularly arranged, and with characteristic nuclei. Such a growth springing from the adventitia of a blood vessel is designated a *perithelioma*. The important point to note morphologically is the persistence of the central lumen. Lazarus-Barlow believes that this characteristic feature is doubtless due to the greater rapidity with which the blood flows through the capillaries together with the high hemal tension both of which militate against cellular proliferation inward. His conclusion that because of these physical peculiarities enthelomatous growth should be more common in the case of lymphatics and peritheliomatous growth in the case of blood vessels is verified clinically and by the histological findings of all recorded endothelial tumors. It must be admitted however that it is difficult in some cases to definitely conclude where the growths originated, although the presence of red blood-corpuscles in the lumina of peritheliomata will usually determine their origin from the blood vessels.

If adds Lazarus-Barlow the growth shows lumina containing a fairly circumscribed mass of albumin which has undergone coagulation in the process of fixation and has given rise to fibrin and a certain amount of granular debris the growth has probably originated in a lymphatic.

If on the other hand, the proliferation of

the endothelial cells takes place inwardly the central space lined with endothelial cell will become choked with a mass of cells. Such a growth is known as an *endothelioma*.

According to these two hypothetical methods of growth continues this pathologist

It should be possible to divide the endotheliomata into the *peritheliomata* and the *endotheliomata*. Further if the perithelioma process occurs in different situations but in close contiguity the effect will be that of a number of spaces each more or less closely resembling the original space but separated from one another by a mass of cells produced by the outward proliferation and coalescence of the endothelial lining. On the other hand, in a growth of the endothelioma type a number of cell masses will be seen corresponding to normal lymphatic spaces in which the lumina have been distended and filled with cells and which are separated by ordinary connective tissue. A combination of the two processes may occur leading to a type of growth that may fairly be called a *perienthelioma*.

To this distinction Bayon (11) adds that all growths presenting a radial disposition of cells around blood vessels the endothelial lining of which is intact may be termed *peritheliomata* even if it cannot be conclusively shown that they originate from the perithelium, that is from the endothelial cells covering the adventitia of the blood vessels.

HISTOLOGIC CONCLUSIONS CONCERNING ENDOTHELIAL TUMORS

As a primary corollary then it may be stated that both endotheliomata and peritheliomata are in reality endothelial tumors that is taking their origin in endothelial cells and secondly that they are more or less motely still very closely allied to if not constituting a true variety of sarcomata. More over from a morphologic standpoint, it is evident, from the foregoing analysis that it is admissible to use the expression *peritheliomata* to designate only a peculiar class of the growths springing from the delicate external layer of cells around the minute blood vessels and showing the characteristic radial disposition of the tumor-cells which

according to von Hanseemann (60) is due to the growth cells being more readily nourished in that position. The characteristic cellular proliferation begins at the external wall of the vessel and not in its lumen as in simple hemangio-endothelioma but they are not as Barbour (10) claims in reality endotheliomata derived from the lymphatic. Zeit (198) emphasizes this distinction when he remarks it is wrong to speak of a *perithelioma* as arising from a lymph vessel because perithelial membranes cover the outer surface of the adventitia of blood vessels only in a one-cell layered mosaic of flat endothelium like cells. They have only been found with blood vessels of certain organs called perithelial organs. A perithelioma cannot therefore be spoken of as arising from lymph vessels nor from blood-capillaries. The term *perithelioma* is confined to certain tumors of the blood vessels of perithelial organs only. Yet so-called perithelial tumor or angiosarcomata do occur in nonperithelial organs which are morphologically similar to the true peritheliomata. From a histogenetic point of view it is desirable that the term be reserved for a class of tumors arising from perithelium only.

With this reservation Zeit concludes. In order then to arrive at a histogenetic classification of these tumors we would have to be able to distinguish whether the proliferation of cells had their origin in the true perithelium of blood vessels which lines the outer surface of the adventitia in perithelial organs (*perithelioma*) in the inner or both endothelial layers of a perivascular lymph space or in the adventitia cells or perivascular cells of blood capillaries. Pick (134) and Rosthorn (155) call all these endothelium like layers *perithelium* and their proliferation a *perithelioma*. Borst (10) also wants to use the name perithelioma for all these tumors with the understanding that it is a kind of offspring of endothelioma. In case one is able to prove that the growth originated from the endothelium of the perivascular lymph spaces it should be called *endothelioma perivascular* (Borrmann's (18) *periendothelioma*). Borrmann thinks he can distinguish morphologically between the two types as follows *peri-*

thelioma when the vessels are surrounded by many layers of cells which are arranged [with their long axes] radially and vertically to the wall of the vessel *periendothelioma* when the vessel are surrounded by many layer of cells which are arranged concentrically around the wall of the vessel. Zeit differs with this view and prefers to use the name *hemangio-endothelioma perivascular* for the so-called perithelial or perivascular tumors. On the other hand the *hemangio endothelioma intravascular* of Zeit originates only from blood-capillaries and has been called by Ziegler *hemangioma hypertrophicum* by Nawroth *hyperplastic capillary angioma* and by Borrmann *capillary endothelioma*. These tumor consist of a stroma of fibrous tissue with gland like tubes filled with blood and lined with one layer of endothelial cells which may be cubical or cylindrical in shape.

THE CLINICAL ANALYSIS OF ENDOTHELIAL TUMORS

With this hasty summary of the histological distinctions between the two groups of endothelial neoplasms it is interesting to proceed to an analytical study of the clinical peculiarities of these tumors with special reference to their occurrence in the female generative organs. An exhaustive investigation of endothelial tumors was made by Rudolph Volkmann (190) in 1895 and more recently by Max Borst (20) in 1902 while Zeitschmann (100) has presented an exceedingly interesting treatise covering the recorded information up to 1904 concerning perithelioma as occurring in lower animals.

At the most not more than 300 endothelial tumors of all kinds have been recorded to date in the various portions of the human body. It must be conceded therefore that they are among the rarest of neoplasms although it is probable as Roussy and Amicville (156) have claimed that they are commoner than would appear and that many cases were formerly described as angiosarcoma and angiosarcoma plexiforme.

Any part of the body may be attacked by the growth. The commonest sites of surgical interest according to Carless (6) ap-

ing from the blood vessels is a very rare growth—much more so than that arising from the lymph-channels, and this observation is verified by the summary of all recorded endothelial tumors accompanying this paper.

It is unfortunate that there has been some confusion in the employment of these terms. The following résumé may aid in elucidating the matter. Under morbid stimulation endothelial cells wherever found will proliferate and this proliferation may take place inwardly or outwardly or in both directions at the same time. In the words of Lazarus Barlow (96) who with Bayon (11) the English pathologist, has given this subject exhaustive attention. Outward proliferation will lead to the production of a central space lined with endothelial cells, and surrounded by two three or many layers of cells more or less regularly arranged and with characteristic nuclei. Such a growth springing from the adventitia of a blood vessel is designated a *perithelioma*. The important point to note morphologically is the persistence of the central lumen. Lazarus-Barlow believes that this characteristic feature is doubtless due to the greater rapidity with which the blood flows through the capillaries together with the high hemal tension, both of which militate against cellular proliferation inward. His conclusion that because of these physical peculiarities enthelomatous growth should be more common in the case of lymphatics and peritheliomatous growth in the case of blood vessels is verified clinically and by the histological findings of all recorded endothelial tumors. It must be admitted however that it is difficult in some cases to definitely conclude where the growths originated although the presence of red blood-corpuscles in the lumina of peritheliomata will usually determine their origin from the blood vessels.

If adds Lazarus-Barlow the growth shows lumina containing a fairly circumscribed mass of albumin which has undergone coagulation in the process of fixation and has given rise to fibrin and a certain amount of granular debris, the growth has probably originated in a lymphatic.

If on the other hand the proliferation of

the endothelial cell takes place inwardly the central space lined with endothelial cells will become choked with a mass of cells. Such a growth is known as an *endothelioma*.

According to these two hypothetical methods of growth continues this pathologist it should be possible to divide the endotheliomata into the *peritheliomata* and the *endotheliomata*. Further if the perithelioma process occurs in different situations, but in close contiguity the effect will be that of a number of spaces each more or less closely resembling the original space but separated from one another by a mass of cells produced by the outward proliferation and coalescence of the endothelial lining. On the other hand in a growth of the endothelioma type a number of cell masses will be seen corresponding to normal lymphatic spaces in which the lumina have been distended and filled with cells and which are separated by ordinary connective tissue. A combination of the two processes may occur leading to a type of growth that may fairly be called a *periendothelioma*. To this distinction Bayon (11) adds that all growths presenting a radial disposition of cells around blood vessels the endothelial lining of which is intact, may be termed *peritheliomata* even if it cannot be conclusively shown that they originate from the perithelium—that is, from the endothelial cells covering the adventitia of the blood vessels.

HISTOLOGIC CONCLUSIONS CONCERNING ENDO- THELIAL TUMORS

As a primary corollary then it may be stated that both endotheliomata and peritheliomata are in reality endothelial tumors, that is taking their origin in endothelial cells and secondly that they are more or less rootedly still very closely allied to if not constituting a true variety of sarcomata. Moreover from a morphologic standpoint, it is evident, from the foregoing analysis, that it is admissible to use the expression *peritheliomata* to designate only a peculiar class of the growths springing from the delicate external layer of cells around the minute blood vessels and showing the characteristic radial disposition of the tumor-cells which

according to von Hansemann (60) is due to the growth-cells being more readily nourished in that position. The characteristic cellular proliferation begins at the external wall of the vessel and not in its lumen as in simple hæmangio-endothelioma but they are not as Barbour (10) claims in reality endotheliomata derived from the lymphatic. Zeit (198) emphasizes this distinction when he remarks it is wrong to speak of a *perithelioma* as arising from a lymph vessel because perithelial membranes cover the outer surface of the adventitia of blood vessels only in a one cell layered mosaic of flat endothelium like cells. They have only been found with blood vessels of certain organs called perithelial organs. A perithelioma cannot therefore be spoken of as arising from lymph vessels nor from blood capillaries. The term *perithelioma* is confined to certain tumors of the blood vessels of perithelial organs only. Yet so-called perithelial tumors or angiosarcomata do occur in non perithelial organs which are morphologically similar to the true peritheliomata. From a histogenetic point of view it is desirable that the term be reserved for a class of tumors arising from perithelium only.

With this reservation Zeit concludes. In order then to arrive at a histogenetic classification of these tumors we would have to be able to distinguish whether the proliferation of cells had their origin in the true perithelium of blood vessels which lines the outer surface of the adventitia in perithelial organs (*perithelioma*) in the inner or both endothelial layers of a pervascular lymph space or in the adventitia cells or pervascular cells of blood capillaries. Pick (134) and Rosthorn (155) call all these endothelium like layers *perithelium* and their proliferation a *perithelioma*. Borst (19) also wants to use the name perithelioma for all these tumors with the understanding that it is a kind of offspring of endothelioma. In case one is able to prove that the growth originated from the endothelium of the pervascular lymph spaces it should be called *endothelioma pervasculare* (Borrmann's (18) *periendothelioma*). Borrmann thinks he can distinguish morphologically between the two types as follows *peri-*

thelioma when the vessels are surrounded by many layers of cells which are arranged [with their long axes] radially and vertically to the wall of the vessel *periendothelioma* when the vessels are surrounded by many layers of cells which are arranged concentrically around the wall of the vessel. Zeit differs with this view and prefers to use the name *hæmangio-endothelioma pervasculare* for the so-called perithelial or pervascular tumor. On the other hand the *hæmangio endothelioma intra vasculare* of Zeit originates only from blood capillaries and has been called by Ziegler *hæmangioma hypertrophicum* by Nawroth *hyperplastisches capillares angiom* and by Borrmann *capillary endothelioma*. These tumors consist of a stroma of fibrous tissue with gland like tubes filled with blood and lined with one layer of endothelial cells which may be cubical or cylindrical in shape.

THE CLINICAL ANALYSIS OF ENDOTHELIAL TUMORS

With this hasty summary of the histological distinctions between the two groups of endothelial neoplasms it is interesting to proceed to an analytical study of the clinical peculiarities of these tumors with special reference to their occurrence in the female generative organs. An exhaustive investigation of endothelial tumors was made by Rudolph Volkmann (190) in 1895 and more recently by Max Borst (20) in 1902 while Zeitschmann (200) has presented an exceedingly interesting treatise covering the recorded information up to 1904 concerning perithelioma as occurring in lower animals.

At the most not more than 300 endothelial tumors of all kinds have been recorded to date in the various portions of the human body. It must be conceded therefore that they are among the rarest of neoplasms although it is probable as Rous and Ameuille (156) have claimed that they are commoner than would appear and that many cases were formerly described as angiosarcoma and angiosarcoma plexiforme.

Any part of the body may be attacked by the growth. The commonest sites of surgical interest according to Carless (26) ap-

pear to be the skin testes, throat, the parotid and submaxillary glands, the neighborhood of the mouth and cheeks the long bones, and the carotid gland. Other regions in which authentic cases have been noted are the eyelid the optic nerve the soft palate the pelvic connective tissue the brain the subcutaneous connective tissue, the muscles the kidney the mamma, and certain serous membranes as the pleura. Wherever occurring these tumors show a marked tendency to undergo hyaline degeneration.

In their relation to sex Carless states that endothelial tumors are slightly more common in women than in men. Karsner (77) endorses this statement. Age exerts a decided influence upon the growth. Only 16.13 per cent of the cases occur before the age of 40 and 73.87 per cent after that age. Karsner claims that the disease appears particularly in the fourth fifth and sixth decades of life that is between 31 and 60 years of age.

About one-third of all the recorded cases have occurred in the female generative organs. Thus Lange (94) up to 1903 collected over 40 cases of endothelioma of the ovary. Since then additional cases in the ovary have been reported by Godart (54) Lincoln (106) Schuermann (163) Federlin (40) Papafannou (128) Heinrichs (65) Procopio (141) Kubo (92) Carl (25) Eymier (39) and Ligabue (103). Perithelioma of the ovary is much rarer but fifteen cases in all having been recorded by Steinhaus (175) Burckhard (24) Krukenberg (90) Menetrier (117) Graefe (56) Pollak (139) Mirabeau (121) Göth (55) Uffreduzzi (184) Neumann (125) Amann (5) Bender and Proust (14) and Barbour and Watson (10). Karsner (77) records a case of primary endothelioma of the omentum. Schmidlechner (162) a case of perithelioma of the labia majora and Barbour and Watson (10) a case of perithelioma of the fallopian tube.

ENDOTHELIAL TUMORS OF THE UTERUS FROM THE CLINICAL POINT OF VIEW

Macnaughton Jones (109) correctly remarks that it is only within recent years that uterine endothelial tumors have been de-

scribed. Comparatively few of these cases are on record and this is especially true of perithelioma but, as Watson (193) has remarked the condition cannot be so rare as the small number of cases indicates. Many of them have been described as sarcomata and many others occurring as secondary changes in fibroids have not been recognized at all. In a large percentage of the cases the tumor has arisen in a pre-existing fibroid, or has itself formed a large tumor in the uterine wall which has been mistaken for a fibroid. A few of the cases, as Watson's and my own were unassociated with perceptible tumor formation having apparently originated in the corporeal mucosa. Now that the existence of these tumors is becoming more generally recognized as well as their intimate association with a pre-existing fibroid change in the uterus, it is very probable that a progressively larger number of endothelial tumors will be placed on record in surgical literature. It is at least suggestive as Lazarus-Barlow (96) states that in the Mid-dlesex Hospital in London where a careful pathological examination of every tumor is made during the period from 1900 to 1904 endothelioma constituted 10 per cent of the malignant tumors of the uterus.

I have been able to gather from the literature just 50 cases of endothelial new formations in the uterus of which 18 were of the peritheliomatous type and 32 endotheliomatous. These are grouped in the tables which are appended with the exception of Svoboda's (177) case of endothelioma of the cervix and Szernyński's (178) and Zembruski's (199) cases of perithelioma, the records of which were not accessible. It is interesting to note that two of these cases occurred in the work of members of this Society. It is to be regretted that the clinical and pathological reports of some of these cases are very incomplete but even so a critical review of the cases elicits interesting and suggestive points. Thus the tables verify the claim already made that endothelioma is much more frequent than perithelioma—about in the proportion of 2 to 1.

Age. The average age of all the cases was 46 years. Perithelioma seems to develop a little later than endothelioma the cases

averaging 48 $\frac{1}{4}$ years while the average age of the endotheliomata was 43 $\frac{3}{4}$ years

The social relations of the patients are not recorded in 11 cases. Seven of the women were single and 29 were married with from none to nine children. One of the women was but 18 years of age another 19 and a third 27 the rest were 30 and older the oldest woman being 68 years of age the next oldest 65 a third 64 and two 62 years old. Sixteen of the women were 50 years old or more. As two-thirds of the women with uterine sarcoma are below the average in child bearing have not reached puberty or have not borne children for a long time a striking clinical difference will here be noted between uterine sarcomata and endothelial tumors.

Symptoms. Bleeding at times amounting to flooding at times merely a slight show is a very persistent symptom only 5 of the cases giving no such history. At a later period in the course of the disease these women would probably have developed the symptom. Generally the clinical manifestations are those of malignancy—bleeding febrile purulent discharge and pain—or those of fibroid tumor—bleeding with a decided tumor mass or uterine enlargement. The cases give a death rate of 29.9 per cent, including the primary mortality—17 per cent—and death from later complications and recurrence.

Site of the tumor. Of the peritheiomata but one originated in the cervix while of 31 endotheliomata the location of which are noted 16 slightly over half sprang from the cervix—7 from the posterior lip 4 from the anterior lip and 5 from the cervix generally without special localization. But 2 endotheliomata developed in the fundus and right cornu while 1 were located in the corpus 2 involving the posterior wall and 10 the interior. Six of the peritheiomata originated in the fundus and 10 in the body of the uterus. It would appear therefore that endotheliomata preferably develop from the cervix and peritheiomata from the uterus itself.

corpus uteri and Shaw (167) in 1913 both call attention to the frequency with which these endothelial growths in the uterus occur in association with or actually within the tissues of fibromyomata and especially when there has been no pre-operative suspicion of malignancy. Shaw remarks that this may possibly account for the few cases recorded many doubtless being thrown away as fibromyomata without microscopic examination. Of the tabulated cases 19 were associated with fibromata or fibromyomata while in 23 cases no such tumorous formation was noted. All the fibroid tumors which had undergone the malignant degeneration were located in the body of the uterus thereby substantiating the claims of Montgomery, Weir Williams and others that sarcoma of the body of the uterus is more common than sarcoma of the cervix.

In 1860 C. Mayer first described uterine sarcoma his case being termed by him a sarcomatous polyp. The occurrence of sarcomatous change in fibromyomata was first clearly described by Virchow (187) in 1862 who pointed out the origin of these tumors from the connective tissue of the myoma. In 1867 G. Veit first described sarcoma of the cervix. Finally Geist (52) in 1913 while speaking of malignant changes in uterine fibroids with special reference to the histogenesis of sarcomatous change in these tumors remarks: "The interstitial tissue of the myoma and the adventitia and endothelium of the lymph and blood vessels have been recognized and accepted as sites of origin of sarcoma. To these must be added the muscle cells proper [of a myoma]." Leith (98) adds suggestively: "We thus have a variety of sarcomatous growths arising within fibroids—the endothelioma the peritheioma the myosarcoma and the myoma sarcomatodes which may be the explanation of the relatively low degree of malignancy exhibited by most of these growths. Those originating in fibroblasts though varying greatly in malignancy show it in greatest degree whilst the myosarcoma is the least malignant of all the other two forms showing varying intermediate degrees." Bayon (111) confirms this view as to the relatively low degree of malignancy of

THE ASSOCIATION OF ENDOTHELIAL TUMOR WITH OTHER NEOPLASMS OF THE UTERUS

Leith (98) in the Ingleby Lectures for 1910 upon the pathology of tumor of the

endothelial tumor stating that metastases are not at all frequent with these tumors which is diametrically opposed to the general expectation when there is taken into consideration the extreme vascularity of the tumors, their intimate approximation to the blood vessels, and their multiplicity of small cells. They are however he adds, characterized by infiltrative and rapid expansive growth but on complete and thorough operative procedure do not show a tendency to recur

CONCLUSIONS

The following deductions may be drawn from this pathological and clinical review

1 Endothelial tumors of the uterus develop late in life—much later than sarcomata—the peritheliomata generally occurring at the most advanced age.

2 These growths are especially prone to occur in a pre-existing neoplasm—a myoma or a fibromyoma

3 While showing a high degree of local malignancy they but rarely give rise to metastatic deposits elsewhere

4 It is probable that endothelial uterine tumors occur more frequently than would appear Hence the importance of early removal of all uterine growths which should always be subjected to a careful pathologic examination.

TABLE OF ENDOTHELIAL TUMORS OF THE UTERUS

(Chronologically arranged)

PERITHELIOMA

CASE 1. Reported by Mary Scharlieb Med Press and Circ March 5 906 p 335 Patient aged 44 single pregnancy *Clinical history* Flooding three years ago cured. For last six months increasing menorrhagia no pain. Flooding from November 3 905 Uterus slightly enlarged. Slightly irregular Small nodules, best felt per rectum. Operation November 6 905 *Macroscopic find* 1 Uterus slightly enlarged Small fibroid tumors upon fundus and posterior wall Mucous membrane shows circumscribed area of malignancy *Microscopic find* 2 Uterine muscle not invaded by glandular tissue. Diseased endometrium shows tubules of cells, actively proliferating Growth springing from outer wall of blood vessels Supravaginal hysterectomy Recovery

CASE 2. Reported by Mary Scharlieb Ibid. Patient aged 50. IX-para, youngest child sixteen years. *Clinical history* Menstrues regular till end of 904. Since then free discharge, recently blood-stained For three months large hard tumor felt in abdomen Frequent micturition. Large hard tumor felt in abdomen Irregular Os patulous with papillomatous mass protruding Operation, No-

vember 905 *Macroscopic findings* Uterus and appendages weigh 3 ounces. Uterus size of 4½ months' pregnancy 6¼ inches long 4¼ inches wide, outer surface smooth Cervix much enlarged Growth has perforated left side of uterus, and projects as irregular mass into left broad ligament tumor involves anterior lip of cervix. On section solid tumor fills cavity extending into the cervix attached to anterior wall mass measures 3 inches in antero-posterior diameter Posterior wall of uterus lined by much thinner but very irregular layer of growth Tumor firm uniformly glaucous-white color, cavity of uterus, 9 inches long *Microscopic findings* Sections of tumor show columns of cells embedded in connective tissue Columns have central cavity containing blood not lined with endothelium This is bounded by vascular wall of varying thickness, which is surrounded by thick layer of tumor cell giving the appearance of growth composed of collection of vascular tubes, the outermost cells of which are formed by masses of tumor-cells. Cells have large amount of protoplasm round deeply staining nuclei and nucleoli The amount of lateral tissue varies Supravaginal hysterectomy Recovery but continued growth of tumor

CASE 3. Reported by E. H. T. Reedy T. Roy Acad. Med. Ireland, 907 vii, 3 7 also personal communication Patient aged 34. II-para. *Clinical history* Operation, 906 Pain in abdomen and back. Slight leucorrhoea. Menstruation normal Losing flesh for years and half *Macroscopic findings* Uterus uniformly enlarged, with some fibroid induration Certain small nodules lie under the peritoneum Malignant tumor situated in fundus Peritoneum studded with small nodules *Microscopic find* 1 Sections of nodules show masses of fairly large flat cells, arranged in somewhat columnar manner and infiltrating the muscle bundles. This condition is quite general over the whole fundus Supravaginal hysterectomy Death on the following day

CASE 4. Reported by G. F. D. Smith J. Obst. & Gynec., Brit. Emp. 908 xiv 35 Patient aged 35 Single. *Clinical history* Irregular bleeding for five months. Uterus small freely movable Operation, July 30, 906. Double ovariectomy in 904. *Macroscopic find* 1 Uterus small 3 inches long ½ inches internally; external surface normal From the fundus projecting down and into the cavity is soft, friable growth paler than the surrounding mucous membrane. *Microscopic find* 2 Tumor-cells slightly elongated in shape springing from the periphery of the smaller vessels. Areas of necrosis. Tumor-cells infiltrate the uterine muscle to the point of attachment of the growth. Total hysterectomy Recovery

CASE 5. Reported by W. A. A. Dorland J. Am. M. Assn. 908 li, 7 Patient aged 65 Single. *Clinical history* Pain in pelvis for 12 months Uterus slightly enlarged anterior Slight leucorrhoea, sanguinolent, odorless No bleeding Operation, October 907 *Macroscopic find* 1 Uterus not much enlarged At the fundus rough excrescence, centimeters in diameter, projecting into the cavity and infiltrating the uterine wall to depth of 1½ centimeters. *Microscopic find* 2 Section of growth shows connective-tissue stroma enclosing epithelial cells, arranged after the manner of the endometrial glands. The scrapings consist of framework of fibrous connective tissue, supporting large cylindrical cells with clear vesicular nuclei. These cells are arranged radially about and attached directly to capillary blood vessels. Panhysterectomy Death on fifth day from adynamic ileus.

CASE 6. Reported by Dornin and Lockyer Proc. Roy. Soc. Med., vol. li, Obst. and Gynec. Sect. 908 Oct., p. 5

Patient aged 49. 1 para. *Clinical history* Abdomen enlarged for seven years. Birth 54 inches. Occasional irregular bleeding. *Macroscope and ng* Fibroid uterus associated with fibroma of right ovary—weight 5 pounds. Uterus six of two fists. (a) Fibroid tumor as large as the uterus springing from the fundus. *Microscopic* Section of tumor shows small round cells lying in close connection with numerous blood vessels and appearing to arise from their outer coats. These cells resemble sarcoma cells. The blood vessels have fairly thick walls and are in no sense embryonic like the blood vessel of ordinary sarcoma. *Hysterectomy* Recovery. No recurrence.

Case Reported by Doran and Lockyer. *History* Patient aged 40. 11 para. *Clinical history* Abdomen enlarged 15 months. Menstruation profuse and irregular. *Macroscope and ng* Multinodular fibroid tumor of uterus—weight 5 pounds. A peritubal mass on the uterine wall left half plain tube mesosalpinx left and a cystic tumor springs from left side of uterus. *Microscopic* Section of tumor shows a serous small smooth pea-like cells springing from the endometrium of the blood vessels. These lie in large or small collections in all color places among the muscles of the uterus and tube. These cells resemble in size, shape and staining characteristics the cells of the lymphomatous sarcoma of the endometrium. *Hysterectomy* Recovery. No recurrence.

Case 8 Reported by J. Ewing. *Proc. N. Y. Path. Soc.* 1909. Vol. 85. Patient aged 48. Married. *Clinical history* Menopause 3½ years ago. There was irregular bleeding at times profuse. Three months later a foul discharge. Uterus enlarged, tender, os patulous. Large polypoid tumor felt in uterine cavity. *Macroscope and ng* Solid round polypoid tumor, 6 cm. firmly adherent to anterior wall, uterus small. Section streaked with extensive necrotic areas. *Microscopic* Section of tumor shows structure distinctly that of hypernephroma. Polyhedral cells in close apposition with well defined borders, clear granular cytoplasm and vesicular nuclei, size 5 to 30 microns. Near the blood vessels the smaller cells predominate. Mitotic figures with well preserved nucleoli are very numerous especially in the deeper portions near the muscularis. No sinusoids and no villi are found. *Hysterectomy* Recovery.

Case 9 Reported by R. F. C. Leith. *J. Obst. & Gynec. Brit. Emp.* 1914. Vol. 47. Patient aged 45. Married. Nullipara. *Clinical history* Menopause at 42. At 39 was tapped for a cystic abdominal tumor and thirteen months later an abdominal section but the growth was not removed because of adhesions and collapsed condition. At 44 increasing abdominal swelling, incontinence of urine. Tumor filled pelvis and reached to umbilicus. *Macroscope and ng* Uterus contains three tumors, the largest in anterior wall (almost entirely converted into cyst) other two solid. Cyst wall composed of sarcomatous elements, solid tumors sarcomatous. The large cystic growth was probably the primary tumor. *Microscopic* Section shows typical perithelioma cells, irregular in shape and size and of an active vegetative type some with several nuclei particularly those bordering upon the walls of the numerous capillaries. The young round cells are clustered close to the endothelial lining of the capillaries—suggesting their origin either from the endothelial cells of the vascular lumen or from the perivascular lymphatics. *Hysterectomy* Recovery.

Case 10 Reported by A. H. F. Barbour and B. P. W. *Am. J. Obst. & Gynec. Brit. Emp.* 1919. Vol. 6. Patient aged 38. 11 para. *Clinical history* Menopause at 48. 11½ five months. Fetid bluish leu-

rogen later blood stained and watery. Tumor attached to uterus. Six of five months pregnancy firm slightly tender uterus freely movable, os patulous, tumor palpable within. *Macroscope and ng* Uterus uniformly enlarged, no adhesions, irregular ovoid shape six inches vertical diameter 4 inches transverse. Tumor grows from fundus upper two-thirds of anterior wall and upper half of posterior wall. Lower pole projects free into uterine cavity. At fundus muscular wall reduced to a mere shell. Section of tumor yellowish white resembling brain tissue in appearance and consistency. Through it many hemorrhages most marked near fundus in this region necrotic area. *Microscopic* Section shows toward uterine wall islands of tumor cells, staining like a blood vessel with no endothelial coat but the other parts replaced by radially arranged cells of irregular outline each containing a large deeply staining nucleus, most of cells lie at right angles to lumen of vessel. In some parts there are appearances suggest e of the origin of these cells from the lymph channels, small spaces being habitable with the cell grouped around them. *Hysterectomy* Recovery. No recurrence.

Case 11 Reported by A. H. F. Barbour. *J. Obst. & Gynec. Brit. Emp.* 1913. Vol. 61. Patient aged 61. Single. *Clinical history* At 55 large loughing fibrous polyp with a thick pedicle projecting from vaginal orifice removed. Well until then began to fail. No pain. Gradually increasing abdominal swelling till size of seven months pregnant. Cystic feel. Uniform surface. *Macroscope and ng* Tumor 23 centimeters long 4 centimeters wide in long entire uterus from its lower pole projects the cervix. Bluish color, soft consistency, contains a large cystic cavity over anterior wall of which stretches the uterine cavity with its walls thinned out, length of uterine cavity 20 centimeters. About the middle of the posterior cavity is the remnant of a septum. Cyst wall thin lined with a layer of soft caseous matter which at lower posterior portion of cyst projects as a growth into cystic cavity. *Microscopic* Cyst walls show the structure of a uterine fibroid. Cavity lined with soft yellowish white necrotic tissue which shows peritheliomatous change. Several small vessels lie in a loose cellular stroma from their walls there is a definite cellular proliferation extending in the form of columns out to the stroma. *Hysterectomy* Recovery.

Case 12 Reported by W. F. Shaw. *J. Obst. & Gynec. Brit. Emp.* 1913. Vol. 62. Patient aged 40. Multipara. *Clinical history* Menorrhagia and metrorrhagia for two years. At 44 fibromyomatous polyp size of egg protruding through cervix removed. Two years later severe hemorrhage. Another egg sized polyp protruding from cervix. Patient anæmic. *Macroscope and ng* Uterus but slightly enlarged. Polypus of a dark color, invariable size of small orange springs from uterine wall, fundus cavity. *Microscopic* Section of tumor shows it to be a fibromyoma extensively invaded with perithelioma, the large cells of which are collected radially round the blood vessels. The uterine wall is not invaded. *Hysterectomy* Recovery. No recurrence.

Case 13 Reported by B. P. W. *Am. J. Obst. & Gynec. Brit. Emp.* 1914. Vol. 80. Patient aged 58. Primipara. Thirteen years last re. *Clinical history* Menopause at 47. No bleeding until 5. Then watery discharge occasionally streaked with blood, intermittent in character. Nine months later curetted. Scrapings showed malignancy. Two weeks later operation. *Macroscope and ng* Uterus 3 inches long 2 inches wide, peritubal uterine face normal. At its inner posterior wall is a small irregular projection on mucosa, 1 centimeter broad and 1 centimeter long. Rest of mucosa healthy. *Microscopic*

findings. Scrapings show large cells of epithelioid character arranged in rows, and in one or two places arranged radially to a vessel-lumen. Section of tumor shows typical perithelioma parts of growth necrotic, but greater part consists of masses of large cells arranged radially to lumina of blood-vessels. The growth is confined to the mucosa. In which small atrophied glands are visible. Base of growth infiltrates the superficial musculature. Here the cells form somewhat irregular columns and masses. Vaginal hysterectomy. Recovery. Subsequent developed squamous epithelioma of anterior vaginal wall near urethra, involving both sets of inguinal glands. Death.

CASE 4. Reported by F. W. N. Hautahn, *J. Obst. Soc., Edinb.* 924, xxvii, 33 also privet communication. Patient aged 32. *Clinical history.* Much pain in back slight menorrhagia. Ragged irregular condition of cervix, simulating carcinoma. *Macroscopic findings.* Uterus normal. Cervix shows growth involving cervical wall. *Microscopic findings.* Characteristic perithelioma. Vaginal hysterectomy. No recurrence.

CASE 5. Reported by F. W. N. Hautahn, *Ibid.* *Macroscopic findings.* Uterus seat of tumor involving corpus. *Microscopic findings.* Characteristic perithelioma. Hysterectomy. Recurrence in three or four months.

CASE 6. Reported by Mrs. F. E. Willey Proc. Roy. Soc. Med. 33 vii, Obst. and Gynec. Sect. 397. Patient aged 45. *Single. Clinical history.* For three years increasing menorrhagia. For six months recurring abdominal pain no leucorrhoea. Uterus size of 3½ months' pregnancy not tender. Appendages normal. Cervix healthy and nullipara. *Macroscopic findings.* Uterus 4 inches long and 4 inches wide outer surface normal. Posterior wall large white tumor 3 inches in diameter projecting into cavity fluctuating of consistency of fat, white in color degenerated in spots resembling coagulated serum. Edge of growth not well defined from uterine tissue. Strands of fibrous tissue from capsule of teraie all extend into tumor. Near the fundus the growth involves the uterine muscle. The endometrium is normal. *Microscopic findings.* Uterine wall invaded by masses of deeply stained tumor-cells these resemble sarcomatous tissue the cells are spindle-shaped and are anormally arranged. At places the entire tissue is composed of closely packed cells, with little intervening tissue. In other spots the cells are arranged in narrow channels, suggesting small empty capillaries and in other places the growth has the structure of perithelioma, being formed of thick walled tubes with central lumina. Subtotal hysterectomy.

II. ENDOTHELIOMA.

CASE 1. Reported by J. A. Amann, *J. Inaugural Dissertation, Muenchen*, 80 p. 5. Patient aged 35. VI para. *Clinical history.* Five years profuse yellowish white leucorrhoea. For 12 months pain in abdomen and back. No bleeding save last period of fourteen days. *Microscopic findings.* Tumor size of hazel ut on thickened posterior lip of cervix, consistency dense surface gray ragged. *Microscopic findings.* Tumor springs from deeper layer of cervical mucosa—from the endothelium of the lymph-vessels and lymph-channels. It consists of connective tissue stroma in which are numerous anastomosing cells, strands and masses rich contain central lumina. Removed by thermocautery. Recovery. No subsequent report.

CASE 2. Reported by J. McFarland, *Med News*, 894, iv p. 63. (From practice of D. C. P. Noble.) *Macroscopic findings.* Uterus shows large ragged ulcerating fibrous tumor projecting from the upper posterior surface into the uterine cavity circumscribed with broad pedicle almost continuous with the terine all. *Microscopic*

findings. Tumor substance unstriped muscle-tissue mixed with much fibrous connective tissue. Scattered throughout are occasional pale lies of uniform small round cells, irregularly arranged, but extending indefinitely into the surrounding lymph channels. Some of the lymph-spaces are filled with proliferated cells, varying in size from that of leucocyte to much larger having 1 to five nuclei, and resembling epithelial cells in places. They contain de-generated protoplasm, hyaline in nature. Here and there are areas of necrosis. It is an endothelioma arising from the lymph-channel. Complete hysterectomy. Recovery. Six months later multiple recurrence in chest, breast, loin, thigh. Death.

CASE 3. Reported by H. B. Deal, *Am. J. Obst.*, 895, xiv p. 300. Patient aged 45. II para. *Clinical history.* Menopause at 4. For over three years profuse atery discharge from uterus, blood-tinged for week slightly offensive. Uterus small free movable. Operation, September 3, 1904. *Macroscopic findings.* Uterus small. Small circumscribed tumor in right cornu. *Microscopic findings.* Angiosarcoma of the endotheliomatous type. Vaginal hysterectomy. Recovery.

CASE 4. Reported by J. C. W. Radmacher, *Inaugural Dissertation, Wuerzburg*, 895. Patient aged 43. *Clinical history.* Woman who died of mammary tumor. *Macroscopic findings.* On posterior lip of cervix a tumor the size of walnut. *Microscopic findings.* Section shows growth springs from the endothelium of the lymph-channels.

CASE 5. Reported by L. Dick, *Arch. f. Gynaek.*, 895, xlv. Patient aged 35. *Macroscopic findings.* Uterus shows submucous mass endometrium thickened below tumor. *Microscopic findings.* Section shows endothelioma originating in the lymph capillaries. Hysterectomy.

CASE 6. Reported by A. Dietz, *Arch. f. Gynaek.*, 896, lx. Patient aged 3. Null para. *Clinical history.* Periods irregular. Leucorrhoea for 12 months. Papillary tumor projecting from posterior cervical lip, endometrium long slightly bleeding, friable. Uterus not enlarged. *Macroscopic findings.* Uterus normal size. *Microscopic findings.* Section of tumor shows scant connective tissue stroma, the characteristic appearance of endothelioma—grouping of cells in central lumina. Blood vessel walls normal. Endothelioma lymphaticum. Vaginal hysterectomy. Patient died in three or four weeks. Cause not given.

CASE 7. Reported by Grape, *Inaugural Dissertation, Greifswald*, 897. Patient aged 54. *Clinical history.* Tumor projecting from vagina. *Macroscopic findings.* Metastatic growth from primary terine tumor. *Microscopic findings.* Section shows that tumor cells had invaded the musculature. Characteristic endotheliomatous formation. Vaginal hysterectomy.

CASE 8. Reported by E. Hudson, *Bull. J. Hosp.*, 1904, lxv p. 36. Patient over 50. *Clinical history.* Menopause ten years ago. For eight years severe pain in pelvis radiating to bladder. Slight hemorrhage three weeks ago. Tumor on both cervical lips. *Macroscopic findings.* Uterus not enlarged. *Microscopic findings.* Section shows the tumor springs from the endothelium of the lymph-spaces. Hysterectomy. Death fourteen days later from sepsis.

CASE 9. Reported by P. Kroeber, *Arch. f. Gynaek.*, 901, lxx p. 625. Patient aged 48. *Clinical history.* Had prediabetic bleeding. Hard, friable tumor on posterior lip of portio. Operation in 1900. *Macroscopic findings.* Uterus uniformly enlarged. Tumor involves the posterior cervix and extends through internal os into substance of corpus. The growth lies nearer the mucosa than the perosa. *Microscopic findings.* Mucosa of portio cervix and corpus intact. Characteristic endotheliomatous ar

arrangement of cells in groups in the small lymph-vessel. Abdominovaginal total extirpation. Death sixteenth day from peritonitis.

CASE 10. Reported by C. Gebhard. *Arch. f. Gynäk.* 1903, xlii, 1. Patient aged 42. Nullipara. *Clinical history.* For one year profuse bleeding. Tumor in left parametrium. Operation. 1903. *Macroscopic findings.* Tumor attached to the cervix. *Microscopic findings.* The tumor springs from the endothelium of the lymph-vessel—a typical endothelioma of the lymph-spaces. Hysterectomy.

CASE 11. Reported by H. Robb. *Am. J. M. Sc.* 1890, cxi, 14. Patient aged 65. *Para. 3.* Menopause 15 years. Three years later bloody vaginal discharge. To three weeks grinding pains in lower abdomen, pain in left leg, backache, constipation. *Examination.* Uterus antero-inclined, enlarged, not freely movable. Operation—curettage. *Macroscopic findings.* Scraping the tumor arranged in masses, sometimes solid at times, the central lumina. Cells of all sizes with large nuclei and look and more or less brown granules between the cells. Intercellular substance faintly granular, and some small lymphoid cells. The tumor cells ramify in the muscular tissue of the uterine wall. Cleft-like spaces in the rows of cells are filled with flattened endothelial cells. The cells fill the lymphatics, some of which are blocked, others showing central lumina. Tumor springs from the endothelium lining lymphatics in uterine wall. Endothelium of lymph-vessels atrophic. Uterine cavity retroverted, cervix uterine. Rec. Well one year later.

CASE 12. Reported by A. P. Horrocks. *A. M. J. Gynaec.* 1900, l, 5. Patient aged 34. VIII para. Abortions. *Clinical history.* For two years bloody flow, bleedings after coitus. Uterus enlarged. Tumor in posterior lip of cervix. *Macroscopic findings.* Uterus enlarged, in posterior position. Lip almost shaped like more size of plum. It is slightly raw, coarseness dense. *Microscopic findings.* Tumor section shows a cellular structure, lymph spaces of the villi in the endometrium enlarged and filled with tumor cells. Endothelium of lymph spaces. Vaginal hysterectomy. Recovery.

CASE 13. Reported by P. K. Koerner. *Ibid.* Patient aged 36. IV para. *Clinical history.* Marked cachexia, profuse hemorrhage. Uterus small, parametrium infiltrated. Ulcerated tumor in posterior lip of cervix. Operation. *Macroscopic findings.* Vaginal epithelium lacerated and that of cervix normally atrophic. Small cell infiltration, deeper substance of cervix beneath the epithelium. Characteristic endothelioma formation. Vaginal total extirpation.

CASE 14. Reported by P. N. Hansen. *Vierteljahr. f. Path. Anat.* et Berl. 1903, cxviii, 8. Patient aged 53. III para. *Clinical history.* Puberty at twenty, for two years growth of lower abdomen. Menstruation. Abdomen very large, adema. Operation. February 6, 1902. *Macroscopic findings.* Large tumor of uterus covered with serosa, anastomosing vessels lying in gelatinous mass. *Microscopic findings.* Tumor shows spots of cervix. Proliferation of endothelial cells in the lumina of the capillaries. Capillary endothelioma (hemangio-endothelioma) of uterus. Serosa antero-inclined. Death a few hours.

CASE 15. Reported by O. Silberberg. *Arch. f. Gynäk.* 1903, l, 4. Patient aged 65. Married. *Clinical history.* Somewhat profuse leucorrhoea, blood for two days. Curetted and cauterized. Refused operation. *Macroscopic findings.* Uterus enlarged, tumor in lower part of cervix. *Microscopic findings.* Scraping shows dirty gray color, characteristic endothelial structure

with colar meshes. Cellular proliferation in the lymph-vessel.

CASE 16. Reported by Rimmann. *Inaugural Dissertation.* Breslau, 1902. Patient aged 48. VI para. *Clinical history.* For three months profuse menstrual bleeding, every three weeks. On posterior lip of portio a tumor of the consistency of medulla. *Macroscopic findings.* Uterus enlarged, the tumor in the posterior wall. *Microscopic findings.* Section shows masses of small lymph cells from the endothelium mixed with spindle cells of the wall. Proliferation of the endothelium of the vessels. Abdominal total extirpation.

CASE 17. Reported by Rimmann. *Ibid.* Patient aged 36. *Para. 3.* *Clinical history.* For three months irregular bleeding. On portio small cauliflower-like growth easily bleeding, soft consistency. *Macroscopic findings.* Section shows diffuse colar endothelioma, prongs from lymph vessels. Vaginal total extirpation. Recovery.

CASE 18. Reported by O. von Franqué. *Zentralblatt f. Gynäk.* 1903, xli, 23. Patient aged 17. Married, nullipara. *Clinical history.* Puberty at 14. Menstruation irregular for past year. Last menses three months ago. Whitish leucorrhoea for six months. No pain, no bleeding. Cervix at tumor, bled and base cauterized. Ten days later operation. *Macroscopic findings.* Tumor projected from uterus, resembles placental tissue. It is on the portio and extends laterally into parametrium, especially on left side. Uterus 9.5 centimeters long, 4 wide and 3 deep. *Microscopic findings.* Section shows characteristic endothelial tumor. Tumor springs from endothelium of the lymph-channels. Total vaginal hysterectomy, removal of adnexa. Recovery.

CASE 19. Reported by P. pere. *Arch. Ital. di Gynec.* 1903, vii, VII para. *Macroscopic findings.* An inoperable terrene tumor found in a dead woman. Uterus centimeters long, cervix 3 centimeters long. Cervical mucosa healthy. A tumor in cervical tissue. *Microscopic findings.* Section of tumor shows an infiltration of connective tissue with large round cells, some cylindrical, some flat. Muscle tissue degenerated. Marked proliferation of endothelium of the lymph-vessels—a true lymphangiosarcoma.

CASE 20. Reported by P. Kirchgesner. *Zentralblatt f. Gynäk.* 1903, xlii, 97. Patient aged 34. III para. *Clinical history.* For 3½ years a yellow bloody discharge. A walnut-sized polyp in upper vagina springing from anterior cervical lip. Uterus not enlarged. *Macroscopic findings.* Uterus normal size. Tumor size of walnut in middle of anterior cervical lip. *Microscopic findings.* Section of tumor shows typical endothelioma, tumor formation, the growth springing from the walls of the lymph-capillaries—endothelioma lymphaticum. Total vaginal extirpation. Death in four days from septic peritonitis.

CASE 21. Reported by R. C. B. Maunsell. *Brit. Gynec. J. Lond.* 1905, xvi, 177. Patient aged 40. *Para. 3.* *Clinical history.* Prolonged menorrhagia. Progressive weakness, welling up of lower abdomen, mild purulent discharge from uterus. Cervix below umbilicus. Menstrual suppression from December 1902. Sinus opened in March 1903. In August 1903 bleeding from cervix. *Macroscopic findings.* Firm nodule situated in the lower part of the pelvis, 1.5 centimeters in diameter, 1.5 centimeters in length, 1.5 centimeters in width, 1.5 centimeters in depth. Median line dull, peritoneum not adherent. Cervix normal size. Tumor adherent to uterus with right body of uterus. *Microscopic findings.* Cervix ter, body of uterus, normal. Right half of uterus, no right corn, no tumorous with glabrous in 34 centimeters. Cervical circumference 35 centimeters. Transverse

circumference. Right tube springs from right side of tumor is normal in length. Right round ligament springs from tumor 5 centimeters below apparent origin of tube. Uterine cavity normal. Tumor enclosed in capsule of terine tissue lower portion an irregular firm myoma-like growth, upper portion cystic cavity lined with thin layer of same growth. *Microscopic findings.* Section of tumor shows a dense connective-tissue stroma containing alveoli of varying size, generally small. In these are masses of small cells with round nuclei and thin layer of protoplasm. The tumor resembles carcinomas, but the cells are smaller than cancer-cells. The cells in the alveoli are derived from the endothelium of the blood vessels. In some places connection can be traced between the normal endothelium of the vessels and the tumor-cells. The endothelial growth commences from the inner or endothelial lining of the blood-vessels. Endothelioma of terine fundus. Supravaginal hysterectomy; both adnexa removed. Recovery. No recurrence.

CASE 3. Reported by Cova, Arch. Ital. di ginec. 904, vii. Patient aged 35. Multipara. *Clinical history.* Fetal weeks bleeding. On the anterior cervical lip bloody mushroom-like growth, size of nut. *Microscopic findings.* Section of tumor shows alveolar spaces filled with leucocytes and cubical and polyhedral endothelial cells. These cells have also proliferated into the musculature of the terus. Vaginal hysterectomy. Recovery. No recurrence.

CASE 4. Reported by L. Federlin Beltr. J. Geburtsh. u. Gynaek., 904, viii, p. 9. Patient aged 3. Married sterile. *Clinical history.* Menstruation pausing off. Abdominal tumor reaching above the umbilicus. *Microscopic findings.* Uterus normal in size; its musculature thick, and in its walls three tumor nodules—to the right left, and in the posterior wall. Tumor of left ovary. *Microscopic findings.* Primary endothelioma of the ovary with metastasis in the posterior terine wall and in the right inguinal glands. Section of tumor shows alveolar structure with typical endotheliomatous formation. Total hysterectomy and removal of adnexa.

CASE 4. Reported by M. Graef. Arch. f. Gynaek. 904, xi, no. 72. Patient aged 50. *History.* Sanguinolent leucorrhoea with clots for some time. On portion vaginalis cauliflower-like canceroid the size of an apple. *Microscopic findings.* Section of tumor shows parallel and 1 piece radiating masses of cells, with large darkly-staining nuclei, of irregularly oval shape. The endothelium of the vessels is intact. Vaginal total extirpation. Death eight months later.

CASE 5. Reported by Marzucco. Arch. Ital. di ginec. 904, v. *Microscopic findings.* Section shows the tumor to be made of proliferating endothelioma.

CASE 56. Reported by H. Ravenius, Arch. de. med. exper. et d'anat. path., 905, xlvii, 3. Patient aged 44. *Clinical history.* Patient died from abdominal tumor which reached to the umbilicus. *Microscopic findings.* Tumor firm, of grayish-white color; lardaceous in appearance of fibrous consistency. Growth has invaded omentum, peritoneum, uterus, parametrium, and lymph-glands. In the prelumbar mesenteric, and inguinal regions it originated in the ovary. *Microscopic findings.* Section of tumor shows the characteristic endotheliomatous arrangement.

CASE 7. Reported by F. R. Zeit. J. Am. M. Ass. 906, xlv, 567. (Practice of D. Emil Klein.) Patient aged 68. *History.* Patient gave the clinical symptoms of uterine carcinoma. *Microscopic findings.* Uterus normal in size of hard, fibroid consistency 3 inches long 1½ inches broad. Uterine cavity obliterated. Entire cervix and all corpus uteri (except

the fundus) composed of hard tumor-like mass, of white, scirrhous appearance. Cut surface smooth white appearance with fine irregular and round monoleukic fields. The mucosa is smooth trophic glistening. *Microscopic findings.* Section of the tumor shows fibella ground substance with solid cellular cords cut in longitudinal and transverse sections. Lymph vessels and lymph spaces lined with proliferating epithelioid cell-masses. These cords of cells appear like cellular cylinders of large diameter (lymph vessel endothelioma) or as delicate cellular papillae of layers of flat cell branching here and there (lymph space endothelioma). The larger endothelial cell masses have numerous so-called lumina containing mucoid material. Other portions of the tumor look like scirrhous carcinoma. It is lymphangio-endothelioma intravascular of the terus. Vaginal hysterectomy. Death in 14 months from multiple metastatic tumors.

CASE 8. Reported by F. J. M. Werny and M. J. Gibson. J. of Path. & Bacteriol. 907, xii, 3. Patient aged 3. Married multipara. *Clinical history.* Well until 48 then irregular terine hemorrhages. Cervix enlarged, polyp removed. Hemorrhage shortly recurred. Uterus size of 6 months pregnancy very hard sensitive. Adnexa normal. Three months later cured. Large succulent masses removed. *Microscopic findings.* Uterus 4½ inches long 5 inches wide all uniformly thickened. Inner surface quite smooth. Embedded in wall of drum-shaped nodules size of hazelnuts, one each above upper and of cervix the other each from fundus, both softer than surrounding tissue lower one greenish that on section. *Microscopic findings.* Lower nodule consists of an intimate admixture of sarcoma (the cancer large spindle cells mixed with irregularly shaped cells giant-cells some with numerous nuclei. The carcinomatous portion consists of groups of large cells clear with large cellular nuclei cells round square, and cylindrical. The groups in many places show central lumina, either empty or choked with debris of polymuclear leucocytes. Some of the lumina surrounded with but single layer of cylindrical epithelium. Upper nodule composed of groups of large cells with or without lumina, they are embedded in dense fibromuscular stroma. The endothelial cells lining the lymph-cysts in the terine wall between the nodules are multiplied to produce rows of large cells markedly hyperchromatic. Some proliferation of endothelium of the small blood-vessels. Combined sarcoma and endothelioma of uterine wall. Hysterectomy.

CASE 30. Reported by M. H. Phillips, J. Obst. & Gynaek. Brit. Emp. 908, xiii, 3. Patient aged 50. Married nullipara widow fifteen years. *Clinical history.* For nine years increasing menorrhagia severe epigastric cramps for fourteen months intermenstrual hemorrhage. For several months offensive leucorrhoea. Back ache. Loss of flesh and strength. Profuse purulent leucorrhoea, containing necrotic material. Uterus size of four months' pregnancy but filled with firm, rounded tumor the size of golf-ball undergoing necrosis below. *Microscopic findings.* Uterus 3½ centimeters long 7½ inch and 7 anteroposteriorly anterior all greatly thickened by the new-growth, which almost obliterates upper part of terine cavity. Upper part of tumor gray color with reddish brown areas of hemorrhage friable deeply fissured presenting necrotic ragged surface to the uterine cavity. Lower portion ovoid in shape; yellowish-white of firm consistency. Fibrous smooth surface. *Microscopic findings.* Tumor largely composed of irregular masses of cells lying between the muscular and fibrous bundles. The cells are mainly polyhedral in shape but there are also numerous rounded and spindle-shaped cells. All have cell-defined nuclei, moderately rich in chromatin, and

HÆMANGIOMA CAVERNOSUM

REPORT OF A CASE

By WILLIAM E LOWER MD FACS CLEVELAND OHIO

CLASSIFICATION AND ETIOLOGY

IF one may judge from the literature published under the general head of *hemangioma* there is considerable confusion concerning the real nature of this condition. In the reported cases for example there are several instances in which tumors classified as hemangiomata apparently were really either angiomas or nevi. Nicholls classifies as hemangiomata those tumors consisting of arteries capillaries and veins which are supported and held together by connective tissue or by tissues homologous with it such as adipose and mucoid tissue. In his differentiation of all hemangiomata into three groups simple arteriole and cavernosum he includes in the latter class those in which there are large vascular spaces or sinuses lined with endothelium. With its reticular blood spaces the hemangioma cavernosum is similar in structure to the corpus cavernosum of the penis. The irregular spaces are filled with blood they communicate with each other and they are sur-

rounded with a retiform fibrous tissue which also contains elastic fibers the network varying in thickness in different parts of the tumor. The mass is fed by a single artery and discharges its blood into the dilated veins.

A hemangioma cavernosum is evidently the result of some anomaly in development the exact nature of which is unknown. Nicholls finds this growth in situations corresponding to the embryonic lines of fusion such as the facial or branchial clefts. Karsinsson defines the usual positions of hemangioma cavernosum as the anterior and lateral parts of the neck where it often extends along the whole of the neck from jaw to clavicle.

Fig. Case of hemangioma cavernosum baby four months old showing size and location of the tumor.

Fig. Case of hemangioma cavernosum baby four months old showing size and location of the tumor.

Fig. 3. Case of hæmangioma cavernosum, showing result after excision, also the line of incision.

or it may be limited to one part as to the submaxillary or the supraclavicular fossa. It may extend from the very front to the back of the neck, or from the base of the skull to the clavicle. In fact, cases are recorded in which the tumor has passed under the clavicle and has extended into the axilla, and others in which it has invaded the mediastinum after passing behind the sternum. Whatever its situation this growth has a tendency to ad here closely to the sheath of the great vessels especially to the jugular vein.

In Lexter Bevan it is stated that human goma cavernosum is partly expansive and partly infiltrating in character; it may be slow and continuous in growth or it may increase rapidly after a stationary period. Not infrequently an encapsulated hæman gloma is found which has ceased to grow. In most cases, however, the mass gradually infiltrates the neighboring tissues including both the cellular spaces and the muscles themselves. After thrombosis and cicatricial contraction of parts of the tumor the involu tion may be complete.

DIAGNOSIS

The peculiar color and form of this variety of hæmangioma practically assures the diag

nosis. Another distinguishing characteristic is the fact that the cyst may be decreased by pressure immediately assuming its original size and form when the pressure is removed. The tumor is bluish in color and increases in size when the patient coughs or cries. It is encapsulated and palpable and since it is fed by a large artery it pulsates. Morris thinks all cavernous hæmangiomata are pre sent at birth though they often are not noticed immediately.

TREATMENT

The usual treatment of a hæmangioma cavernosum is its complete extirpation al though Carl Beck has devised an ingenious method by which the masses of vessels are gradually transformed into connective tissue by a subcutaneous spiral ligature. In this manner the circulation is shut off within the tumor. This procedure is repeated until the tumor has been diminished to the smallest possible nodule of connective tissue and the healthy skin enlarged to the utmost. Then the hard connective masses are excised and the borders united in fine linear union. It is necessary to ligate the largest afferent vessels.

CLINICAL HISTORY OF CASE

The appearance and treatment of a typical case of hæmangioma cavernosum is well illustrated by the following history of a case of my own.

The patient, baby of four mo. this, was referred to me by Dr. Schmoldt and on January 2, 1906, was sent to Lakeside Hospital. The father was living and well; the patient being the only child of a second marriage. The mother had history of kidney trouble and pain in the back, but no dyspnea or swelling of the feet. The family history was negative for malignancy or heart disease.

The patient, full-term baby, was bottle fed, and had never been sick. Soon after birth the mother noticed a small lump about the size of a walnut just above the clavicle on the right side of the neck. This mass was quite soft and was the color of the surrounding tissue. Palpation was not painful. The tumor gradually increased in size until the child was three months of age when it began to assume a bluish tinge. Whenever the baby cried the mass appeared to increase in size but there was no accompanying pain. At the time the case first came under my observation, the mass had reached the size of a

Fig. 4. Case 1. Hemangioma cavernosum showing the shape of mass after excision.

Fig. 5. Case 1. Hemangioma cavernosum showing section through wall.

large lesion and occupied an area on the right side of the neck extending from beneath the scapula and clavicle almost up to the ear (Fig. 4). It was bluish in color and increased in size when the baby cried or was held up by its feet. On palpation it was found to be soft and seemed multilocular in character. Light did not penetrate the mass. On continued gentle pressure it decreased slightly in size and some pain was caused. The skin was freely movable over the tumor which was somewhat adherent to the underlying tissue, no definite pedicle being discerned. The roentgenogram showed a very definite outline of the tumor (Fig. 3).

Under nitrous oxid and oxygen anesthesia an incision was made around the base of the tumor with the idea that if complete removal became too hazardous it might still be possible to ligate or compress the vessels supplying it. By sharp dissection I was able to cut around the growth and finally to remove it intact. The cyst was in close proximity to the large vessels of the neck, extended behind and below the clavicle was in direct contact with the pleura its tip being behind the scapula. The blood supply apparently came from a branch of the subclavian artery. Hemostasis was secured by fine silk ligatures and the wound was closed with continuous sutures of No. 10 silk. The dressing were put on very loose so as not to interfere by pressure with the circulation in the flap. There was an immediate sharp rise in temperature but the patient made a complete and rapid recovery.

The pathological examination confirmed our diagnosis of hemangioma cavernosum. The tumor weighed 15 grams and measured six by five centimeters (Fig. 4). It was coarsely lobulated, reddish purple in color and fluctuant. The surface was covered by numerous small fat tabs. The mass was soft cystic thin walled and was apparently divided into numerous small and large communicating cavities. The contents of the mass consisted of co-

agulated clots of thin brownish chocolate colored fluid and some old broken down blood-clot. The inner lining was smooth glistening and membranous. In some of the smaller spaces there were present organizing blood clots adherent to the wall. The smaller and larger spaces were often connected by fine cord like structures resembling chorda tendinae. No very large or definite blood vessels were found entering or emerging from any of the spaces.

A macroscopic examination of a section through the wall (Fig. 5) showed a fibrous tissue framework in which were numerous fairly large thin walled endothelial lined spaces filled with blood. Many of the vessels had well-defined coats while others were simple spaces lined with endothelium. There was considerable lymphocytic and eosinophilic infiltration chiefly around these blood vessels. There was also considerable coarse brownish pigment scattered about chiefly intracellular. The walls of the large spaces consisted of a thick fibrous inner coat lined by endothelium in places and of an outer muscular coat. The histological appearance was that of greatly distended veins having well defined fibrous and muscular coats. The lesion was comparable with cystic hygroma the blood vessels instead of the lymphatic system being involved in this case. The diagnosis of the pathologist was congenital blood cyst or cavernous hemangioma.

AN OPERATION FOR THE RELIEF OF EPISPADIAS IN THE MALE¹

By J. DELLINGER BARNEY M.D. F.A.C.S. Boston

IN view of the well known difficulties encountered in dealing with epispadias in the male I wish to describe an operation for its relief which we have found to be simple and efficient.

There are certain definite indications for operation (1) to relieve urinary incontinence (2) to change the point of exit and the direction of the urinary stream and of the semen (3) to change the direction and length of the penis (4) to restore the penis to a more normal appearance.

As a result of the more or less complete urinary incontinence and of the point of exit of the urine at the base of the penis the skin of the suprapubic region is constantly macerated, inflamed and at times ulcerated. The position of the penis in relation to the abdominal wall is such that the stream of urine is directed almost vertically upward acting as a sort of spray against the pubes.

Furthermore the direction and small size of the penis make coitus difficult or impossible, while the point of exit of the semen at the penopubic junction makes impregnation

highly improbable. The restoration of the penis to as nearly normal a direction as possible is, therefore, much to be desired while an improvement in the appearance of the organ does much to eliminate that sense of shame and sensitiveness which so often harasses the victim of a malformation of the genitals.

Although a simple plastic operation such as is here described, cannot be expected to do away with urinary incontinence entirely, marked improvement often takes place, a feature already noted by Stettiner in an extensive survey of the literature. In babies and young children even when normal, there is little or no volition in the control of the vesical sphincter. But as the child grows older control is gradually gained and can often be developed to a remarkable degree by a system of muscle training aimed directly at the sphincter. I have used this successfully for a number of years in the case of the bladder in tabetics but it must be

Epispadias & Chel. Orth.
Boston M. & S. J. 10 Dec. 1914

Fig. 1. Diagram of penis. A Refreshed edge of pubic skin fold, B line of incision through glans to prolong urethral gutter to its end, C button-hole incision through prepuce, D refreshed edge of prepuce for suture to A.

Fig. 2. Diagram of plastic operation. A as in Fig. 1 ready to be sutured to D Fig. 1. The inner or mucous layers (straight edges) are approximated one to the other after which the outer layers (serrated edges) are united.

The outer (serrated edge) layer of the button-hole incision C Fig. 1 is then sutured to the inner or mucous layer (straight edge) B is the newly-formed portion of the urethra.

Fig. 3. Diagram of penis after operation, showing lines of suture at A, D and C. The entire urethra is now roofed over except the short portion formed by B at which point the urine now makes its escape.

Fig. 1. Epispadias before operation. Penis drawn down. The almost circular defect in the prepuce is clearly seen. The small columnar prepuce.

Fig. 2. Epispadias before operation. Penis drawn down. The urethral gutter is visible. The small prepuce is also shown.

remembered that in epispadias one is dealing with an imperfectly developed phancter muscle.

None the less such training is to be regarded as a highly essential post-operative measure and if the patient is old enough and intelligent enough to cooperate there is every prospect of success. It is also important that the patient should be kept under fairly regular observation. The vesical phancter must be not only brought to but maintained at the highest possible point of efficiency and this can be accomplished only by constant attention.

The technique of the operation is as follows:—
1. The urethral gutter already formed is carried out to the very end of the glands by dividing the structure longitudinally and to the proper depth as shown by the dotted line *B* in Fig. 1. In order to prevent its edges from again uniting the groove is kept constantly lined with gauze or better with rubber tissue until the mucosa has covered the raw surfaces.

The prepuce always voluminous (seen in profile in Fig. 4) is used to form a roof over the urethral gutter. To this end a transverse button hole incision (C Fig. 1) is made through it just below the frenum and extending laterally nearly to its edges. At the same time the lower edge of the prepuce is denuded by the removal of the narrow strip of skin *D* (Fig. 1) and a similar procedure is carried out on the fold of pubic skin which roots the urethra at the root of the penis (1 Fig. 1).

The plans is then drawn through the button hole, lit in the prepuce so that the denuded lower edge of the latter now comes well up on the penile shaft (*D* Fig. 1). It will also result that the glans is completely surrounded by the edges of the button hole incision (C Fig. 2). The newly formed portion of the urethra is indicated at *B* (Fig. 2).

4. The plastic is now completed by suture of the cut edges—4 (Fig. 1) approximated to *D* (Fig. 2) the inner layers (represented by a straight line) being united one to the other with No. 00 chromic catgut, the outer layer (represented by serrated edges) being united in the same manner but with fine silk or Pagenstecher linen. The unusual redundancy of the prepuce allows this union to be made without tension. The edges of the button hole (C Fig. 2) are then sutured to one another (straight edge to serrated edge in the diagram) with silk or Pagenstecher linen.

The completed sutures have the appearance and position indicated in the diagram (Fig. 3, 4*D* and *C*) while the new portion of the urethra, the new meatus is seen at *B*. The rest of the urethra is completely roofed by the plastic flap which can be readily retracted like a normal prepuce.

The more or less vertical position assumed by the penis in epispadias is to be attributed to its unusually short suspensory ligament. While in my experience the plastic operation already described has been sufficient to restore

Fig. 6 Roentgenogram of the symphysis showing separation of the pubic bones.

the penis to an essentially normal position other writers (Duplay Stettiner) have spoken of the desirability of cross-cutting the suspensory ligament and suturing it longitudinally to accomplish this purpose.

While the entire operation can be done at one sitting it has seemed desirable to do Part I as a preliminary step allowing two or three weeks to elapse before performing the more extensive plastic operation. This will allow the newly formed portion of the urethra to become thoroughly covered with mucosa. Furthermore every chance should be given the wounds to heal *per primam*. The bladder should therefore be constantly drained by an inlying catheter of the self-retaining type or in the opinion of some surgeons, by a catheter brought out through a small perineal incision. The latter method however has the objection that in order to do this the corpora cavernosa, which in epispadias, underlie the corpus spongiosum and the urethra must be separated or incised in their perineal portion, a procedure which is not easy to accomplish and which may be accompanied by considerable bleeding.

Yet in spite of every care it seems to be the general experience as it has been mine, that the plastic flaps will fail to unite at one or more points. These fistulae are a source of annoyance, but can be easily closed by suture at a subsequent time.

In adults the entire operation can be done with novocaine anesthesia. In infants and young children full ether anesthesia must be given.

The following case illustrates well the essential points of epispadias and of the operation described.

Fig. 5 Appearance of the penis three years after operation. The prepuce is small and completely retracted and the direction of the penis is normal.

A 7 year 10 month old boy (February 4, 1913). Family history no other congenital defect. Past history unimportant. Present illness: Malformation of penis with urinary incontinence since birth. The patient wet the bed almost every night and his clothes are wet all day. Sometimes he is aware that urine is escaping but usually is not. At times he goes for two hours without urinating. During erection the penis is held loose to the abdominal wall. It has never itched or itched.

Physical examination: Healthy looking intelligent boy with no demonstrable abnormalities congenital or acquired except of the penis. Both testes normal size on examination and sensation, and are fully descended. There is a typical and complete epispadias, but the malformation cannot be fully appreciated till the penis is drawn down by the prepuce (Fig. 5). The nearly vertical position assumed by the penis at small size and its voluminous and prolike prepuce has already been shown in Fig. 4. A roentgenogram of the symphysis (Fig. 6) shows very considerable separation of the pubic bones (a constant feature of all such cases). The pubic skin is red thickened and covered with pustules (Fig. 5). The stream of urine forms a sort of spray

against the pubes but when the penis is pulled downward the stream can be fairly well directed into a basin. When the boy coughs or makes any muscular effort which fixes the diaphragm urine is seen to gush from the urethra. Urine normal. Training of the vesical sphincter started and continued daily with good response.

February 21. Can hold urine for four hours. Confinement of pubic skin is greatly improved since it has been kept dry. Under ether the urethral gutter was extended to the end of the glans by a longitudinal incision (B Figs. 1 and 2). The edges of the wound were separated by a strip of rubber tissue. Self retaining catheter to bladder was kept in place for 5 days. March 2. Training of sphincter has been continued. The patient can now hold urine in the day several hours and often passes nearly a pint at a time. He keeps dry all night by being aroused once or twice to urinate. March 3. Under ether a plastic was done on the prepuce (Figs. 1, 2 and 3) and a self retaining catheter inserted. There was good union of the skin edges except for a small area at junction of 4 and 5 through which urine leaks. March 13. Discharged but is to return for closure of the fistula.

October 6, 1913. Re-entry. There is no frequency of urination. He has good control day and night. The penis hangs in a nearly normal direction. The urethra now runs to the end of the glans and the newly formed part is lined with mucosa. The pubic skin is healthy. October 21. —

Under ether the small fistula in plastic was closed by suture. Self retaining catheter inserted. October 30. Discharged. To return for observation.

August 1914 seen in Out Patient Department. His condition is greatly improved. The preputial flap now covers the entire urethra except at its distal extremity. There are no fistulae. A stream of urine issues from the end of the penis so that the patient can stand at a urinal without wetting his clothes. He says he does not leak at night and can retain urine for several hours. Urine normal.

November 1914 the patient writes that he has no trouble with urination.

January 1, 1916. Patient was seen at hospital. His general condition is good. Urinates 5 or 6 times a day, gets up sometimes once at night. There is considerable incontinence by day but never wet bed at night. He passes a good stream and directs it well. Sex function evidently normal but has no emissions and has not attempted coitus. Plastic looks well and prepuce covers nearly whole of glans. Rectal examination shows prostate small but normal in contour. Vesicles not felt.

The patient has had no training in the control of the sphincter since he left the hospital. From my experience in this case and in others I do not hesitate to say that if exercises for the education of the sphincter could be undertaken with fair regularity and frequency the diurnal incontinence of which the patient now complains could be greatly improved or even entirely done away with.

ECTOPIA TESTIS TRANSVERSA WITH INFANTILE UTERUS

By ARTHUR E. HERTZLER, M.D., KANSAS CITY, MISSOURI

THE condition in which both testes find their way into one scrotal pouch was designated by von Lenhossak as *ectopia testis transversa*. But one testis of course is ectopic. The other one under goes a normal descent and is accompanied by its fellow which instead of descending into its own side crosses over to the opposite side and accompanies or follows its normal fellow.

The cause of this transposition is found in some early developmental disturbance. The nature and cause of this disturbance furnishes the most interesting problem in this lesion. Though rare some 13 cases having been described enough data is available not only to make possible some conclusions relative to

the clinical treatment of this condition but presents data of importance in the whole problem of developmental anomalies of the genito-urinary system.

The specimen which I have to report made its appearance in the literature in 1907. Dr. Halstead at that time operated on the patient for hernia and noted the testicular transposition. He reported it and presented some comments on the origin of this condition. His report is as follows:

D. C. B. American single age 42 entered the Cook County Hospital in January 1904.

History. Patient has had a left inguinal hernia of large size since early childhood. Of late this hernia has increased in size until now the tumor measures eight inches from the pubic p. n. to

Fig. Below are the testes showing the coverings detached to the right. Above the testes is the infantile uterus on either side of which are the epididymides.

the lower limit of the scrotum. Two months ago the hernia which had previously been reducible became irreducible and painful. In addition to the hernia he has for several years been suffering from severe hemorrhoidal disease. His object in entering the hospital was to secure by operative treatment relief from both diseases.

Exam. athen. On entrance, examination showed a well developed middle aged man. Nothing worthy of note was found except large left inguinal hernia distending the scrotum to the size of child's head. Rectal examination disclosed the presence of large mass of fecal material protruding from the anus.

Operation. In clinic January 7, 1904, assisted by Dr. R. H. Renhouse surgeon. After the usual preparation, an incision 3½ in. in length was made over the hernia exposing the sac. The sac was opened and the adherent loops of small intestine constituting the content of the hernial sac were after being freed returned to the abdominal cavity. In separating the sac it was noted that the spermatic cord was of unusual size. While freeing the sac from the cord the remaining contents of the left side of the scrotum were brought into the incision. This was found to be the structure which in superficial examination closely resembled a uterus with

the tubes and ovaries attached. Upon closer inspection it was found that the central body representing the uterus, consisted of a fusion of the epididymides of the two testicles. The testicles were not closely adherent to the heads of the fused epididymides, but swung free from the attached lower half of each with the entire mass dislocated forward into the operative wound. The fused heads of the epididymides occupied position behind and somewhat below the testicles. The testicles were enclosed in common tunica vaginalis. The vasa deferentia could be traced separately from the globus minor upward behind the fused epididymides to a short distance above the globus major where they approached each other and apparently became fused into one cord close to the internal ring. There were two spermatic arteries and two sets of veins (these were of large size and, with the large vasa deferentia, of unusual amount of fatty tissue greatly increased the size of the cord). The testicles were small and in size were decidedly out of proportion to the large mass representing the fused epididymides.

Examination showed the right side of the scrotum to be empty. The right internal ring was closed.

This patient reentered medical records by consulting Dr. A. E. Spalding of Luverne, Minnesota, November 1, 1913. The following is abstracted from Dr. Spalding's report:

At that time the patient presented enlarged scrotum containing several ounces of fluid which was removed by needle. He again presented himself for examination October 6, 1904. At this time the scrotum was as large as two fists and was causing much pain. On October 29, 1904, the scrotum was removed. The mass was exposed through a long inguino-scrotal incision, the cord isolated and tied. This being done, second cord, larger than the first, was exposed. This part of the cord cut like cartilage and showed a dense-walled tubelike structure between the two testicles. When the mass was severed, coffee-colored fluid escaped.

The specimen was sent to Dr. L. W. Littig of Davenport, Iowa. It was through the kindness of Dr. Littig that I was enabled to study the specimen.

The specimen presented a bilobed mass surrounded by thick capsule and tubercles above in a long pedunculated process. The lower portion of the mass is made up of two lobules which are testicular in form, slightly smaller than normal testicle and when arranged parallel with each other and with the central axis of the mass they are easily recognized as testicles. Situated posterior to these bodies are corrugated tubules enclosed in a fibrous sheath, free below but united above. These are readily recognized as epididymides after the fibrous tissue

is dissected off. Leading from the upper poles of these are wound cords, obviously vasa deferentia. These pass upward over an elongated pyriform mass. This mass is unattached to either epididymis or testis.

This body forms the most interesting feature of the specimen. It begins just above the upper poles of the testes as an elongated pyriform body 2 centimeters in its transverse diameter and 1 centimeter in its anteroposterior diameter. It gradually narrows to 6 millimeters at its termination where it is tubular (Fig. 1). Its termination shows that it was severed during the operation and that the entire specimen was not obtained. When opened in a longitudinal direction it shows a triangular lumen 1 centimeter wide below gradually narrowing above. The anteroposterior diameter is only a millimeter or two. The cavity is lined by a smooth mucous membrane. The cut surface of the wall of this mass is a uniformly deep red in color.

The walls of this body are formed of non striated muscle fibers. The lining is a mucous membrane made up of a low columnar epithelium with simple tubular glands lined with cuboidal or low columnar cells. In short the structure is that of an elongated infantile uterus.

The testicles and appendages present an entirely normal structure.

The interest in this specimen lies less in the transposition of the testis rare as this condition is than in the presence of the small uterus a condition noted in the literature in but one other instance. Case 7, reported below.

Various theories of the origin of this condition have been advanced and these are presented in conjunction with the case reports.

The following brief abstracts represent all the cases that I have been able to collect from the literature. In some of the cases reported a careful dissection of the parts was not made and therefore a detailed description of the condition could not be given.

CASE 1 Reported by v. Lenhossak.¹ This specimen was removed at autopsy by the author's father in 1845. The patient was a man of 35. Both testicles were of normal size and contour and both lay in the bottom of the scrotum on the left side the right however being 2.5 centimeters higher than the left. The vasa were differentiated a few centimeters from their origin but approached each other and became so closely bound together by connective tissue that one might have thought that they were one. Thus bound together they passed through the inguinal canal to the abdomen and at the upper end of the prostate they again became divided, the left entering a normal seminal vesicle on the left

side the right going by a sharp angle to the right to enter a normal seminal vesicle on the right side.

The author suggests that this condition was probably due to either a faulty development of the right testicle on the left side or to the action of certain forces which carried it to the opposite side. In favor of the view that the testicle developed on the wrong side are the various examples of a similar condition in the kidney. A double kidney with two ureters has been reported by Stocquart.² This is an example of the transposition of an antimeric

CASE 2 Reported by Jordan

Patient age 8 had hypospadias in the third degree. The right side of the scrotum was small being marked only by a small prominence. The left side was about the size of a goose egg. Upon opening the processus vaginalis at operation two testicle like bodies were noted in the scrotum from which two cords extended to the rings. Three months later the hernia recurred and a new hernia operation was performed the total contents of the scrotum being removed. There was a single vas for both testicles which was large and out of proportion to the age of the patient. The thickness of its walls increased from above downward and below it ended in an ampulla which was broad, particularly in its transverse diameter. The vasa arose from the corners of this and the epididymus was much enlarged and fibrous. The right vas was normal in size and led to the bursa inguinalis to a lobule of fat. This vas had no epididymis but some epididymal canals were present instead of the epididymus. No testicle was present on this side.

The cause of this condition is to be found in an early fusion of the wolffian ducts in that part lying nearest to the sinus urogenitalis while that portion lying nearest to the testicle remained free. They fused abnormally in the same manner that the muellian ducts normally do. The thought must be entertained, however that well-developed muellian ducts may have played a rôle. These changes certainly take place before the descensus (Examined by Kjaatsch.)

CASE 3 Reported by Linser

Patient a boy age 2 1/2 years. Both testicles lay in a serous cyst in a right-sided inguinal hernia. The testicles lay side by side were of equal size and the epididymides were well formed. The vasa were separated and I found to extend to the base of the bladder but they could not be traced with certainty to the seminal vesicles.

The author believes that there was a double anlage on the right side and that the left had either atrophied or an anlage had never formed.

CASE 4 Reported by Christopherson

Patient age 22 came to the hospital with a swelling in the right inguinal region, extending from the external abdominal ring into the scrotum.

¹Archiv. Arch. f. path. Anat., etc., Berl., 579, 1877, p. 44.

²Deutsch. med. Wochenschr., 1893, xix, 5, 5.

Berlin. Klin. Woch., 1900, xxix, 15.

Brit. M. J., 1900, 4, 3, 2.

Upon opening the right inguinal canal a jelly-like mass was found extending through the canal and into the scrotum. This mass was about the thickness of three fingers and unencapsulated. There were two spermatic cords coming through this same canal, one of which, traced downwards, ended in the epididymis of the descended and very much enlarged testicle. The other cord ended in frayed out ends which were lost in the embryonic jelly-like tissue at the top of the scrotum. This cord lay to the inner side and behind the other cord, both cords felt and looked natural and were easily separable from each other. There was no cavity in the left side of the scrotum nor was there any sign of a descended processus vaginalis.

The author thinks that the fully developed and descended testicle was the left because the prostate was well developed on the left side but seemed absent on the right.

CASE 5. Reported by Berg.

Patient, age 13 had had a left sided rupture since birth. The right side of the scrotum was poorly developed and there was a large scrotal hernia on the left side. At the bottom of the left half of the scrotum was a fair-sized testicle, its free concave border pointing downward. From its right pole a normal-sized cord passed upward to near the root of the penis, then curved sharply to the left and was lost near the opening of the hernial ring. When the patient coughed slightly a smaller testicle could be felt at the left external ring which could be pulled down into the scrotum. A cord passed from it into the hernial ring. The right external ring was very small and no cord could be felt to enter it. At operation both testicles and cords were found to be intimately connected with the hernial sac on the left side. Both cords passed through the left inguinal canal. The upper testicle was the smaller and its cord had a distinct mesentery. This cord passed up into the left inguinal canal, through the internal ring, across the space of Retzius to the right inguinal region where it descended to the pelvis. The larger testicle lay in the bottom of the sac its cord passed up into the left inguinal canal and descended on the left side of the bladder to the pelvis. The right internal ring was exposed and found to be closed. The scrotum showed no evidence of division into two compartments. Both cords and testicles were treated as one and the radical hernia operation completed in the usual manner.

CASE 6 Reported by Romanowski and Winter.

Patient, age 61 died of pneumonia. On section there was noted a fold which extended from the foramen inguinale laterale across the anterior wall of the pelvis, behind the upper surface of the bladder, to the left of the foramen inguinale laterale where it disappeared. The plica differentialis was absent on the right side but was well developed on the left.

The right side of the scrotum was empty. The external ring on this side was very small and out of it came a small connective tissue band which ended like a ligamentum teres. On the left side the external ring was much enlarged and the cord thickened. Upon opening the sac two testicles were noted the right situated slightly above the left which was small and deformed. The right was larger and less deformed but had the epididymis on its summit, from the center of which the vas arose. The processus vaginalis was open to near the external ring but from this point on it was completely obliterated. The left was run in its normal course to the base of the bladder and into the seminal vesicle. The right was however traced the bladder obliquely over to the right side its course corresponding to the plica differentialis already noted. The right spermatic vessels arose at the normal place and described a normal course to the linea terminalis, from which point they followed the previously described peritoneal fold from right to left to the left ring. A gubernaculum Hunteri could be traced from the external ring through the canal and across the summit of the bladder in company with the vessels.

The author thinks that there must have been some normal connection between the two testicles which made it possible for the left to take the right with it in its descent.

CASE 7 Reported by Cornil and Brouard.

Patient, age 9, had a uterus in the tunica vaginalis which was united with two testicles. This uterus measured 9.3 centimeters in length, the body being larger than the cervix and the walls somewhat thickened. On one side the tube emerged normally but became adherent to its extremity to the testicle. On the other side the cornu of the uterus was united to the testicle by a fibrous mass. On section of the uterus the walls were found to be thick, the mucosa congested and presented transverse plications separated by ridges millimeters in diameter.

Histological examination. (1) Uterus. On section it was found that the transverse plications represented numerous glands and tubes lined by a tall epithelium. Between the depressions there was thicker rich in small cells and contained fewer glands. Toward the body cavity the mucosa was more papillary. These papules were formed by inflammatory tissue with hypertrophied glands lined with tall epithelium. (2) Testicles. Sections made at the point where the tube attached showed a normal tube and epididymis united by connective tissue. The testicles were normal and spermatogenesis very active. The fibrous band going out from the opposite cornu showed likewise tube and epididymis united by fibrous tissue. There was not the vestige of an ovary. Section of a cornu showed a tube in its interstitial tissue.

This condition was due to a diversion in development consisting of an increased development of the uterus due to the fusion of the müllerian ducts.

The wolffian and muellerian ducts must have developed side by side because they were united by a common connective-tissue envelope.

CASE 8. Reported by de Castelli

Patient age 23 came into the hospital to be operated on for a right sided hernia. The hernia was congenital and had gradually increased in size and become very painful. The left side of the scrotum was found to be empty. The right side contained two testicle like bodies, which were painful on pressure. From these came two cords which disappeared into the inguinal ring. At operation the cord was exposed accompanied by the artery and veins. Within the canal was a testicle and from this ran a fibromuscular cord connecting it with a second testicle in the scrotum.

CASE 9. Reported by Bottaro³

Patient age 13 had no history in his family of hernia or testicular anomalies. An oblong body about the size of a walnut was noted in the right inguinal region. This was somewhat sensitive and was reducible but a part of the mass remained in the inguinal canal. The left inguinal canal was found to be free and a diagnosis of abdominal retention of the left testicle was made. At operation two cords and two vaginal processes were noted extending down the inguinal canal one going to a testicle in the scrotum the other to one in the inguinal canal.

CASE 10. Reported by Lowe

Patient age 3 was brought to the hospital to be operated on for a left inguinoscrotal hernia. The hernia appeared to be congenital but no reliable history was obtainable. When the structures in the canal were being isolated from the sac two cords were discovered and these were traced to two testicles lying in the scrotum. They were each the size of a normal single testicle. After the sac was ligatured the testicles were returned to the scrotum. After this reduction the scrotum appeared highly

unsymmetrical the left side being very full and the right quite empty.

CASE 11. Reported by Marsh⁴

Patient age 3 was operated on for a large congenital hernia of the left side. Upon exposure of the ring two cords were found passing down to two testicles which were enclosed in one tunica vaginalis. The child died of cholera some 36 hours later and at autopsy a careful dissection of the part was made. There was only one vesicula seminalis situated on the left side and it was considerably larger than normal. In connection with it was a very large vas as thick as an ordinary drawing pencil which took the normal course as far as half an inch from the internal ring where it divided into two of equal size which passed down the inguinal canal into the scrotum to the two testes. The right spermatic artery crossed over the middle line about three inches below the umbilicus and meeting its fellow of the opposite just inside the internal ring joined with it to form a single trunk. This trunk divided again before reaching the external ring the two vessels being distributed to the testes in the ordinary manner.

CASE 12. Van der Horn van den Bos⁵ presented a case in which incidentally in the course of a hernia operation he found that both testicles had passed through the right inguinal canal into the right side of the scrotum.

CASE 13. Reported by Widhalm⁶

Patient age 4 was married and had three children. The right testicle was somewhat atrophic. He had had a hernia on the left side since childhood. The sac was filled with omentum and there was marked cyst formation. There was a hydrocele about the size of a fist on the cord and lower down a smaller cyst which contained two testicles of equal size. Behind they were united by a band form epididymis and off from this came two independent vasa.

PRIMARY CHORIO-EPITHELIOMA OF FALLOPIAN TUBE FOLLOWING RUPTURED ECTOPIC GESTATION

By HARRY J. HARTZ, M.D. PHILADELPHIA
 Demonstrator of Gynecological Pathology Jefferson Medical College

P RIMARY chorio-epithelioma of the fallopian tube is of comparatively frequent occurrence when we take into consideration that tubal gestation forms but a small proportion of all uterine pregnancies. Of approximately 300 cases of chorio-epithelioma that occurred up to 1905 the primary tubal variety comprised about 3.5 per cent of the total number.

In 1905 Risel (1) made an exhaustive study of primary chorio-epithelioma of the tube and collected 11 cases in the literature which he reviewed in great detail. He reports an interesting case of a woman 35 years of age in whom apparently a chorio-epithelioma followed a tubal abortion.

The woman had had three normal labors, the youngest child was five years of age. For about four months after the onset of vaginal bleeding a bloody tumor measuring sixty centimeters, of left tubo-ovarian region was removed. Six weeks after operation symptoms of intestinal obstruction developed and one month following the onset of symptoms, operation disclosed an inoperable bloody tumor in the pelvis between the uterus and rectum. Shortly after operation, the woman died, seven months elapsing between the advent of symptoms and fatal termination. Post-mortem examination showed the genitalia and uterus free from the growth but numerous metastases were found in the liver and both lungs.

In addition to the above 11 cases recorded by Risel, Leipmann (2) adds 7 more making a total of 18 cases of primary chorio-epithelioma of the tube up to the year 1914. In Rosner's (3) case reported in 1912 the tumor attained the size of a man's head. In one of the two cases reported by Davidsohn the tumor developed in the stump of the tube which had been removed for a ruptured ectopic gestation. Lefquist's case is also quite interesting.

In 1906 the patient was operated upon for tubal pregnancy. The tube was cleared of all gestation products but was not excised. Two years later a pregnancy in the same tube recurred, and at opera-

tion the tube was removed. Pathological examination revealed an early development of a primary chorio-epithelioma of the tube.

In the majority of the cases reported recurrence was the rule the patient succumbing to the disease but in a comparatively short time after onset of symptoms.

The case that I am reporting was operated upon in St. Joseph's Hospital by Dr. P. B. Bland and was referred to him by Dr. Koplin of Trenton New Jersey. The following history was obtained.

A S. 34 years of age, white, married. She began to menstruate at 13 years, was regular and normal. The patient was married for twenty years had six normal pregnancies and four abortions. The last pregnancy terminated in abortion four months prior to the onset of symptoms. Five weeks before the patient complained of vaginal bleeding accompanied by severe cramp-like pains in the lower abdomen. A diagnosis of ectopic gestation was made and operation devised. The operation was performed in December 9, 1914. The abdomen was opened. The right tube showed pregnancy with rupture. The uterus was enlarged and soft and was the size of pregnancy of about six weeks. The tube and ovary were removed and the abdomen was closed. The pathological report of the specimen is as follows.

The mass consists of tube and ovary and gestation sac in collapsed condition. The tube measures 5 centimeters in length and 4 centimeters in diameter at its widest portion which is situated near the fimbriated end. The lumen is filled with clotted blood and the walls of the tube are considerably thickened. Between the lower border of the tube and ovary there is an irregularly shaped sac in collapsed condition measuring 5 centimeters in diameter and lined by a shaggy dark red membrane. Adherent to these shaggy villous-like projections are masses of clotted blood. Under the microscope sections of the tubal wall show an attached placenta. At points the chorionic epithelium extends into the thin wall of the tube for some distance and there are masses of these cells in the lumina of some of the veins. This involvement of the wall of the tube is more extensive than usual and justifies the term chorio-epithelioma.

Diagnosis. Primary chorio-epithelioma of tube following ruptured tubal gestation.

Two years after operation the patient is in the

st health. Her menses are normal, lasting three or four days. Her work is arduous assisting her husband in a grocery store from early morning until late at night besides which she attends to her regular household duties and takes care of her children and with all this hard work she says she has never felt better in her life.

Leipmann strongly emphasizes the fact that sharp differentiation should be made between primary chorio-epithelioma of the tube and the so-called ectopic chorio-epithelioma. The term ectopic chorio-epithelioma should be reserved for only those cases that designate the location of the primary growth in other structures and away from the ovumidus or placental site and entreats that it is incorrect to apply the term to primary tubal tumors that originate at the placental site. Metastatic or secondary growths occur from the tubal growth just as readily as they do in uterine variety. But also after a tubal pregnancy an ectopic chorio-epithelioma of primary growth remote from the tubal placental site has been described.

Primary chorio-epitheliomatous tumors remote from the placental site of the uterus and fallopian tubes have been observed in 21 cases by Findley. In no instance was it possible to trace a direct anatomical connection between the placental site and the primary tumor. The tumors arose during the course of pregnancy at varying periods after the completion of normal pregnancy and following complete and incomplete abortions. In nearly all cases it has been possible to trace a direct clinical relation between the pregnancy and the tumor formation. The vagina is most often the seat of secondary invasion of metastases in cases of primary chorio-epithelioma of the placental site but it is also true that it is the most frequent site of a primary growth. Findley reported 14 such instances in the 21 cases collected by him. The interval between the last known pregnancy and the development of a chorio-epithelioma varies considerably. It usually

Fig 1. Primary chorio-epithelioma of fallopian tube following ruptured tubal gestation. A. Uterine neoplastic cells in lumen of blood vessel. B. Tubal lumen. C. Perivascular small round cell infiltration.

occurs shortly after the termination of the pregnancy or may be delayed several years after the last labor or abortion. Recently Outerbridge (6) reported a case of a primary chorio-epithelioma of the vagina that developed eight years after the last known pregnancy. In one of the three cases of chorio-epithelioma of the uterus that I exhibited before the Pathological Society of Philadelphia last year the tumor developed at the placental site in the uterus six years after the last known pregnancy. The onset of symptoms in this patient developed three years after the menopause had occurred.

CHONDROMA OF THE PELVIS¹

By J. HUBER WAGNER, M.D. PITTSBURGH
Assistant in Clinical Pathology

NUMEROUS articles have been written upon true chondroma and other forms of cartilaginous tumors arising from various parts of the body. These tumors whether enchondroma, echondroma, osteochondroma, chondrosarcoma, or osteochondrosarcoma were, by most authors and especially those of the earlier times, classified as enchondroma. Since 1836 when Jean Muller gave the first complete description of enchondroma, until the present day a hundred or more articles upon the subject are readily found in the literature. Most of these articles appeared in the French and German literature before 1890. Since then relatively few reports have appeared and only a few of them, dealing mostly with the report of cases, in the English. In this paper I have attempted to summarize the work of others as well as give a description of three cases of enchondroma of the pelvis coming under our observation.

Chondromata are tumors composed of cartilage-cells with a varying amount of matrix and connective tissue stroma. These tumors may be composed of any of the three types of cartilage, hyaline, elastic, or reticular or may be composed of any two or all three types with variable proportions of each. However the tumor most frequently met with is that of the hyaline variety. In the latter there is an attempt to reproduce the true hyaline cartilage, with relatively few cells scattered sparsely throughout a homogeneous matrix.

Classifying chondromata according to their manner of origin they are spoken of as echondromata or enchondromata. Echondromata are outgrowths of cartilage occurring in regions where cartilage is normally present, as in the region of a joint, the larynx or trachea. Such a tumor results through a process of hyperplasia or overgrowth of cartilage. Echondromata are homoplastic. The enchondromata on the other hand are masses of cartilage or cartilaginous tumors having no

connection with areas of normal cartilage formation. These are considered under the heteroplastic group and develop where cartilage is not normally found.

In the gross these tumors vary considerably in shape and size. They are as a rule, irregularly globular and range from the size of a hazelnut to a mass 100 centimeters in circumference. They may be single or multiple. As a rule and especially those which attain a large size present a lobulated surface and are attached to the parent tissue in a sessile manner. They are surrounded by a capsule of fibrous connective tissue which sends trabeculae into the tumor dividing it into many lobules of variable size. These trabeculae carry nutrient blood and lymph vessels. In color these tumors vary from white to bluish gray.

On section, the cut surface presents a bluish ground glass appearance in which white bands of connective tissue divide the tumor into various sized lobes. In consistence the enchondroma is elastic, but this may vary from a soft and gummy character to bony hardness.

Degeneration of these tumors due to the limited supply of nourishment of those portions of the lobules most removed from the trabeculae which carry the blood and lymphatic supply is quite frequent. The degeneration may be myxomatous, calcareous or fatty and in frequency occurs in the order named. Occasionally a well-defined mass may undergo myxomatous degeneration leading to the development of a true cyst, or the whole tumor may be composed of a myxomatous matrix in which very few cartilage-cells are seen, a myxochondroma. Some specimens show the deposition of calcium salts in the matrix with a shrinking of the cartilage-cells giving rise to a type of calcareous degeneration but without bone formation. Fatty degeneration is described by some authors as an overabundance of fat droplets in the cellular cytoplasm, where it is normally present.

Degeneration is more likely to occur in those tumors of the homoplastic group or echonchondromata where the trabeculae are not so abundant and where there is less tendency to form lobules.

The pelvis in view of its embryological development and numerous centers of ossification, its articulation and relation to other parts is a not uncommon site of chondromata and has many locations from which they may arise. These are (1) from cartilage at the symphysis pubis (2) from the cartilage of the ischiosacral synchondrosis (3) from the cartilaginous disc at the sacrovertebral articulation and (4) from the cartilage of the acetabulum. The tumors arising from the above named places are of the enchondroma group. However they may also arise from cell rests which may be located at (1) the junction of the ascending ramus of the ischium and the descending ramus of the pubis (2) the junction of the acetabulum and the ilium ischium or os pubis (3) any portion of the pelvic bones where connective tissue exists or (4) the tumor may arise by extension of growth from the surrounding parts. These are of the nature of enchondromata.

Clark reported one case of chondroma of the pelvis occurring in a middle aged woman. This was first observed as a tumor above the hip and in the presence of other signs a diagnosis of medullary cancer of bone was made. The patient became rapidly emaciated anæmic and died. At autopsy all of the os innominatum was involved in a tumor mass. The tumor measured $8\frac{1}{2} \times 9$ inches filling the pelvis and displacing the rectum, vagina and bladder. Microscopic examination showed the tumor to be entirely composed of cartilage and its malignancy was due to its position.

An enchondroma of the pelvis developing at the site of injury was described by Potter. The patient was a female 37 years old who gave a history of a fall ten months previously and two days before confinement. In falling she struck her buttocks on a stone floor. The injured area was quite painful and tender for a few months. Five months after the injury she noticed a small hard swelling on

the right buttock. The mass enlarged and grew along the ascending ramus of the ischium and descending ramus of the pubis reaching the size of a six months foetal head. It filled the pelvic outlet causing difficult urination and defecation and preventing intercourse. At operation the tumor had an irregular surface and was covered by a fibrous capsule. Microscopic examination showed it to be composed of a fibrillated cartilage frequently showing several cartilage-cells in single lacunae. Many areas of calcareous degeneration were present in the tumor.

Several other similar cases with a history of trauma at the site of tumor formation have been described by Halthouse and others. In his researches Wartmann described eight enchondromata two from the pelvis four from the hand one from the lung and one from the parotid gland. He has studied some five thousand sections of these tumors with the following conclusions. He confirms the opinion of Virchow who indicated that enchondromata arise from connective tissue. He also claims that by a process of metaplasia the endothelium of lymph and blood vessels may give rise to enchondromata and further that many chondromata arise from cartilaginous emboli within the blood vessels.

The following are three cases of enchondromata of the pelvis which have come under our observation. The first two originated in the pelvic bones while the last had its origin in the femur and by metastasis extended to the pelvis.

CASE 1. Mr. E. H. K. age 38 years. Occupation, farmer (white). He has always had good health. Two years previously the patient received a sharp injury by being thrown on an iron rod. It did not trouble him much at the time, but later he noticed a small growth at site of injury.

On examination there was found on the inside of the left thigh and below the perineum a hard immovable growth about the size of a man's fist adherent to bone. The soft tissues over it were not involved. The glands were not enlarged. He was not inconvenienced in walking. There was slight pain which radiated toward the knee. There was no castration nor loss of weight. His general condition was good.

An operation was undertaken under general anesthesia. An incision was made along the inner side of the thigh transverse to the tumor. The tumor which was adherent to the fascia and arose from

the ascending ramus was chiseled away from the bone and some of the tissue in the neighborhood was removed. Recovery was good. The patient left the hospital 4 days after entrance and thirty-nine days after the operation.

Pathological examination. This tumor was a large mass about the size and shape of a man's fist. It measured $0 \times 7.5 \times 6.5$ centimeters. The surface was very irregular and nodular. It was composed of nodules varying in size from pin head to a marble. The tumor was covered by a capsule of dense connective tissue of a glistening character. Scattered diffusely over the tumor mass were small lobules of yellow fat. These were bound to the fibrous tissue capsule. Over about one-fourth of the surface the capsule was missing. Here the tumor had been separated from its attachment. This part was very rough and had many fibrous tags hanging to the surface. In many places it had the appearance of the pulp of an apple and was finely granular. This cut portion was studded with fine chalk like areas varying in size from pin head to a large pea or bean. These areas were very irregular in outline and of a calcareous nature.

On cutting through the tumor it was found to be composed of many distinct nodular masses of cartilage. Each mass was definitely outlined but was united to the neighboring lobules by dense fibrous tissue. The cut surface was of bluish gray color and had a finely granular or frosted appearance. In the center of several of these there were irregular chalky masses of calcification. Throughout the tumor there were thick strands of dense white fibrous tissue.

Microscopic sections of the tumor showed it to be mainly composed of cartilage and fibrous tissue. The latter save for the main trabeculae as small in amount and passed through the mass in all directions, dividing it into small lobules. This connective tissue stroma was loosely arranged and contained relatively small number of nuclei.

In some parts of the sections the lobules of cartilage were mainly composed of a clear hyaline matrix in which the cells were sparse. The cytoplasm of the cells was contracted leaving almost vacant lacunae save for the centrally placed nucleus. Again in other places the cells were more abundant and the matrix less in amount. This did not have the appearance of mature hyaline cartilage but had a streaked appearance due to prominent fibers in the matrix. Here the cartilage was not arranged in the well-defined lobules, but had an irregular architecture with ill-defined borders. At times it was difficult to differentiate true cartilage-cells from the fibrous connective tissue cells of the trabeculae.

At the border of the sections and adjoining the fibrous stroma, the cartilage-cells were lying in meshes of collagen fibers of the connective tissue but as one advanced from the fibrous trabeculae the cartilage-cells took on a more mature appearance and the collagen fibers became fewer in number gradually disappearing from the hyaline

matrix. The cell walls were very indistinct and could not always be made out. This was particularly true where the cartilage was more mature. In other parts of the specimen, as many as ten cartilage-cells were surrounded by a single indented capsule. **Diagnosis** Chondroma of the ischium.

CASE. Mr. J. B. age 5 years. Occupation, carpenter (negro). Patient had been in good health until 8 years ago (34 years) when he had typhoid fever. He made a good recovery and was perfectly well till five years ago (47 years) when he had trouble with his bowels and was compelled to use purgatives. Gradually but slowly constipation became more marked. Two years ago he had frequency of micturition, associated with some pelvic pain. Gradually but slowly his condition became worse. Six months ago he noticed a hard firm enlargement above spine of the left pubic bone. Being a carpenter he attributed the development of the mass to injury occasioned by the use of a saw. This tumor gradually became larger. One month ago he noticed a similar mass at the right of the pubis. It progressively became more constipated and emaciation was more frequent. He has not lost much (if any) weight.

On examination he appeared to be fairly well-nourished man. A firm tumor was found projecting above the pubis on either side and filling up the anterior portion of the pelvic cavity. The finger could be inserted into the rectum for a distance of about one inch. There appeared to be but a small space posteriorly to the bowel. Examination elicited no tenderness.

A large nodular mass composed of numerous lobules of bluish white color was removed from the posterior surface of the horizontal ramus of the pubic bones. The tumor extended laterally on both sides of the symphysis. The patient made an uneventful recovery.

Pathological examination. The tumor mass was very irregular and nodular and composed of various kinds of tissues. It had the shape of a large potato and measured $3 \times 7.5 \times 5.5$ centimeters. The tumor was covered by an irregular manner by a fibrous capsule to which many fibrous tags were attached. There were many thick fibrous bands running over it in various directions. In places the tumor was of firm bony consistency in others it was more elastic and at times it even appeared cystic. There were about thirty smaller pieces of tumor which during removal had been separated from the main mass. They varied in size from a walnut to one-third the large tumor and were similar to it in structure.

For the most part the tumor was occupied by lobular masses of cartilage which had a dense bluish white, glistening appearance, and surrounded by a definite fibrous capsule. On section, some of these masses of cartilage seemed to coalesce with the neighboring masses. In other parts, they existed as separate lobules and were attached only through intervening thick bands of fibrous connective tissue. These bands traversed the tumor in all directions

nd appeared to arise from the surrounding fibrous capsule. On closer inspection this artilage was a bluish-gray color it was smooth and had the appearance of frosted glass. This artilage was quite elastic. In another portion of the tumor there was some firm white calcified tissue which was irregular and nodular representing or suggesting calcification of definite artilaginous nodules. These calcified areas could easily be broken into small nodular masses each of which was separated from the next nodule by a capsule.

Attached to and embedded in the dense fibrous capsule was a mass of fat which was of a dull yellow color. On section through the cystic portion of the tumor the interior was found cavitated in a very irregular manner. These cavities extended through the tumor mass in many directions. The artilaginous substance in this region and surrounding the cavity was very soft and easily broken. In the thick bands of connective tissue were many congested blood vessels. The tumor had in places a pink hue.

Micoscopic sections of the tumor showed it to be composed of a hyaline cartilage. The cells were of various sizes and shape and lay in lacunae surrounded by a matrix of varying consistency. Groups of cells loosely or loosely arranged were found. The cells were mostly oval but a gradual transition from stellate to oval forms were also frequently seen. Some of the cells were surrounded by a capsule or thickened portion of the matrix. Others showed no capsule; however and still others showed a single capsule surrounding from three to twelve cells. In some of the cells a fine network was seen extending from the contracted central mass to the cell wall. Running through the tumor were strands of fibrous connective tissue which contained blood vessels. Several of these were seen to change by gradual transition into artilage cells of the hyaline variety. The artilage gradually assumed a more adult type as one advanced from these fibrous trabeculae inward. The matrix of the cartilage had a homogeneous pink hyaline appearance. In some places however minute fibers could be distinguished in this substance.

CASE 3. Mr. S. age 18 years. Occupation, student (white). For the clinical report I am indebted to Dr. B. Z. Cashman of the St. Francis Hospital. About five months previously a small growth was noted on the external surface of the right femur. Two months later this had extended to the inner side of the shaft. The patient lost five pounds in weight during the last few months. There had been some pain in the femur for the last month and some discomfort on the side of the right hip.

A firm mass was found over the inner part of the right thigh from trochanter to middle third. There was no pain on pressure. No change was to be observed in the overlying skin or veins. No other mass was present in the pelvis. The X-ray showed an egg-shaped softening below the greater trochanter.

On January 21, 1915 a small piece was excised

for examination and a diagnosis of chondromyxoma was made. A no anesthetic was added suggesting liability to recurrence.

An operation was undertaken for the removal of the growth. The mass was easily tripped from the femur and pelvis by the hand. While removing the tumor a sensation like running the hand through a ball of raked ice was obtained. The operation was followed by treatment with the actual cautery. Patient discharged February 5.

March 1, 1915. One and one half months later a mass the size of the original was found beneath gluteus maximus and attached to the femur and ilium. This mass was also removed and autopsied April 3, 1915. No evidence of recurrence. April 4, 1915. A mass was noted below the descending ramus of pubis and attached to the femur. Patient was referred to an X-ray expert who treated the case for four weeks with X-rays. The mass became softer but larger. The patient then sustained a pathological fracture of the femur. A sinus developed and blood drained from the area of injury. July 1. The patient was treated at Baltimore for 43 hour continuous radium. The mass continued to grow. October 10, 1915. Patient home. Marked edema and redness over the mass which appeared smaller. General health somewhat improved. February 1916. Patient died. No autopsy.

Pathological report (January 1, 1915). There were received numerous small irregular pieces of soft cartilaginous tissue representing a tumor about the head of the femur. The largest of these masses was 4 x 3 x 5 centimeters. These pieces of tissue were of a pale translucent appearance. The tissue was of the peculiar consistency of young cartilage and was quite friable. Running through it were strands of fibrous tissue forming trabeculae and carrying small blood vessels. The tissue was of a uniform structure and appearance. The cut surface was smooth glassy and firm. No areas of necrosis were observed. The tissue was distinctly translucent and in the smaller pieces which were very numerous and sometimes blood stained, the fibrous trabeculae stood out quite prominently as opaque, white strands. A firm stroma was seen to penetrate the solid gelatinous substance from these trabeculae. In many of the smaller pieces the surface was gritty owing to the presence of small particles of calcium salts. One small piece not over 1 centimeter in diameter consisted chiefly of compact cancellous bone. This was covered on one surface by the cartilaginous tissue.

Micoscopic. Sections of the tumor mass showed it to be composed of a matrix of a hyaline character in which many cartilage-cells were found. These cells were of irregular size and shape some being oval large and multinucleated. Many were spherical having a wide protoplasmic rim and contracted lacunae. Others were rather spindle shaped or stellate. No mitotic figures were observed. The cells were rather loosely distributed and nowhere

tion and growth of bony and cartilaginous parts are much retarded.

Enchondromata may also result from an inclusion of cartilage-cells (anlage) during the development of certain organs. Those likely to occur in the pelvis are enchondromata of an undescended testicle or an ovary. These organs are developed in close apposition to the vertebral column and may include an anlage of cartilage from the intervertebral discs, which later may take on the power of growth and give rise to a tumor. This was shown by Virchow to be the probable source of enchondromata of the parotid gland in which an anlage or inclusion was obtained from the branchial arches.

Francois reported a case of enchondroma of the ovaries occurring in a patient 74 years of age, but does not give any view as to their mode of origin. On the other hand Wartmann in his classical researches upon enchondromata has observed and described the endothelium of the blood and lymph-vessels retroverting to a type of embryonic mesodermal tissue from which it then developed into cartilage-cells and formed tumors.

Enchondromata of the pelvis usually develop during the third and fourth decade. Of the 60 cases reported in which attention was called to the age of the patient, 46 have occurred between the age of 20 and 40 years, and 29 of these between 30 and 40 years. Considering these tumors in the order of their frequency in particular locations those arising in the pelvis stand fourth the bones of the hand femur and tibia respectively being more frequently involved in the order named. In these latter locations, they very often are the late outcome of arthritis and particularly of arthritis deformans. Heredity seems to play little or no part whatever in the development of chondromata, although those occurring on long bones have been found in three successive generations. These tumors occur about equally in both sexes. Of 105 cases reported, 59 occurred in females.

Considering these tumors in regard to their rate of growth and duration one can say very little, as they are usually removed surgically at an early period. However one can say that they are, as a rule, of slow growth, but

may suddenly take on the qualities of rapid growth and cause the death of the patient. Livert in his statistics on enchondromata in general taken before the days of modern surgery reports 12 cases lasting from one month to two years before death 11 cases from two to ten years 12 cases of ten to twenty years duration and 3 cases more than forty years duration.

Many enchondromata of the pelvis are clinically malignant mainly because of their position in relation to the various pelvic organs. This was the more true before the days of antiseptic and aseptic surgery when the tumors were allowed to develop to an enormous size. Some of these tumors possess characters of true malignancy as is shown in one of our tumors having metastases. This process it is pointed out by Wartmann, takes place by the development of buds which grow into the lumina of vessels are broken off and carried to distant parts. The organ most frequently involved is the lung. Some of the tumors spread to distant parts by continuity and in this way show their malignancy. This is more apt to occur in tumors of a soft character whose cells are irregular in size and shape and simulate in appearance embryonic cartilage-cells. The matrix of these tumors is soft and of a gelatinous nature often myxomatous. This is well shown in our Case 3 with metastases involving the pelvis. Francois cites a case reported by M. Dolbeau showing a metastasis of enchondroma of the tibia to the pelvis. The more cellular these tumors are the more prone they are to develop typical sarcomatous masses of fibrous type.

Gibbs reported a case of enchondroma in the breast of a bitch growing side by side with a sarcoma, but having no connection with it. In some instances it was impossible to differentiate the two types of cells save by special staining methods. It is possible that many cases of this kind with metastases and other signs of malignancy have occurred in the human, and hence reported as malignant enchondromata.

Enchondromata may be differentiated in the gross from similar growths by observance of the following. These tumors are definitely

outlined and globular in shape while malignant tumors are irregular in shape and outline. Pain is not so marked if present at all and not of the lancinating type as sometimes found in malignancy. Pain in exostoses is present from the beginning while in enchondromata it is absent until the growth is quite large. There is no involvement of lymphatics and only in rare cases are the blood vessels engaged. Keen is of the opinion that enchondromata arising in children are usually benign while those arising in later years are more liable to become malignant.

From our experience and study as well as that of others it is evident that enchondromata of the pelvis most frequently arise in fibrous connective tissue and develop through a process of metaplasia following a stimulus usually a definite injury. Furthermore their clinical malignancy is mainly dependent upon their position and only rarely do they adopt a sarcomatous character and show true tissue malignancy.

I wish to acknowledge the valuable assistance given me by Dr O Klotz in the preparation of this paper.

DEPARTMENT OF TECHNIQUE

THE APPLICATION OF ANOCI-ASSOCIATION TO OBSTETRICS

THE COMBINED USE OF SCOPOLAMINE NITROUS-OXIDE-OXYGEN AND LOCAL INFILTRATION

B. CARL L. HOAG M.D. SAN FRANCISCO

Assistant in Surgery University of California Medical School

IN a paper read before the Pan American Medical Congress last June (1) I pointed out the way in which the principles of anoci-association could be applied to obstetrics. I wish briefly to review these points before reporting the results of my work since that time.

The principles of anoci-association are too well known to need description here. The acceptance or rejection of this system constitutes one of the most warmly debated subjects of present day surgery. There are those who are firmly convinced of its merits and others equally sure that it is only a fad, soon to follow the numberless panaceas once hailed with enthusiasm but now forgotten. Whatever may be its future as a system, it has already left its mark upon the technique of every clinic in promoting the more careful handling of tissues, sharper dissection and reduction of trauma.

The principal objections seem to be that there is a lack of muscular relaxation under nitrous-oxide-oxygen, and that there is difficulty in securing it by local nerve-blocking.

During the past three years it has been my good fortune to study a large number of cases operated under nitrous-oxide-oxygen and anoci-association. This experience has convinced me that success depends almost entirely on the care and thoroughness with which the local infiltration is done and those who have succeeded have done so by making the nerve-blocking as complete as that necessary for operation under local anesthesia alone.

Since the appearance of the articles by Webster (2) and Lynch (3) in March, 1915, the use of nitrous oxide in obstetrics has rapidly increased. When we remember how many surgeons have discarded it on account of the lack of relaxation in the abdominal wall we cannot help feeling that the percentage of severe perineal tears must rise, unless the pelvic muscles should happen to be very different in their reactions under the gas. Since there are no reasons for expecting such a

difference, I believe we should be prepared to meet the difficulty. One way would be to change to one of the more relaxing anesthetics such as ether or chloroform at the time of delivery; another would be to use nerve blocking locally. If relaxation can be secured in the abdominal wall by the use of novocaine and quinin urea, it seems likely that the same results could be obtained in the perineum.

Of the 30 cases receiving perineal injections, 20 were given nitrous-oxide only. Group I, four were given nitrous oxide-oxygen until the time of actual delivery when chloroform or ether was substituted; Group II, and six received chloroform in the usual way. Group III. The perineum in all cases was injected with 0.25 per cent novocaine varying in amounts from 60 to 150 cubic centimeters. Eleven received in addition from 30 to 40 cubic centimeters of per cent quinin urea solution each. The maximum amount of the two solutions injected in any one case was 175 cubic centimeters. The injection was made as the head appeared in sight. The vulval edges were turned back and a long needle was inserted at the mucocutaneous border the fingers of one hand being in the vagina to note its position. At this period the perineal floor is flattened out by the oncoming head, but not stretched to any degree. Even though the field is large both the levator ani muscles and the perineal body can be readily infiltrated. Novocaine was injected first and the quinin-urea immediately afterward, when used.

For the purposes of this paper we are concerned chiefly with the 20 cases in Group I that received nitrous-oxide-oxygen only. Seventeen of these received from one to five doses of scopolamine during the first stage before nitrous-oxide-oxygen was begun. The initial dose of scopolamine was 1/300 grain combined with either morphine 1/6 grain or narcophin 1/5 grain. This was followed usually at irregular intervals by the same dose of scopolamine without the

Read before the San Francisco County Medical Society February 1916.

morphine or narcophin. In four of the prolonged labors a second smaller dose of either the morphine or narcophin was given. These drugs were given first to reduce the amount of gas used and secondly because many of the nervous patients became more quiet and took the anæsthetic better.

It should be emphasized that an excessive amount of scopolamine often proves worse than none because the patient must be mentally clear to give the proper co-operation with gas analgesia. In none of these cases was the amount sufficient to produce anywhere near the mental condition observed in so-called twilight sleep. I believe its use in these amounts is just as advisable in obstetrics as in general surgery and for the same reasons.

Nitrous-oxide-oxygen analgesia was begun before the end of the first stage or at the beginning of the second according to the distress of the patient and to her ability to pay for the gas.

Pain. There was a marked difference between the private and the clinic patients in regard to the success of the procedure as far as pain is concerned. The private cases all intelligent women schooled in the part they were to play and at

tended by professional anesthetists suffered very little. Some of them had absolutely no pain others asked for more anæsthetic and complained of distress but after it was all over could not remember having had much pain. In the other group of clinic cases conditions were less favorable. The women were less intelligent some could not even speak English. With the first few cases the anæsthetic was given with a new type of machine by men unskilled in the use of gas. Under these circumstances in some cases the gas did not give enough relief so that chloroform or ether had to be substituted. These are the cases that make up Group II. Later better results were obtained as regards analgesia but still not as good as in private cases.

During the delivery of the head analgesia was succeeded by complete anæsthesia in all cases. I believe this is an important point. It greatly lowers the danger from those sudden expulsive contractions which so often produce tears. It has been found advisable after years of experience with chloroform and I do not see why it should not be used with nitrous-oxide-oxygen. In fact the indications for complete anæsthesia are greater with such a light anæsthetic.

In the first 20 cases, delivered under nitrous-oxide-oxygen and anocid alone nineteen were primipara and the other a II-para. The ages varied from eighteen to thirty-one, the average was twenty three years. In all but one, the position was left occipito-anterior or right occipito-anterior. One was a right occipito-posterior which persisted and was delivered as a brow with low forceps. In spite of this complication, the nitrous-oxide-oxygen worked satisfactorily.

Length of labor As far as they go the figures in the nitrous-oxide-oxygen cases indicated shortening of the second stage. The time averaged one hour and forty minutes, which, I believe is less than is usually seen in a similar group of primiparae. Certainly the time was not lengthened.

Forceps Forceps were used three times. Of the two low forceps cases, one was the brow delivery just mentioned. In the other they were used to terminate labor after the head had been on the perineum one hour. In a third, mid forceps were resorted to because the fetal heart had dropped to 100. This last case had received nitrous-oxide-oxygen during the pains for thirty minutes only. It does not seem then, that the need for forceps in any one of these cases could be attributed to the anesthetic.

Lacerations Careful records were kept even the first degree lacerations, small skin or mucous tears were noted. These were present in 10 cases. In the 20 cases there were only three second degree lacerations, each one of which was to be expected under the conditions present. The first was in the mid-forceps case already described the second had a contracted outlet and in the third, the head was born unattended.

Perineum The perineum in the 30 cases were watched carefully for complications attendant upon the injection of novocaine and quinin urea. No abscesses, sloughs, areas of redness or infiltration occurred. In a few cases, there was some edema and considerable tenderness on the second and third day but apparently on more than in other cases in which it was not used. Those perineae that had to be repaired healed promptly.

Perineal injections There is no doubt in my mind that the novocaine did improve the relaxation. The perineum is a large field to be thoroughly injected, but the distribution of these large quantities of solution is materially aided by the pressure of the head against the muscles. The quinin urea¹ in the quantities used was apparently of little service in relieving

the soreness after delivery but it may have aided in keeping up the local anesthesia in the more protracted cases.

Babies All but two of the babies in the 30 cases were born alive pink, and in excellent condition breathing spontaneously. One was still-born at about eight months. No fetal heart had been heard for several days. In the other case the mother a III para had been sent in from the Out-patient Department because the fetal heart had gone up to 170. The cervix was stenosed mid forceps had to be applied and the child was born with the cord tightly coiled about its neck. Nitrous-oxide-oxygen had been given for only fifteen minutes, followed by ether for one hour. This child could not be resuscitated and death was plainly due to suffocation on account of delay in delivery. In neither of these cases, then, can death be attributed to the nitrous-oxide-oxygen.

CONCLUSIONS

1 In conclusion I wish to emphasize that this experience, brief as it is is in accordance with that accumulating rapidly on all sides today that nitrous-oxide-oxygen analgesia is safe to both mother and child.

2 The use of limited amounts of scopolamine during the first stage is a distinct advantage, shortening the time during which gas is required and making the analgesia more complete.

3 The work done so far has encouraged me in the belief that the injection of the perineum is a distinct help in securing relaxation of the outlet. This point gained, gas-oxygen in experienced hands will do as well as either chloroform or ether. The lack of any complication whatsoever resulting from the perineal injections should encourage those who feel timid about its use.

4 The combined use of scopolamine nitrous-oxide-oxygen, and local infiltration offers a practical and efficient means of conducting labor and extends analgesia in its broadest sense to the obstetrical field.

In closing it is a pleasant duty to thank Dr. Breitstein for the generous and open minded way in which he gave me access to material at the University of California Hospital. I wish also to thank Drs. Seaver and Gelston for their valuable help in carrying out this work.

¹ It should be remembered in using anocid-injections that quantities must not be used on the skin, mucous membranes, gums or cervix as sometimes produces sloughs in these tissues.

PERINEAL ANÆSTHESIA IN LABOR

BY ROBERT W. KING, M.D., DENVER, COLO.

WHILE marked advancement has been made in the realm of anesthesia as applied to the local and general blocking of the sensory nerves of various parts of the body, it is strange that so little attention has been paid to applying these methods to the sensory innervation of the female perineum—especially since the agitation of twilight sleep has engaged the attention of profession and laity. The literature of this subject is remarkable because of its scarcity; the subject apparently has not engaged the attention of American investigators and practically the only work of importance that has come to my notice has been carried on in Germany.

What work has been done has been directed toward the blocking of the pudic nerve but this has not received the attention it deserves.

The pain of the dilatation of the cervix is not of the same intensity as that suffered by the birth of the head and seldom requires anesthesia of any sort. The suffering caused by the advancing presentation on the perineum has been attributed to the stretching of the soft parts and this pain is always more severe in primipara than in multipara.

A further knowledge or understanding of the sensory innervation of the female perineum and the part played by Colles' fascia in the production of pain in childbirth will modify this view and a better understanding of the anatomy of the part will lead to better success in attempting to block the nerves.

By blocking the pudic nerve in the ischio-rectal fossa there will be a fair degree of anesthesia of the anterior triangle and perfect anesthesia of the posterior. The anesthesia of the anterior portion will not be perfect because part of its sensation is derived from the inferior pudendal, genitocrural and ilio-inguinal nerves (Fig. 1) that do not enter the posterior triangle. The major portion of the pain in the second stage of labor is due to the stretching and rupture of Colles' fascia which is more sensitive than the integument of the part and which also varies in density and elasticity in different subjects. As Colles' fascia is always more or less torn in the primipara and not so frequently or to so great an extent in multipara it is readily seen why the suffering is more intense in the former than in the latter.

Anatomically Colles' fascia corresponds to the

lateral extension of the hymen and like that structure it possesses great sensibility to pain. If this point is fully understood and the sensory paths and fascial planes (Fig. 2 and 3) are studied in the illustrations it will be possible for the general practitioner to safely and easily block the sensory innervation and deliver the patient painlessly or at least with a minimum degree of pain rendering the employment of other anesthetics unnecessary.

My former objection to blocking the nerve in the ischio-rectal fossa has been because of the low vitality of this fat-filled space and the possible danger of puncturing the pudic artery.

Infiltration of the fossa has not been followed by any adverse circumstances however and I am now blocking the nerve of both the anterior and posterior triangles of the perineum in women who have given birth to a number of children or who present evidence of much laceration of Colles' fascia.

There are many apparent advantages of this method over the administration of general or spinal anesthesia in childbirth or gynecologic operations which make it very desirable that it should receive a thorough trial in clinics having suitable material.

I have had much difficulty in working out the innervation and fascial planes as here given owing to the lack of suitable material in the dissecting room and the fact that the published works on anatomy that I have had access to have with one exception dismissed this important part by referring the student to the male analogues. The later works on obstetrics and gynecology have also shown an unexpected lack of knowledge of this subject due perhaps to the supposed unimportance of an intimate knowledge of the female perineum to the general practitioner.

ANATOMY

The pear-shaped space of the perineum is divided into an anterior and posterior triangle by a transverse line passing between the tuberosities of the ischium midway between the anus and vagina. The lateral angles of the anterior portion vary greatly in different subjects and the tuberosity must be carefully palpated and the proper injection chosen in reference to the parts to be anesthetized. The anterior triangle contains all the sensory nerves innervating the perineum in the third degree laceration extending just to the

Fig. 1. The right side shows the distribution of the sensory nerves of the female perineum. The left side shows the landmarks and sites for entering the needle in blocking these nerves in labor or perineal operations.

The posterior triangle contains the sensory nerves of the region to the coccyx, the anus, Colles' fascia and the triangular ligament, and a part of the periphery of the anterior triangle.

Fascial planes The superficial fascia of the anterior triangle consists of two layers; the peripheral layer contains fat and varies in thickness in different women (Fig. 3); it is continued over the posterior triangle forming a meshwork containing the fat of the ischioanal fossa. The second or superior layer of the superficial fascia of the anterior triangle is Colles' fascia and is an aponeurotic membrane which is very sensitive to pain. Passing forward this layer is represented by Scarpa's fascia of the abdomen and the suspensory ligament of the clitoris. Across the vaginal orifice it is represented by the sensitive hymen. Posteriorly it is reflected behind the transverse perineal muscles and blends with the two layers of the triangular ligament and the perineal body, laterally Colles' fascia is attached to the rami of the pubic arch. This fascia forms the floor of the superficial perineal interspace the roof being the inferior layer of the triangular ligament.

The deep perineal fascia is the urogenital diaphragm or triangular ligament. It also consists

Fig. 2. Dissection of the female perineum. On the right side Colles' fascia is removed showing the sensory innervation and blood supply of the superficial perineal interspace and ischioanal region. On the left side Colles' fascia is reflected showing the cuticular bulb and gland and the inferior layer of the triangular ligament cut to show the artery of the bulb in the deep perineal interspace. In the ischioanal fossa the anal fascia is removed and the space cleared showing the location of the pudic vessels and nerves.

of two layers that become continuous behind, blending with the perineal body and Colles' fascia. Anteriorly these layers are separate, laterally and anteriorly both layers are attached to the pubic arch and between them is situated the deep perineal interspace.

A study of these fascial planes demonstrates the ease by which the spaces may be infiltrated and the contained structures subjected to the influence of the solution for a considerable time, owing to the impervious nature of the fasciae and their attachments, when intact making it impossible for the solution to escape except anteriorly from the superficial interspace beneath Colles' fascia.

The perineal spaces The superficial interspace contains all of the sensory nerves of the anterior triangle except a few fibers of the genitocrural and ilio-lingual nerves. It also contains the principal vessels, the superficial muscles, and the vestibular bulb and gland (Bartholin's gland) the location of which must be remembered or failure may result if injection is made into them

Fig. 3 Diagram illustrating the fascial planes and spaces governing the extent of the anæsthetic infiltration. Note the anterior projection of the ischio-rectal space.

The deep perineal interspace contains no nerves necessary to block in labor the dorsal nerve of the clitoris which enters this space leaves it and passes into the anterior portion of the superficial interspace.

The ischio-rectal fossa is generally stated as being situated in the posterior triangle but reference to Figs. 3 and 4 will show that there is an anterior projection between the levator ani and the superior layer of the triangular ligament passing nearly to the symphysis. The solution will readily infiltrate the loose tissue of the space but it is necessary to use a greater amount than in the anterior injection. Alcock's canal which is a sheath formed by the obturator fascia contains the pudic nerves and vessels supplying nearly all the structures of the perineum. The situation of this structure about 4 centimeters above the margin of the tuberosity marks the depth to insert the needle for the injection. Care must be used not to make the injection into the obturator muscle or the dissipation of the solution may prevent sufficient anæsthesia of the perineum. If the solution is injected into the fossa it will have effect upon the perineal nerve and also the hæmorrhoidal and sacral nerves giving sensation to the structures of the posterior triangle.

TECHNIQUE

1 Prepare a 2 per cent solution of novocaine in normal saline sterilize it by boiling allow it to cool and add $\frac{1}{4}$ of a minum of 1:1000 solution of adrenalin chloride to each cubic centimeter.

Fig. 4 Diagram illustrating the situation of Alcock's canal and the anterior projection of the ischio-rectal fossa.

2 Palpate the pubic arch to be sure of the landmarks.

3 Wash the site of each injection with alcohol or benzoin followed by the official tincture of iodine.

4 Spray each site lightly with ethyl chloride before entering the needle.

5 In the anterior triangle enter the needle 2 to 4 centimeter above the lower margin of the vagina and 2 centimeters from the ramus. Pass the needle to 4 centimeters in depth, corresponding to the level of the hymen or its remains and the expression of sudden pain as the needle meets the positive resistance of Colles' fascia will indicate the proper depth pass the needle through the fascia and inject the solution. In the anterior triangle use $1\frac{1}{2}$ cubic centimeters of the 2 per cent solution for each injection.

6 In the posterior triangle incline the needle laterally and enter it midway between the anus and tuberosities to a depth of 4 centimeters. In the posterior triangle use from 3 to 10 cubic centimeters of a 1 per cent solution in each injection. Varying as to the adiposity of the subject.

The injections are made bilaterally.

8 Primipara require only the anterior injection.

9 Multipara may require both anterior and posterior injections.

SUMMARY

1 No adverse results have followed nearly 100 injections. A slight superficial necrosis of the inner lips of the labium has followed the injection.

of stronger solutions of adrenalin but this in all cases cleared without harm

2. Anesthesia begins in a few minutes and is prolonged two to four hours

3. Lacerations are diminished in number and extent for the consciousness without pain of the patient allows retardation or advancement of the presenting part at will, thereby developing the fullest elasticity possible.

4. Hemorrhage from lacerations is greatly

diminished due to the adrenalin and lessened extent of tears.

5. Repair is greatly facilitated because of the duration of the anesthesia

6. Benzoin or alcohol and iodine sterilization of the obstetric area can be rapidly and painlessly carried out under this procedure when the posterior triangle is infiltrated.

The general practitioner can safely and easily apply this method at the bedside

AN OPERATION FOR BACKWARD AND DOWNWARD DISPLACEMENTS OF THE UTERUS

B. JOHN M. ALLEN M.D. F.A.C.S. St. JOHNSBURY VERMONT

THE operation described below has been performed fourteen times during the past twelve months and has given so uniformly good results in all these cases that the writer deems it worthy of report. The fourteen patients presented varying degrees of backward and downward displacements of the uterus from simple retroversion to complete prolapse. The ages ranged from 25 years to 64 years. In most of the cases repair of the pelvic outlet as well as attention to the cervix uteri was necessary. Where the cervix was badly lacerated, much en-

larged, or greatly elongated it was amputated by the circular method, which measure of course lightened the load markedly.

The abdomen is opened in the midline by a four inch incision the lower limit of which is about one and one half inches above the symphysis pubis. The skin and fat are pushed back from the edges for one half inch throughout the whole length of the incision and any work upon the adnexa or lower abdominal contents is carried out. Holding the edge of the rectus sheath taut

Fig. 1. First step. Two parallel strips A cut from the rectus sheath.

Fig. 2. Second step, showing forceps pushed through broad ligament just below round ligament, from behind forward and up through peritoneum, posterior rectus sheath and fibers of rectus muscle, ready to grasp end of strip.

117. Third step showing uterus in situ. The incision is made in the posterior surface of the uterus between uterine ends of the round ligament.

118. Fourth step in the operation. The strips are sewed in the incision and to each other.

a strip of this about one fourth of an inch wide is cut from the margin as long as the incision. The upper end is severed and the lower end is left attached. The uterus is next brought up high enough to make the posterior surface easily of access as low as the origin of the round ligaments and a shallow cut is made across this surface from the origin of one round ligament to the same point upon the other side. In making this cut the knife is held at an angle to the uterus of forty five degrees so that later on the incision may be completely closed. The uterus is then drawn to one side and held firmly while the next important step is taken. An eight inch hæmostat with jaws curved to a right angle with the blade is thrust from behind forward through the broad ligament on a level with the end of the incision on the posterior surface of the uterus and made to traverse the following structures in the order named: the parietal peritoneum and posterior rectus sheath the fibers of the rectus muscle. Thence it is made to emerge at the edge of the wound with ut having pierced the anterior sheath of the rectus and at or near the level of the lower end of the incision in this latter structure. The jaw of the hæmostat are then opened and the free end of the strip of the rectus sheath previously cut is grasped and the hæmostat is withdrawn until the jaws appear at the point where they entered i. e. at the end of the groove in the uterine wall just below the round

ligament. The same procedure is carried out upon the opposite side the ends of the strips are cut to proper length if too long and they are then sutured carefully to the bottom of the groove with twenty-day gut. The ends may be made to meet in the midline of the uterine wall or may overlap. The cut in the uterus is then sutured with one gut and one or two stitches are made to include the strip the round ligament and the broad ligament on either side. The uterus will then be seen to be in most excellent position hanging free and unattached to other structures and no raw surface for adhesions will be found other than the small area upon the two small strips of aponeurotic tissue which is almost negligible in amount.

The chief advantage claimed for this operation is that the new support is made of tissues which will not stretch out in a few months after active life has been resumed. Also the uterus is made one of two links of a chain which will hold the vaginal walls in place. Better anatomic position is secured and maintained than in many of the other varieties of operations for the relief of these conditions.

All patients so far have been completely relieved of the distressing symptom complained of prior to operation. It is therefore obvious that this method can only be used in patients past the menopause or in others where the tubes have been tied or other means of sterilization employed.

SPONTANEOUS EVOLUTION IN SHOULDER PRESENTATIONS

WITH REPORT OF A CASE

BY RALPH M. CARTER, A.B. M.D. GASTON BAY WISCONSIN

STEPHENSON in a recent article, states that spontaneous evolution in transverse presentations has been observed only twice in 13,000 consecutive labors at the Johns Hopkins hospital, and all authorities agree that it is a very unusual occurrence. On account of its rarity therefore, a report of the following case may be of interest.

On February 27, 1906 I was called to attend Mrs. K. living eleven miles in the country. I found a woman 34, five feet six inches in height and well developed. She informed me that she had passed through five previous labors, all normal and not particularly difficult. Pains in the present labor began about 5 p.m., and the bag of waters ruptured about 8 p.m., followed shortly by the prolapse of an arm. Hard pains then ceased, except for an occasional one. A midwife was in attendance, but with the prolapse of the arm, she rightly decided that the case was beyond her skill.

Under conditions as aseptic as possible considering the circumstances, I made an examination with light anesthesia, administered by the midwife. I found right scapulo-anterior with prolapse of the left arm which, as of good color. The cervix was fully dilated, and the uterus closely applied to the fetus in the condition of Killian passive contraction. The shoulder was firmly wedged into the pelvis, and it was impossible to get the hand into the uterus to perform version. Without using more force than I cared to employ under the circumstances, I absolutely no skilled assistance at hand. As the uterus was not markedly thinned, there were no hard pains, and the patient's general condition was excellent. I decided to move her to the hospital. She stood the trip in the aut. very well, arriving at the hospital at the end of the eleven miles drive in practically the same general condition as when left her home. She had few pains en route but they were not hard ones.

A few minutes after her arrival the pains increased markedly both in number and intensity and in short time, she was having violent bearing down pains at intervals of 1 or three minutes. She was placed immediately on the table, and light ether anesthesia administered. The prolapsed arm had now become very much swollen and congested, and the shoulder had rotated beneath the pubis. Almost without pause, spontaneous evolution by the method of Douglas took place. The chest, abdomen, and breech were consecutively forced over the perineum, followed by the legs and the other arm after which the head was extracted without difficulty. The placenta followed within five minutes.

The child was dead, but as shown by the changes occurring in the prolapsed arm, death had been very recent. It weighed six pounds, and was fully developed. The neck was markedly elongated.

The mother made an uneventful recovery and left the hospital on the eleventh day.

Transverse presentations are always pathologic. While the above case demonstrates that they

sometimes terminate spontaneously yet with very rare exceptions, the children all die and very frequently the mothers, if aid is not given. If left to Nature, several terminations are possible.

1. Spontaneous rectification may occur. This usually takes place during the last month, and is brought about by the contractions of pregnancy. It occasionally occurs during the early part of the first stage.

2. Spontaneous version may be brought about during the first stage of labor or rarely in the beginning of the second. The head or the breech may come to lie over the inlet, usually the former.

3. Spontaneous evolution may take place.

4. The pains continue, no advance is possible, the uterus ruptures, and the patient dies from hemorrhage or infection.

5. The pains may cease, the fetus be retained and become infected, decomposing and giving rise to a pyæmia, in which condition general sepsis and death usually follow.

Spontaneous evolution may take place according to one of three methods: (1) That of Roederer also known as *spontaneous expulsion* or *evolutio corporis conduplicato*. This is much rarer than ordinary spontaneous evolution, and requires a much roomier pelvis in proportion to the size of the fetus. The shoulder is forced down into the pelvis and the body is bent, bringing the head and thorax into apposition. Both the latter enter the pelvis together and emerge simultaneously from the vulva, following the birth of the shoulder. (2) The method of Douglas of which the above case is an illustration. In this method, which usually occurs in cases with prolapse of an arm the head is arrested above the inlet, the neck becomes very much elongated, and the chest, abdomen, and breech are forced out alongside the arm, followed by the legs, the other arm, and the head. (3) The method of Denman, which is the rarest of the three. This usually takes place in back posterior positions. The head rotates posteriorly the shoulder ascending simultaneously with the descent of the breech which finally comes down and out. A fourth method, or at least a hitherto undescribed modification of the method of

Douglas has recently been observed by Stephen son In his case, the left shoulder with pro-lapsed arm became fixed beneath the pubic arch as in Douglas method. Following this the but tocks emerged from the outlet with their anterior surface in contact with the inner surface of the arm This latter method must be extremely rare and the force required for it to take place is undoubtedly very great

The above-described mechanisms while they are very interesting in that they demonstrate the marvelous adaptability of the processes of Nature to unusual circumstances occur so rarely in practice that they should never be depended upon

For spontaneous evolution to occur we must have a roomy pelvis a small easily molded fetus and very strong pains It always occurs late in the second stage Once started however the rapidity with which the process is completed is astonishing a fact which has been remarked upon by several observers and illustrated in my own case From the onset of the severe pain to the birth of the placenta the time was fifteen minutes. The total duration of labor was eight hours.

Since it is practically impossible to predict in which cases evolution will take place and since

the results of neglected transverse presentations are so serious expectancy in the hope of evolu-tion has no place in the treatment of this class of cases If seen early in labor a short wait to see if spontaneous rectification or version will occur may be justified If neither of these takes place version should be performed as soon as conditions will permit Oftentimes deep anesthesia will allow turning where otherwise it appears im-possible Above all gentleness and care in all manipulations should be the first consideration and if the shoulder is deep in the pelvis the uterus contracted closely about the child and the latter does not turn easily attempts at version should be abandoned If the lower uterine seg-ment is greatly thinned version is contra-indicated as a rupture will almost surely occur In these cases decapitation should be performed In exceptional circumstances when the child is living the woman is in good condition and the surroundings favorable cesarean section may be considered

BLOOD TRANSFUSION WITH PARAFFIN-COATED NEEDLES AND TUBES

By BETH VINCENT M.D. F.A.C.S. Boston

THE results obtained by the transfusion of blood are probably less dependent upon the particular method employed than upon any other factor pertaining to the subject The indications for a transfusion and the selection of the donor are more important than the technique of the operation. The therapeutic value of the blood is the same whether transferred by the citrate method as described by Weil¹ and Lewi-son² with the glass cylinders of Kimpton and Brown³ the pipet-cannula apparatus of Satterlee and Hooker⁴ or by the syringe method of Linde-man⁵ For this reason each surgeon should familiarize himself with the method which suits his own needs The following method has been

useful to me and may meet the requirements of other operators

For the past three years I have used a glass tube or flask with a paraffin coating which inhibits the coagulation of blood and allows ample time to transfer it from donor to recipient The tube resembles in principle and differs in shape from the cylinders described by Kimpton and Brown and the pipet of Satterlee and Hooker⁴ This method is easy and practical but requires a skin incision to expose the vein in both donor and recipient which is not necessary in many cases

Recently I have modified the tube so that it can be used with a needle of special design which obviates the skin incision on individuals with suitable veins After a year's experience with the needle and tube at the Massachusetts General Hospital and in my private work I find that this

Satterlee and Hooker Surg Gynec. & Obst 14, 1904, 55

is the case with the donor at least, in a large percentage of transfusions.

The tube (as shown in Fig. 1) is a cylinder with a capacity of 300 cubic centimeters; the upper end of which is closed with a rubber cork. About 3 centimeters below the end is a side opening where connection is made with a bulb syringe which is used to express the contents of the tube. The lower end of the cylinder terminates in a glass tip through which the blood enters and leaves the tube. About 2 centimeters above the end of the tip is a ground glass joint by means of which a tight connection can be made with the needle.

The needle is 6 centimeters long and consists of a shaft and a socket of about equal length. The socket, which is the special feature of the needle, is made of an unusual depth so that there is no contact between the needle and that portion of the glass tip which projects into the socket below the ground glass joint. The needle is made in two sizes, number 14 and 16 gauge. I find that I use the larger size in most cases.

PREPARATION OF TUBE AND NEEDLE

The tubes are cleansed with hot water, wrapped in a towel with the cork and a short piece of rubber tubing and sterilized and dried in the autoclave. The process of coating the tubes with paraffin is then carried out under aseptic conditions. I have used 54 paraffin and various mixtures of stearin, paraffin and vaseline for coating but find that a commercial article sold under the name of "parowax" serves all practical purposes.

The paraffin which has been melted and sterilized in a metal dish is aspirated into the lower end of the tube and the outlets are covered with pads of gauze while the tube is turned to make the wax run over all the inner surface. The excess of paraffin is allowed to run out at the tip leaving a small amount in the tube to cover the cork when the tube is placed upon end to cool. This forms a disc of wax which makes the cork airtight, a condition which is essential to the proper use of the tube. As the tube cools a coating of paraffin appears on the inner surface. One should make sure that this covering is uniform and that the outlets are patent before the tubes are done up in sterile towels and put aside for future use.

The needles are cleansed, dried, and heated until sterile in a dish of melted paraffin. With sterile forceps a needle is then taken from the dish and the excess of wax is removed by shaking or by blowing air through the needle with a bulb syringe during the process of cooling to prevent the formation of a plug of wax in the lumen. The

needles are then sterile and coated and can be kept in a sterile box until needed.

This process of coating the tubes and needles requires some practice and is bothersome to the surgeon. It is one of the disadvantages of the method but the work can be delegated to any intelligent nurse. Prepared and put up in this way the needles and tubes may be kept indefinitely and are always ready for immediate use.

USE OF NEEDLE AND TUBE

The method of using the needle and tube varies with the case to be transfused and the experience of the operator. The tube should be used without the needle in cases in which the veins of both donor and recipient are small or hidden by a heavy layer of subcutaneous fat or when the surgeon lacks practice in vein-puncture and is unable to enter the vein without causing a hematoma. Under these circumstances it is advisable to expose and open the vein through a skin incision and insert the tip of the tube directly into the vein as described by Kimpton and Brown. The blood is usually taken from one of the larger veins in the donor's elbow while any vein in the arm or leg which will admit the glass tip can be used in transferring the blood to the recipient.

In most transfusions the veins of the donor are large and easy to puncture with the needle while the veins of an anemic recipient are apt to be small and hard to locate. For this reason it is usually advisable to take the blood from the donor into the tube by means of the needle, then disconnect the needle from the tube and inject the blood into the recipient through the glass tip which is inserted directly into a small vein previously exposed by skin incision.

Figure 2 shows the manner of using the needle and tube to take the blood from a vein at the donor's elbow. The arm is prepared with iodine and a small amount of novocain is injected into the skin over the selected vein which is made prominent by a tourniquet applied above the elbow. The application of the tourniquet is important. It should be placed directly on the skin and adjusted by the operator so as to secure the maximum venous tension without stopping the arterial flow. The needle is connected to the tube before making the puncture and inserted into the vein toward the wrist. As soon as the vein is entered the blood appears at the bottom of the tube and steadily rises to the top by virtue of the pressure in the vein. The rate of flow is increased if the donor works the fist during the procedure. When the tube is filled, which

Fig. 2. Coated glass tube with needle and bulb.

Fig. 3. Shows use of needle to take blood from vein at the elbow.

usually takes three or four minutes the flow is checked by releasing the tourniquet. This should be done before the needle is removed to avoid the formation of a hematoma. As the needle still attached to the tube is withdrawn pressure is made over the vein at the site of puncture. The needle is then disconnected from the tube and rinsed in cold salt solution. During this time the tube is kept in a horizontal position with the tip up to prevent the escape of blood. To complete the transfer place the finger over the upper opening of the tube to control the flow of blood depress the lower end and insert the tip into the vein of the recipient.

Figure 3 shows a tube half filled with blood which is being injected by this technique into the internal saphenous vein just above the ankle.

The average transfusion requires at least 600 cubic centimeters of blood. In most cases if a hematoma does not form around the vein it is possible to take two and sometimes three tubes of blood from the same vein by reinserting the needle through the original skin puncture. It is not necessary to use a fresh tube and needle for each transfer of blood. If cleaned immediately with cold salt solution they may be employed a second or even a third time in the same transfusion. A single tube and two needles usually

suffice for a transfusion although one should always be prepared with at least two coated tubes and extra needles.

The combination of needle puncture for the donor and incision for recipient is the practical method in most transfusion but under certain circumstances it is possible to use the needle on both the donor and the recipient. In such cases after the tube has been filled with blood from the donor as already described a needle is inserted into the median basilic or median cephalic vein of the recipient made prominent by a tourniquet above the elbow. As soon as a blood flow from the needle the tourniquet is loosened the tube filled with blood is connected with the needle and the content expressed by means of the syringe.

This needle and tube method without incision applies especially well to the infant with an open anterior fontanelle where the blood is injected into the superior longitudinal sinus as suggested by Helmholz.

Fig. 3. Show technique of inserting glass tip int. vein which has been exposed and opened through skin incision. Position of tube to inject blood int. internal saphenous vein.

In my last seven cases of haemorrhagic disease of the newborn I have employed this method with very satisfactory results. The blood is taken by means of the needle from an elbow vein of the father who usually serves as the donor. One half a tube or 150 cubic centimeters of blood is sufficient as the amount required to transfuse these cases varies from 90 to 120 cubic centimeters. The infant is placed at the end of a table with the head on one side, as shown in Figure 4, and held firmly in this position by an assistant. The needle is inserted at the posterior angle of the anterior fontanelle exactly in line with the sagittal suture. The sinus is just beneath the skin and dura and large enough at this point to be located easily even in a newborn infant. As soon as the needle enters the sinus the fact is revealed by the flow of blood from the outer end. The needle is then held firmly in place while connection is made with the tube and the blood is slowly injected. The blood must be injected slowly to avoid a too rapid increase of intracranial pressure. In two of my cases this caused vomiting and disturbed respiration which corrected itself as soon as the flow of blood was

Fig. 4. Show position of infant head and point at which the injection of blood is made into the longitudinal sinus.

checked temporarily. Air pressure in the tube should be released by detaching the syringe before the needle is withdrawn. There is no bleeding of any amount from the sinus even if the puncture has been made with a fairly large needle.

The chief disadvantage of this method of transfusion lies in the preparation of the needles and tubes but this process is not difficult and may be done in advance. The coated needles and tubes can be kept indefinitely and are always ready for immediate use. In practice the method is certain and flexible. The combination of needle and tube allows the surgeon to make a choice of procedures to suit his own operative experience and the need of the individual case. The tube with open incision is a sure method for any transfusion and under favorable conditions the use of the needle with the tube materially simplifies the operation.

WIRING THROUGH THE OBTURATOR FORAMEN FOR SYMPHYSIS PUBIS SEPARATION

FOUR INCH SEPARATION OF THE SYMPHYSIS PUBIS PROTRUSION OF BLADDER BETWEEN THE SEPARATED BONES ANKYLOSIS OF THE SACRO-ILIAC JOINTS INVALIDISM FAILURE OF POSTURAL AND SUPPORTIVE MEASURES RESTORATION OF FEET BY WIRING THROUGH THE OBTURATOR FORAMEN

By SILVESTER J. McNAMARA, A.M. and F.A.C.S. BROOKLYN

SEPARATION of the symphysis pubis sufficient to cause invalidism is rare.

The history of the case is that of a woman 38 years old the mother of six children. The patient is of small stature and is inclined to be corpulent. She was attended by the same physician in all six confinements the last one being instrumental. She was not able to get around after the last confinement unless he supported herself on a chair which she pushed in front of her.

Some months after her last delivery she was taken with severe pains in her right side and was removed to the Kings County Hospital where she was operated on for acute gall bladder disease. When it was time to leave the bed it was found that she could not walk and on examination showed a separation of the symphysis pubis to the extent of four inches, with a fluctuating tumor between the separated bones which was found to be bladder.

Postural treatment and various devices were used but the patient complained so bitterly that they had to be discontinued. Compression by various appliances including support by plaster-of-Paris girdl taking one thigh was tried but with no success. At last a pigskin girdle reinforced with a shaped to her hips was put on and she was allowed to go home.

At no time were we able to bring the separated ends of the bones near enough together to hope for union even though we could find no device to hold them there.

Furthermore all attempt to bring the symphysis together caused the patient to cry out with the intense pain produced in the sacro-iliac joints. After a short time at home she returned to the hospital in about the same condition we first found her. After various consultations with my colleagues on the gynecological and obstetrical

services, as well as with the general and orthopedic surgeons, it was decided to bring the bones together by surgical means. The study of the symphysis in the dried specimen did not argue well for plating owing to the anclous nature of the bone irregularity of its surface and the nature of the strain. The obturator foramen presented one possible route for a safe and firm support.

A recentric incision about seven inches long was made exposing the space between the separated ends and the separated end of the joint was exposed mostly by blunt dissection. As the patient was in the elevated lithotomy position a catheter was placed in his bladder because of the unusual distention of the urethra and displacement of the bladder. The field of operation was enlarged by a longitudinal incision downward. An attempt was made here to bring the separated joint together by traction of the assistants making lateral pressure but without result.

The patient was turned on the side and one of the assistants with all his weight and strength and a jumpy jerky motion finally succeeded in breaking up the adhesions that had formed at the sacro-iliac joint and allowed the separated symphysis to come together.

The patient was replaced in the dorsal position, and with one finger behind the pelvic bone the obturator foramen was located on the patient's left. A long needle was passed on the finger followed by carrier and a No. 1 silver wire was carried over the right side and passed from within out and brought together in front and slowly twisted assisted at each twist by lateral compression. Particular attention was given to see that the bladder and urethra were not injured either by the compression or by the suture.

As the separated ends came closer and closer together the twisting of the wire became more difficult chiefly for two reasons: first the receding oblique surface of

Fig. 1. Four inch separation of symphysis pubis.

Fig. 2. Showing distortion of the sacro-iliac joint.

Fig. 3. Post-operative roentgenogram showing wire through the foramen and plate across the symphysis.

the symphysis and second the strain of the silver wire as evidenced by the great force necessary to twist it. The wire was twisted until the bones were in contact, the ends of the symphysis having been previously curetted.

Feeling that this single suture did not fulfill all the requirements for fixation of the pelvic girdle, two single Lane plates, one screw in each end, were placed across the symphysis, and the wound closed leaving small gutta-percha drain in each angle.

Convalescence was rapid and complete. Healing took place *per primam* throughout except at the site of one drain, which continued to discharge serous-sanguinolent fluid of small quantity which was later found to be due to small piece of the gutta-percha drain that became separated and kept up the irritation.

Eight weeks after the first operation, as the roentgenograms showed that the screw in the Lane plates had become dislodged, the plates were removed, perfect union followed, and the patient was allowed to sit up with supporting belt on.

It is now about 8 months since she had walked on, and it was necessary for the patient to learn again how to step. This was accomplished and she left the hospital walking very well on the level, but a little diffident on going up and down stairs.

Fig. 4. Roentgenogram showing result 6 months after operation.

It is now more than 10 months since the silver wire was inserted through the obturator foramen and up to this time it has given no sign of penetration there.

CONCLUSIONS

1. That inability to walk during the post-operative convalescence should call for an examination of the symphysis pubis.

2. That any separation of the pubic joint should call for a retention apparatus of suitable size and fitted to keep the separated bones in contact.

3. That in cases of unusual separation which are filling standing, the obturator foramen affords the safest and surest method of restoring the integrity of the pelvic girdle.

4. That in our hospital records no case has presented itself requiring operative procedure for separation, nor has any analogous case been found in surgical literature.

TRANSPLANTATION OF THE ABDUCTOR HALLUCIS TENDON IN THE SURGICAL TREATMENT FOR HALLUX VALGUS

B. JOSEPH E. FULD, M.D., NEW YORK

Instructor in Operative Surgery, College of Physicians and Surgeons, Columbia University; Assistant Visiting Surgeon, Government Hospital

ANY operation for hallux valgus must have in view (1) the correction of the deformity, (2) the prevention of recurrence, (3) the preservation of the longitudinal arch.

The usual operation of the resection of the head of the metatarsal bone meets only the first requirement. To meet the second requirement

I devised and found feasible a transplantation of the tendon of the abductor hallucis from its usual insertion in the plantar surface of the base of the first phalanx to the periosteum covering the middle of the inner surface of the same bone. To meet the third requirement, I have confined the bone section to the exostoses, when possible,

Fig. 2 Showing bony projection *B* & *C* of excision

without resection of the head and follow this by suture of the capsule over the denuded bone area deep to the transplanted abductor tendon to prevent involvement of the transplanted tendon in the subsequent and inevitable callus.

The histories of a moderately large number of cases treated by this operation show that it will be rarely necessary to resect the head of the metatarsal bone.

After a thorough trial of the various operative methods this operation has given me the best results. The simplicity, ease and safety with which it can be performed in my opinion warrant its trial in these cases. It allows the patient to walk well and absolutely without pain; the great toe remains in perfect position and is naturally mobile and it does not affect the weight bearing function of the foot.

TECHNIQUE

The steps of the operation are as follows:

1. Under general anesthesia forcibly move the great toe in all directions stretching the contracted tissues.

Fig. 3 *B* Bony projection *T* tendon of abductor hallucis *C* capsule.

Fig. 4 *C* Capsule *T* tendon of abductor hallucis to be transplanted

2. Paint the foot and toes with iodine.

3. Make a slightly curved incision about two inches long beginning one half inch in front of the bony prominence on the inner side of the great toe. A semicircular flap of skin and subcutaneous tissue is dissected free from the bursa and turned down over the joint so that the subsequent scar will not be at a point of pressure (Fig. 1).

4. The soft parts are retracted. The tendon of the abductor hallucis is now seen under the head of the metatarsal bone and is dissected free from its attachment to the base of the first phalanx (Fig. 2).

5. A flap is now made including the bursa, capsular ligament and periosteum and turned down exposing the bony deformity to view (Fig. 3).

6. Apply the chisel to the bone at the junction of the condyle and globular head of the meta-

Fig. 4. *T* Tendon transplanted and sutured *C* capsule sutured.

tumal and excise the hypertrophied bony projection longitudinally backward (Fig. 3)

7. Irrigate the wound with hot saline solution.

8. Replace the capsule to cover the raw surface of the bone and fix it with catgut sutures.

9. The tendon of the abductor hallucis is now transplanted to the middle of the inner surface of the first phalanx, and sutured with fine silk or Pagenstecher thread, to the periosteum (Fig. 4)

10. Close skin in usual manner

11. A plaster-of Paris bandage is applied to the foot and toe holding the toe in a slightly overcorrected position and allowed to remain for a week or ten days

AFTER TREATMENT

If the patient carefully observes in strictness as to the wearing of properly shaped shoes, no further post-operative treatment will be necessary

APPARATUS FOR USE AFTER HARE-LIP OPERATIONS

By HERBERT L. SMITH, M.D., NASHUA, N.H., HAMPSHIRE

FOR many years I have used a device made of brass spring wire to take the strain from the sutures after hare lip operation. The wire is bent into a shape something like a broad wishbone, the end of each arm pushing the cheek and lip toward the median line. Ordinary corn plasters are fixed to the loops of the wire. These will adhere to the skin for ten days or more.

Although I use deep tension sutures of silk on

the inside of the lip it is chiefly the wire spring which holds the edges in position. The mucous membrane is sutured with catgut and the skin with horsehair. The method of application is shown in the illustrations. In this case the apparatus was made of No. 10 wire. In older children a larger size has sometimes been used. The accompanying picture was taken a week after operation.

Fig. Device made to keep the strain from sutures after hare-lip operations.

AN IMPROVED SUBSTITUTE FOR IODIZED CATGUT SUTURES

II BACTERIOLOGICAL TESTS

BY CASSIUS H. WATSON, B.S., M.D., BR. KLAN

In a previous communication (1) the author reported certain experiments which demonstrated that a double salt of iodine—potassium mercuric iodide—possessed marked advantages over iodine for the impregnation of catgut sutures. Briefly, the results were as follows:

1. Potassium mercuric iodide in water and alcoholic solutions possesses more than ten times the germicidal efficiency of iodine.

2. Sutures impregnated with this double salt have a tensile strength 6.5 per cent greater than plain sutures and 16.5 per cent greater than iodized sutures.

3. Sutures impregnated with the double salt when sealed in tubes containing a suitable storing medium show no deterioration when the tubes are subjected to boiling water.

The substitution of potassium mercuric iodide for iodine seemed to constitute such a distinct improvement in the preparation of antiseptic sutures that it was deemed desirable to develop a method for thus impregnating suture materials and then to subject such products to exhaustive bacteriological tests. The experiments reported below were planned to determine—

1. The efficacy of the procedure in producing sterile sutures and

2. The degree of antiseptic or germicidal powers imparted to such sutures by their impregnation with potassium mercuric iodide.

To this end therefore raw dehydrated catgut sutures were treated with an alcoholic solution of this salt placed in tubes with various storing fluids and the tubes sealed. Heat sterilization was omitted in order to make the conditions of the test more exacting. All tests were controlled with samples of plain chromic and iodized catgut from several reliable manufacturers.

II. STERILITY TESTS

Experiment Technique. The tubes containing the sutures were immersed for one hour in warm bichloride of mercury solution (.001) drained free from the solution, broken the suture removed with sterile forceps, washed quickly and thoroughly in 100 ccm sterile water the adherent water roughly removed by draining the suture against the inner surface of the container and then immediately placed in tubes containing 75 ccm of nutrient broth. Duplicates were placed in similar tubes of broth covered with a thick layer of sterile liquid paraffin to insure anaerobic conditions. All tubes were incubated for seven days at 37°C. At the end of that time, if no visible growth had appeared, as further control agar slant were inoculated with portions of the broth in which the suture had been incubated. Twelve tubes each of lots and were tested.

Result. All tubes showed absence of growth, and sub-inoculation of the broth on agar proved their sterility.

Experiment. Sutures of both plain and chronic catgut impregnated with potassium mercuric iodide are not tubed, but instead were preserved in paper envelopes. They were subjected to no heat sterilization, and further no preps. clones were taken in handling them to prevent bacterial contamination. Twelve sutures were tested as in Experiment.

Result. All remained sterile.

Experiment 3. I order to determine whether the absence of growth in the broth in Experiments 1 and 2 was due to the actual sterility of the sutures or to the inhibiting action of the impregnating substances on bacteria already in the gut the strands from ten of each of the incubated broth tubes of sutures and were removed under aseptic precautions, washed again in water and planted in fresh tubes containing 75 ccm. of broth.

Result. In no case was there growth.

The outcome of Experiments 1, 2 and 3 would seem to attest the efficiency of the method for insuring the complete sterilization of the suture materials.

III. COMPARATIVE BACTERIOSTATIC EFFICACY OF SUTURES IMPREGNATED WITH IODINE AND WITH POTASSIUM MERCURIC IODIDE

Experiment 4. Twelve tubes from lots A and B and A and B and four tubes each of all the other lots were first tested for sterility by the method described above. After seven days incubation all were found to be sterile.

To each tube was then added 1 ccm. of 24 hour broth culture of virulent and actively growing strain of staphylococcus pyogenes aureus. Table I shows the result after further incubation of seven days.

Experiment 5. T test further the inhibiting action exhibited by all the sutures of lots A and B and A and B and of two sutures of lot 9 and one suture of lot 8 the broth tubes containing these particular sutures were then inoculated with 5 mm. loopful of 48-hour pellicle of pure culture of bacillus subtilis. The result may be thus tabulated.

In none of the tubes containing sutures A and B and 1A and B was there growth, while only one tube of lot 9 showed freedom from infection. The inhibiting power of the sutures impregnated with potassium mercuric iodide was marked.

Experiment 6. I order to determine whether the inhibition of growth in the tubes containing sutures A and B was due to an antiseptic or germicidal action the following test was made.

From 12 tubes each of lots A and B and 1A and 1B which had been inoculated with staphylococcus from 24 tubes each of lots 1A and B and A and B inoculated with bacillus subtilis, and from one tube of lot 9 all 12 which had shown no growth on incubation (Experiments 4 and 5) 5 and 10 ccm. of the broth as pipetted in 75 ccm. of fresh broth. The purpose was to dilute the possible content of impregnating substance dissolved from the suture in the first broth tube and by this dilution to do away with any purely inhibiting action. If growth occurred, it could then show that the suture possessed merely antiseptic properties while, if no growth occurred

it would indicate that the catgut contained a sufficient amount of the impregnating substance not only to inhibit but actually to kill the organisms. The result is shown in Table III.

9	0	0	0	0	0	0	0	0	0	0

1. *permeant* sutures of lot 1 and 2 were washed sterile with distilled water in deep petri dishes the covered with sterilized agar which had been inoculated with staphylococcus aureus and the plates incubated.

It was felt that such an experiment would in the first place approximate *in vitro* the conditions existing about a suture planted in human tissues further it would demonstrate to what degree impregnating substances diffuse through such a medium and to what extent an antiseptic or germicidal zone is thus created.

Figures 1 and 2 show in a striking way the marked inhibitory power of catgut impregnated with potassium mercuric iodide as compared with iodized catgut. The lighter areas about the imbedded sutures represent zones of no bacterial growth while the darker portions in the plates are masses of staphylococcus colonies. It should further be remembered as has been shown in Experiment 6 that in the case of the former sutures the inhibiting action is truly germicidal while in the case of iodized sutures the action at most is only antiseptic. It seems particularly significant that the potassium mercuric iodide can diffuse and exert an inhibitory action to such an extent through a medium as dense as agar. Iodine on the other hand has only a slight diffusibility.

If this experiment can be considered as a criterion of the conditions obtaining about a suture

imbedded in human tissues it is evident that catgut sutures impregnated with potassium mercuric iodide protect the tissues against bacterial infection to a much greater degree than do the usual iodized sutures.

DISCUSSION

Experiments 1 and 2 demonstrate that the process of impregnating catgut sutures with potassium mercuric iodide renders them sterile and the efficacy of the method is attested by Experiment 3 which shows that even when such sutures are preserved and handled with entire neglect of aseptic precautions they remain sterile. In Experiments 3, 4 and 5 the results prove that sutures impregnated with potassium mercuric iodide have sufficient inhibitory power to prevent the growth of staphylococcus pyogenes aureus and even of the sporulating bacillus subtilis while the ordinary iodized sutures have little or no such action (one suture out of 64 inhibited both the staphylococcus and bacillus subtilis but failed to kill them). Experiment 6 shows further that this inhibiting action of potassium mercuric iodide is not merely bacteriostatic but is truly germicidal.

CONCLUSIONS

1. Potassium mercuric iodide is an improvement over iodine for the impregnation of suture materials in so far as their physical properties are concerned (1).
2. Sutures impregnated with potassium mercuric iodide possess a decidedly greater inhibiting power on the growth of bacteria than do sutures impregnated in the usual way with iodine.
3. The inhibiting action of potassium mercuric iodide sutures is a germicidal one.

TRANSACTIONS OF SOCIETIES

CHICAGO GYNECOLOGICAL SOCIETY

REGULAR MEETING HELD FRIDAY EVENING, APRIL 21 1916 WITH THE PRESIDENT
DR. CHANNING W. BARRETT IN THE CHAIR

EXTERNAL INCOMPLETE RUPTURE OF THE UTERUS FOLLOWING SUBPERITONEAL HEMORRHAGE

Dr. A. J. WIGGAM (Augustana Hospital, service of
Dr. R. W. Holmes)

On February 7 1906 at 1:15 p.m. Mrs. A. H. was admitted to Augustana Hospital in labor. The patient was married, 38 years of age, mother of six children, the oldest being 6 years and youngest 4½ years. Each birth had been normal and easy. Labor was due February 17 1916 as the patient had menstruated last on May 19 1915. The patient did not know when she conceived or when life was felt. From the history obtained it would seem she had had no trouble during the pregnancy. On February 6 at 3 p.m. the patient went into labor. At 3:30 a.m. the following morning physician was called and found the head floating membranes intact, and slight amount of dilatation. At 2:30 p.m. the same day the head was fixed, with complete dilatation, and the membranes intact which were then ruptured artificially. At 5 o'clock the occiput was to the right and the head low. Without anæsthesia forceps were attempted several times, but without success in locking the instrument. As the patient had not been prepared on admission to the hospital she was taken care of at the hospital by the nurse in the delivery room. The patient was catheterized, but only a few drops of bloody urine was obtained. Labor was strong and the pulse was 114 at 10:45 p.m. after the preparation was completed. Five minims of pituitrin was given hypodermatically and contractility became active. Diastals of recti muscles was very marked. At 10:50 the pulse was 132. Five minims more of pituitrin was given hypodermatically and at 11:05 o'clock a female child weighing 8 pounds 13 ounces was born spontaneously. At 11:10 the placenta was expressed by Crede.

At 11:20 the patient had a pulse of 40 and respiration of 32, and was fairly comfortable. Sometime after midnight she vomited a large amount of yellow fluid. Proctodials of 500 cubic centimeters of normal salt-solution was given at 2 a.m. and again at 6 a.m. and all was absorbed. The patient did very well and at 5:3 p.m. the first day of the puerperium (February 28) the patient was given an ounce of oleum ricini on account of dyspepsia

from excessive tympany and an enema the following morning with good results. At 8 p.m. the first day of the puerperium (February 28) the patient was catheterized. As the patient had voided 4 ounces at 10:30 a.m. the catheterized urine was cloudy specific gravity 102. It was acid, albumin was present 1 gram per liter leucocytes 1 hyaline casts, granular casts and some amorphous urates were found.

On the second day of the puerperium (February 29) at 4 p.m. the patient had a temperature of 100 pulse of 88 and respirations of 20 no chest findings. There was considerable tympany but the patient stated that she always had this with each puerperal period and that she usually got relief with oleum ricini. From that time on patient had fever involuntary bowel-movement and was not doing well. About midnight (March 1) the patient vomited a great deal of coffee-ground fluid, but after gastric lavage she felt quite comfortable. The following morning she complained of severe abdominal pains and omitted great deal of clear fluid. The temperature was 100 pulse 40 thready weak, and of poor volume. Respirations were 24. At 4 p.m. the fourth day of the puerperium (March 2) the temperature was 104 pulse 140 respirations 36 and there were involuntary bowel-movements. During the afternoon of March 3 and morning of March 4, the patient had involuntary urination but was quite comfortable. Temperature 100 pulse 40 and respirations 38 at 4 a.m.

About 8 a.m. on the fourth day of March, the fifth day of the puerperium, the patient suddenly collapsed, the pulse became thready and weak and of low volume, recorded as 60 at 8:50 vomited coffee-ground material, became pulseless, and died at 9:35 that morning.

Post-mortem examination of her pelvic viscera was permitted and this was performed by Dr. Karl Lewis. The abdomen was distended, and on opening the peritoneum, an almost explosive gush of blood escaped from the incision, running over onto the floor. Few fresh adhesions were present. The uterus was hardly involuted. The peritoneum separated from the uterus from within the left broad ligament across the anterior wall almost to right broad ligament. The bladder was separated to the vaginal attachments. In the uterine wall under

the left broad ligament an incomplete external rupture was found. This was probably due to a rupture of an intramural blood vessel with a development of a subperitoneal hematoma, which when dissected separated the loosely adherent peritoneum of the anterior uterine wall and the bladder and ruptured enteroabdominally on the fifth day of the puerperium.

The baby was born with asphyxia pallida and was revived with difficulty. The child did not breathe well for 10 to 15 minutes and oxygen was administered. The following morning it died respirations becoming slower and slower. The child had several convulsions.

Dr. RUDOLPH W. HOLMES. On admission this patient was exceedingly tympanitic, which continued until her death. She stated she always had this tympany with each puerperium. The question arose had the uterus been bruised by the forceps attempts was the injury due to prolonged pressure of the lower segment against the pelvic brim or was it due to stretching of the lower segment that is a threatened rupture of the uterus. On account of the tympany this could not be determined. In a cursory review of the literature I find the report of a case in the service of the Boston Lying in Hospital some ten years back which presented a rupture of a sinus posteriorly in the lower segment. The patient died of an intraperitoneal hemorrhage. We know that vessels rupture occasionally into the broad ligament producing a broad ligament hematoma.

A MEMBER. When do you think the rupture occurred?

Dr. HOLMES. Unquestionably during labor or at least shortly post partum. Unquestionably an interstitial intramural hematoma formed within the cavity found in the uterine wall under the anterior fold of the left broad ligament. Later under the influence of the mild peritonitis and metritis, the wall broke externally after an extensive dissecting hematoma had raised the loosely adherent peritoneum and bladder and on the fifth day the peritoneum ruptured. It may not be questioned that the hematomatous sac ruptured at 8:30 a. m. when her collapse came.

A MEMBER. How do you account for the blood which was present in the bladder when she entered the hospital?

Dr. HOLMES. Hematuria is not infrequently found in labor especially obstructed labor due to pressure congestion with minute apoplexies of the vesical mucous membrane and rupture.

A MEMBER. Was the bladder separated from the uterus?

Dr. HOLMES. From the appearance of the specimen the primary rupture occurred at the left broad ligament at which point there was a distinct cavity which almost extended down to the uterine mucosa. The loosely adherent peritoneum of the anterior uterine surface was stripped off from the left to the right broad ligament. Likewise the entire bladder

was separated from the uterus down to the attachment to the vagina. It was as completely accomplished as it would have been in a total hysterectomy.

PERITHELIOMA AND ENDOTHELIOMA OF THE UTERUS

Dr. W. A. Newman Dorland read a paper entitled Perithelioma and Endothelioma of the Uterus.

A CRITICAL REVIEW OF THE LITERATURE PERTAINING TO THE RELATION BETWEEN GYNECOLOGY AND NEUROLOGY

Dr. Richard R. Smith, Grand Rapids, Michigan, read a paper entitled A Critical Review of the Literature Pertaining to the Relation between Gynecology and Neurology.

THE LEUCOCYTES IN PREGNANCY, LABOR AND THE PUERPERIUM

Dr. JOSEPH L. BAER read a paper (by invitation) entitled The Leucocytes in Pregnancy, Labor and Puerperium. (See p. 597)

DISCUSSION

Dr. CHARLES S. BACON. I think the tables given will be very interesting for study when one can look them over a little more carefully than has been possible here.

I have been in the habit of making a routine count generally on the first or second day after labor simply for the purpose of comparing that with a subsequent count that would be made in case of any rise in temperature. We have found always a rather high leucocytosis, about agreeing with that given in the tables tonight. The difference in the reports of various authors have been so great that I had about given up any hope of making any use of the leucocyte count in general in determining the prognosis of the case in any respect whatever. I regard this as the best collection of cases certainly the best work that I know anything about and I believe that we will make use of it in the future.

Dr. GILBERT FITZ PATRICK. In order to check up some of these findings we carried on some investigations in our own clinic. We made use of Bier's pump during lactation and after having used the pump on several occasions in comparing the count we found where the pump had been used rhythmically at nursing and then making a count shortly afterward there was a slight tendency toward an increase of the lymphocytes.

A CONTRIBUTION TO THE ETIOLOGICAL STUDY OF OVARIITIS

Dr. CARL HENRY DAVIS (by invitation) read a paper on A Contribution to the Etiological Study of Ovaritis. (See p. 560)

DISCUSSION

DR. C. S. BACON Without attempting to discuss this paper I would like to ask one or two questions. I understood that the author assumed that fibrocystic degeneration and ovaritis are synonymous terms. I do not know exactly why I understand that it is assumed that bacteria cause the fibrocystic degeneration. I do not know why. To prove that ovarian infection must be hematogenous two cases were given where there was no connection between the vagina and the ovary. In one of those cases, however, there had been an abdominal operation with drainage, and of course that would furnish a mode of entrance for the bacteria into the ovary. In the other case there was no such possibility but I suppose there was the possibility of an infection by the lymphatic route.

Although these objections do not by any means show that there is not a hematogenous infection of the ovary and I suppose all must admit its possibility still in the establishment of a positive pathogenesis and carrying it so far as to suggest the treatment of local infections as local foci for the prevention and cure of infection in other parts of the body it is necessary or desirable at least to absolutely eliminate other methods of infection.

DR. N. SPROAT HEARNEY Experience shows that a blood borne infection can cause pelvic inflammation, as witness the occasional suppurations with bacillus typhosus of ovarian cysts in the course of typhoid fever. I have had one ordinary pelvic abscess which developed during a typhoid fever and yielded the bacillus typhosus in pure culture. Dr. Davis cases with blocking of the lower passages through malformations of development and chronic inflammatory changes in the absence of a history of acute disease absolutely show that also chronic pelvic lesions may result from infection brought through the blood stream. Now, since other departments of medicine and surgery through the work instituted by Rosenow show daily convincing evidences of the production of chronic inflammatory processes in various organs as a result of a chronic distant focus it does not seem strange to me that the same may be true of the pelvis as is true of other fields.

It may be a question as to whether this work of Dr. Davis is conclusive in this particular point that chronic cystic disease of the ovaries results from blood borne streptococcus viridans infection from distant foci.

DR. MARK GOLDSTEIN What has always puzzled me in a case of chronic ovaritis where one opens the abdomen and finds both ovaries affected is which one of the ovaries will be sterile, which one will give trouble later on, and which one is infected by the streptococcus viridans? If we leave the ovary the patient comes back with symptoms worse than the symptoms of the artificial menopause because she has had severe operation and still has the pain complained of before the operation and still which has been operated upon and has not been cured if her symptoms is not satisfied.

I would like to have Dr. Davis explain how we can tell when both ovaries seem diseased, which one is sterile and which is not.

DR. DAVIS (closing the discussion)

While the possibility of a lymphatic infection in these cases has not been taken into consideration the experimental work which has been carried out and which you can read in the *Journal of the American Medical Association* April 15, 1906 I think gives pretty strong evidence of the hematogenous origin. So far as telling which ovary to leave and which one to take out I do not know any more about how to choose between them now than I did two or three years ago. I have studied and gone over carefully the symptoms which are given by the patient. I studied the pathological findings as recorded by the operator. I have studied the ovaries as seen under the microscope and I do not know anything more about how to choose between them now than I did three or four years ago. So that when I am operating on a case I keep in mind and have the nurse read to me the carefully recorded history of the symptoms and if I find two ovaries with apparently not much choice between them, in a young woman, and her pain has all been on the right side, I make it a practice to leave the left ovary. If her pain has been on the left side I make it a practice to leave the right ovary.

CORRESPONDENCE

To the Editor I find that through an error in copying the manuscript for Dr. Murphy's article on "Bone and Joint Disease in Relation to Typhoid Fever" which appears in the August issue of *SURGERY GYNECOLOGY AND OBSTETRICS*, credit was not given to D. Charles M. Jacobs for certain paragraphs taken from his excellent article "Spontaneous Luxation of the Hip-Joint as a Sequel of Typhoid Fever," which was published in the April 10, 4 issue of the *American Journal of Orthopedic Surgery*. We greatly regret this unfortunate error and wish to say that it was an unintentional oversight that Dr. Jacobs' name was omitted.

D. MATTHEIAS, Secretary to the late Dr. Murphy

A CRITIQUE OF NEW BOOKS IN SURGERY

By MAJOR G. SEELIG, M.D., St. Louis

FOR several months past there have appeared comparatively few books devoted to the technical side of surgery. Recently, by contrast, the technical side has been emphasized again, and this month we have three volumes devoted almost unqualifiedly to the Simon pure art side of surgery. Of course a coincidence of this sort—and it is a mere coincidence—calls for no comment. The activities of men as individuals and as groups always show a tendency to manifest themselves in waves. There is this of interest, however, in the three volumes under consideration, namely, that each embraces a different field of technique, thus driving home the lesson that even the so-called carpentry side of surgery demands for its mastery a fairly wide acquaintance with an ever broadening field of activity, a field broadening with such rapidity and such inevitableness that specialization is being forced upon us willy nilly, not only by the demands of an academic grasp of fundamentals, but also by the requirements of specialized technical procedures. We shall probably revert to this later in the review. For the time being it is only necessary to point out that one of the three books is a hardy perennial on general technique—an operative surgery written by a master and appearing now in its seventh edition, another deals solely with the technique of the administration of anesthetics, and finally the last one is devoted to technical procedures on the upper air passages.

As a whole, the three treatises are clear, cut, concise, and admirably specific both in their purpose and in the way they set about to accomplish it. This is saying much, for as a rule the average description of a simple operative procedure is milky maddening. I have often thought that much of the travel side of surgery—the peripatetic meanderings to the clinics of other men—owes its origin to the fact that the descriptive art of surgical writing is so feebly developed. Men want to see for themselves that which the cold and unresponsive printed page fails to drive into their consciousness. In furnishing a tentative explanation of these surgical wanderings I am of course not deprecating them for they are truly among the best things in the life of a surgeon. The point is that men find difficulty in describing a complicated act on paper. The following quotation, selected from the writings of a humorist, is appropos and illustrates the point to perfection. A friend writes to the humorist

inquiring how to tie a bow tie, and receives the following answer: "You hold the tie in your left hand and the collar in the other. Slip your neck in the collar and cross the left hand end of the tie over the right with the left hand, steadying the right end with the other hand. Then drop both hands, catching the left with the right and the other with the other. Reverse hands and pick up the loose ends with the nearest hand. Pull this end through the loop with your unengaged hand and squeeze. You will find the knot all tied and all you have to do is to untangle your hands."

WHEN one finds himself face to face with a heavy tome like this seventh edition of Binnie's classical work, he covertly prays for the gift of condensation. Very recently a critic demonstrated this gift by reviewing Binnie's *Operative Surgery* in remarkably small compass, driving home his opinion in the following short introductory sentence: "In the dozen years Binnie's *Operative Surgery* has been before the profession it has grown steadily in size and importance until it has become as nearly indispensable a reference work as such a book can be." An affirmative and well intoned Amen to the above expression of opinion would constitute an adequate book review in this instance for those who know their Binnie demand no critique and those who do not know him ought surely to have acquaintanceship forced upon them by the information that he is indispensable.

Convention demands, however, more than a recommendation to purchase. It therefore becomes necessary to point out that the seventh edition, like its predecessor, appears in one volume form—bulky and full but manageable with perfect comfort. In common with all the previous editions, this one sets up as its aim the constant endeavor to give aid to the surgeon when he is in trouble. One fact alone furnishes assurance that the aim has been accurate, and that fact is the large number of men who in past years have expressed their dependence upon this book.

The general management of the parts remains as heretofore. There are evidences scattered throughout the whole volume of emendations and deletions and there is a notable addition of quite a number

NEW ALLOW OPERATIVE SURGERY By JOHN FAIRBANK Binnie, A.M.
C.M. F.A.C.S. 7th ed., revised and enlarged. Philadelphia: P.
Blakiston, Son & Co., 1916.

of new cuts that illustrate the text admirably. Several of these cuts are from remarkably recent current literature. In all, three new chapters have been added: one on cardiac surgery, a short one of nearly three pages on retroperitoneal neoplasms, and an appendix on war surgery written by Dr. Walter S. Sutton. This chapter by Dr. Sutton, although it is particularly well done considering the exigency of space, seems to mirror the tendency of the times rather than to possess any large inherent surgical value. This opinion, however, may be faulty owing to the fact that supersaturated as we all are with surgical war reports written in *extenso* we are very apt to sniff at a résumé of thirty pages.

There is practically nothing of consequence in the field of operative surgery that one cannot find in this volume. Furthermore, when he finds it, it is described, without exception, in the most unmistakable fashion. There are no bow tie fassions lying around loose. If one were forced to point out defects he could only mention several bits of evidence of careless proof-reading, and possibly suggest that Dr. Binns, for safety's sake, should point out more clearly the dangers inherent in the various proposed methods of curing hydrocele by the injection of iodine carbolic acid, and other irritant chemicals. In a book of this sort more space ought not to be devoted to insinuating caution than to describing methods of introducing potential agents of gangrene into closed cavities.

But after all has been said the final fact remains that the book comes about as near being a surgical bible as anything non-biblical can.

THIS next book limits itself to the technique of anesthesia. Practically everyone who will first read the preface carefully and then go through the text, will reach the conclusion that this volume is in a class by itself. It has been said by someone that good writing depends most largely upon proper thinking. Here is a book that seems to have been thought out well in advance of writing it. There is definiteness of arrangement, a clearness of exposition and a critical selection of data that makes it serve exactly the purpose that the author had in mind, namely, a ground work upon which the student interne, and general practitioner may acquire a more comprehensive knowledge of the art of anesthesia. I know of no other text that I would so gladly place in hands of junior internes indeed, the great body of internes have been waiting for a practical treatise of just this sort.

Of course it is true that one lays down the book, after going through the three hundred odd pages without a new concept of the theory of anesthesia, of the literature of the subject, or of the underlying physiology or physiological chemistry of the lachrym bodies. But if one cavils at this, it is because he failed to read the preface, and therefore missed the purpose of the work. Flagg's object is distinctly

the *art* as contrasted with the *science* of anesthesia; and it is art with a large A, for nowhere in the text does one find a scintilla of evidence of polemic adherence to any special technique of administration.

Nothing Flagg very wisely says should be permitted to dominate over the art in the broader sense. The technical principles underlying the use of anesthetics serve as the keynote in every chapter.

And these chapters are cleverly arranged so as to be very inclusive without being burdensome to the beginner. Part I, made up of thirteen chapters, is devoted to general anesthesia, local anesthesia and mixed anesthesia. Under general anesthesia, there is discussion of complete and incomplete (rausch) general anesthesia, a detailed discussion of the induction and maintenance of and recovery from general anesthesia, the signs of anesthesia, their significance and interpretation, either by the oral, pharyngeal and intratracheal insufflation methods ethyl chlorid, chloroform, and finally nitrous oxide alone and in combinations with oxygen and ether. Each anesthetic is dealt with under the headings General Considerations and Technique of Administration, and always in the most eminently practical fashion. Carefully selected illustrations do much toward clarifying the text.

The twelve pages devoted to local anesthesia are necessarily totally inadequate and we believe the author could have left them out to advantage, merely confining himself to volatile anesthetics. Local anesthesia has grown to dimensions far and away beyond small compass even when skillfully condensed by Flagg. Of course, such a change of title would have cut out the chapter on mixed anesthesia, but till we think it would have been worth while. By mixed anesthesia Flagg means spinal anesthesia. Heretofore the phrase mixed anesthesia has referred to compounds such as the A. C. E. mixture or to mixed local and general anesthesia. We wonder whether Flagg has not introduced an element of confusion in changing the nomenclature.

Part II is devoted to Factors Incidental to the Actual Administration of the Anesthetic, and discusses preliminary medication, post-operative treatment duties of the nurse, before, during, and after anesthesia, rebreathing emergency anesthesia, anesthetist's records, aspirators, and finally a closing chapter on The Point of View of the Patient. This final chapter on The Point of View of the Patient is, in its way a classic. It breathes a spirit that one rarely encounters in a medical book, and ought to be issued in leaflet form and taught catechism fashion to every anesthetist, be he embryonic or full fledged.

THIS next volume is the one referred to earlier. In this review as forcing upon us the conviction that even from the purely technical side we are grad-

nally being forced into more limited surgical specialization. The development of specialties within specialties and the gradual conquest of the more inaccessible cavities of the body to surgical approach have been a very interesting phenomena in the history of medicine. Nowhere perhaps is this evolution more aptly illustrated than in the field of laryngology. From Bozzini's first attempts to explore the human larynx by means of his crude laryngeal speculum and Garcia's subsequent perfection and practical employment of the laryngoscope until the achievements of the present day the march of progress may be said to have followed instrumental and mechanical inventive genius. The simple Garcia laryngoscope had its limitations for the more inaccessible parts of the larynx could not be examined with it. The introduction of suspension laryngoscopy and bronchoscopy by Killian and by Bruening marked an epoch in laryngeal surgery rendering possible the employment of surgical measures in the deeper parts of the tracheobronchial tree. The efforts of Jackson have still further developed this field of laryngology so that today endoscopy and laryngeal surgery constitute a special field in themselves.

Until within comparatively recent years lung surgery through the bronchi and the removal of foreign bodies from these parts was practically unknown. Jackson by his instrumental innovations his high degree of technical skill and by the repeated demonstrations of his methods upon the profession has so simplified the technique of this comparatively new and difficult branch of surgery that he has placed it within the reach of the surgeon of average skill. In considering therefore Professor Jackson's *Peroral Endoscopy and Laryngeal Surgery* it must be remembered that this field owes its advancement and its present technical development to the ingenuity of the author himself.

The work is not a textbook in the general acceptance of the term. It is an exhaustive reference work that unquestionably occupies the premier rank in this field. The volume consisting of 705 pages, is not confined solely to bronchoscopy and esophagoscopy. It deals fully with the surgical conditions of the tracheobronchial tree and the esophagus. Symptoms and diagnosis are omitted except in so far as they are necessary for the elucidation of the endoscopic text. The essential aim of the author has been to devote his subject matter to the technical aspects of endoscopy and laryngeal surgery and their associated operative problems. The author is quite candid in the discussion of his results and in order that bronchoscopy like any other department of science shall profit by its failures he gives (pages 318-32) the histories of some of his un-

successful cases of bronchoscopy and points out the reasons for the unavoidable lack of success. The book is divided into two parts. The second part is devoted to laryngeal surgery taking up the consideration of Tracheotomy, Intubational Dilatation of Laryngeal Stenosis, Laryngectomy, etc. and is intended for the already experienced surgeon. The same may be said to apply to part one.

Although Jackson is an enthusiastic advocate of direct laryngoscopy he nevertheless makes it a rule whenever such examination is possible to examine every case by the indirect method first except in infants and in urgent cases in adults.

What will appeal to the reader is the orderly arrangement of the work and the thoroughness with which details usually skimped are discussed. Thus the subjects of instruments (the author showing preference of course for those of his own invention or modification and with which he has obtained the best results), anesthesia, source of light, introduction of the esophagoscope etc. are taken up separately and in minutest detail.

That the acquiring of skill in bronchoscopy especially in the extraction of foreign bodies means traveling over an exceedingly rocky road may be judged from the author's dictum that no one should think of attempting for the first time to remove a foreign body from a human being until he has at least 100 times removed a foreign body from a dog.

And again, Endless patience is an essential. The greatest percentage of successes will accrue to him who is so constituted to work calmly and deliberately yet quickly and accurately under severe stress of prolonged work with one eye where a mistake or lack of promptness or accuracy may mean the death of the patient.

The chapters on Foreign Bodies in the Larynx and Trachea, Mechanical Problems of Foreign Body Extraction, Esophagoscopy for Foreign Bodies, Bronchoscopy in Diseases of the Trachea and Bronchi, Diseases of the Esophagus (the latter comprising 89 pages) are all exhaustive treatises on their respective topics and reflect Dr. Jackson's wide experience and keenness of observation. This brings up another point. While other laryngologists may differ with Jackson on some points Dr. Jackson's statements bear the stamp of deep conviction resulting from broad experience.

The book is profusely and splendidly illustrated and it is safe to predict that when the warring nations in Europe will have resumed their former positions in peaceful science there will be a demand for the translation of the work, certainly into German, and perhaps also into other foreign languages.

BOOKS RECEIVED

Books received are acknowledged in this department and such acknowledgment must be regarded as sufficient return for the courtesy of the sender. Selections will be made for review in the interests of our readers and as space permits.

INTERNATIONAL ABSTRACT OF SURGERY

NOVEMBER 1916

COLLECTIVE REVIEW

PRESENT STATUS OF ROUND LIGAMENT SHORTENING AS A SURGICAL CURE IN UTERINE DISPLACEMENT

B. IDNEY A. CHALFANT, M.D., F.A.C.S., PHILADELPHIA
AND
WILLIAM A. MCGEE, M.D., F.A.C.S., PHILADELPHIA

THERE have been many reports of the operation of correcting displacements of the uterus during past years. Two of these were a little publicized, namely, those of that of Franklin H. Martin in 1884 and that of Albert M. L. in 1887. These two articles have been freely used in the preparation of this review.

We have included in this review all of the operations for uterine displacement either abdominal or vaginal but have limited it to those in which the round ligament were utilized. For convenience the following classification has been adopted:

1. Inguinal
2. Vaginal
3. Intra-abdominal
4. Fixation to the anterior surface of the uterus
5. Fixation to the posterior surface of the uterus
6. Fixation to the anterior abdominal wall.

ABDOMINAL PERITONEUM—ALEXANDER TYPE

Alquié in 1844 first suggested this operation and performed it on the cadaver and on animals. The first record that we can find of this work is the report of a Committee of the French Academy of Medicine appointed to investigate the operation. Alquié describes his technique as follows:

With the patient in the horizontal position the uterus replaced the surgeon determines the

course of P. Ovarian Ligament and selects a point in the middle of it at which point a incision is made a little obliquely to the crural arch and about one centimeter in length. If the knife is carried too far a small branch of the superficial epigastric may be cut which can be promptly tied. The crural arch exposed an incision is made in it a little obliquely to its fibers and two centimeters in length always keeping to the middle part of P. Ovarian Ligament. Behind the cellular tissue thus exposed there appears a point of deep red color enclosed in a sheet of dense cellular tissue this is the round ligament called the utero-ovarian. Picked up with tissue forceps this cellular envelope is opened and the cord is seized and drawn out with careful manipulation.

The peritoneum presenting at the ring a delicate incision is made around the cord for the purpose of dividing the cellular fibrous sheath which accompanies it and it is freed with the handle of the instrument. Finally by gentle tension the cord is brought out side—it may be drawn out to the extent of 10 centimeters or more—then a threaded needle is passed through the thickness of the cord and is attached down in the lower end of the incision. The margins of the wound are reunited with two sutures after which the operation is done in the same manner upon the opposite side.

When the condition that this operation was proposed seventy years ago the reception accorded to what would today be rather a minor

operation shows very forcibly the wonderful advances of surgery

After giving an outline of the plan proposed by Alquié, the committee reassured the members of the Academy by stating

"To this brief description, which will suffice to show the importance of the operative procedure involved your committee wishes to add before going further that it is all pure theory that M. Alquié has never performed the operation except upon cadavers, and that he does not seem disposed to employ it in the living subject except in animals. This assurance once given we may proceed with less apprehension in considering his work.

And they finally gave this very qualified approval

The operation (which requires always its duplicate upon the opposite side) not being at all admissible in practice, we have the honor to propose that the Academy give its approval to M. Alquié for having had the prudence not to practice it upon the living subject and that it recognizes that there exists in his work some anatomical considerations worthy of interest.

In (1882) William Alexander (4) of Liverpool published his article in which he reported three cases. He devised the operation and developed the technique without knowledge of Alquié's work which had been done almost forty years before. His technique is very similar to Alquié's.

The operation is performed by cutting down upon each abdominal ring gathering up the ends of the ligaments freeing each from its nerve and gradually releasing them by patient and cautious traction from the neighboring tissues until the position of the uterus as ascertained by the finger in the vagina, satisfies the operator. The ligament is then stitched to the tissues around the ring and the loose ends attached to each other on top of the skin or rolled around two pieces of wood which are fastened together in the middle line.

Adams (5) (1882) of Glasgow had for two years been demonstrating in the anatomical rooms the same procedure but had never performed it on a patient. His technique is practically the same as that described by Alexander.

An incision made over the external inguinal ring and a very careful dissection carried downward expose the pale and struggling fibers of the round ligament as they emerge from the ring and take attachment to the dense areolar tissue of the mons veneris. When these fibers are grasped by the forceps *en masse* and steady traction is made, it is found easily practicable

to draw them freely outward to the extent of one or more inches. In the dissection care should be taken to exclude the inguinal nerve for its rupture under traction implies considerable pain. Under the necessary traction the peritoneum does not follow the ligament as it is extruded, but separates and peels off. There is therefore little risk of an inguinal hernia resulting and any such apprehension is reduced to a minimum when it is borne in mind that inguinal hernia does not commonly occur in the female. The incision about two inches in length should be made obliquely and directed toward the mesial line and this oblique direction will be found to facilitate the search for the ligamentous fibers much better than a vertical opening. The search for the fibers of the ligament must be made cautiously and with much patience and little haste for this is the difficult part of the operation. When fairly exposed clearly traced and isolated they should be grasped by broad pointed forceps—small polyp forceps are very suitable—and following the guidance of the ligaments, the forceps should be thrust well into the inguinal ring and the ligament laid hold of as high as possible. When it begins to yield to the traction it may be pulled out to any desired extent. Five or six catgut ligatures passed over and under the ligament will sufficiently ensure its attachment to the surrounding tissues while separate ligatures close the wound excepting at the most dependent part. Antiseptic dressing strict rest in bed and the action of the bowels restrained for a few days by means of opiates, should suffice for the after treatment.

There have been many modifications of the technique of Alquié Alexander Adams. The opening of the inguinal canal was advocated by Bompiani (6) Roux (7) Kocher (8), Chailot (9), Gardner (10) Cleveland (11) and Edelbohl (12). In an effort to increase the applicability of the operation Goldspohn (13) advocated opening the peritoneum at the internal ring and through this opening separating uterine or adnexal adhesions. This was also suggested by Fritch (14) Maly (15) and Kroening (16). Bouleux (17) for the same reason, combined the Alexander operation with a posterior colpotomy. Peterson (18) with either a transverse or median incision Sandberg (19) with a median laparotomy Kreutzmann (20) Kuestner (21) Schlemminger (22) Rumpf (23), and Palm (24) with a laparotomy by means of the anchor incision of Kuestner Rapin and laparotomy by the Pfannenstiel incision was used by Spaeth (25) Frantz (26) Werth (27) and Littauer (28).

FIXATION OF ROUND LIGAMENTS

Duret (29) and Franklin Martin (30) (1896) separate the distal ends of the ligaments from their attachments and bring one across the symphysis above the fascia and tie them together.

Abbe (31) (1896) splits the fascia over the canal and after separating the distal end from its attachments uses the loose end as a living suture for the double purpose of closing the canal and fixing the ligament.

Impallomeni (32) (1912) using the Pfannenstiel incision drills the os pubis from before backward and passes the free end of the ligament through this opening and sutures it to the ligament in front of the opening. A double pointed nail is then driven across the opening.

Figueras (33) (1913) splits the canal and draws out a loop of the round ligament. By means of blunt dissection and a ligature carrier this loop is passed upward beneath the external oblique out through the fascia again back and out and sutured. He thus makes three punctures of the fascia of the external oblique.

The advantages of the Alqué Alexander-Adams operation are that it does not necessitate opening the abdomen the shortening of the ligaments is in the normal course of the ligaments the strongest portion of the ligament is utilized and it does not interfere with subsequent pregnancy or labor. The disadvantages are its limited field on account of the difficulty of determining the absence of uterine or adnexal adhesions which contra-indicate the operation the danger of subsequent hernia the impossibility of locating and correcting the pathology of other abdominal organs in some cases painful scars and as reported by some operators a rather high percentage of recurrence. The modifications which involve opening the abdomen either by the vaginal or inguinal route have divested the operation of its greatest advantage.

Laparotomy by any of the ordinary methods gives opportunity to care for disease particularly of the adnexa or appendix and permits examination of the organs in the upper abdomen. With the abdomen opened it is much easier to shorten the ligaments by some intraperitoneal method than to make additional incisions over the inguinal canals. This type of operation appears to have at the present time a very limited field of usefulness.

VAGINAL OPERATIONS

Wertheim (34) (1896) seems to have been the first to use the round ligament in vaginal operations. He attaches the round ligaments 1 or 2

centimeters from the uterus to the vaginal wall. In one case he shortened the round ligaments by doubling them on themselves and suturing them with silk.

Guenther (35) (1896) suspends the uterus by the round ligaments by passing a catgut suture from within the abdominal cavity outward through the anterior abdominal wall and tying the sutures on top of the skin.

Kiefer (36) (1896) through the vaginal incision doubles the round ligaments as in Mann's operation.

Vineberg (37) (1896) gives his technique which he has used in two cases. After delivering the fundus Vineberg passes a suture on either side embracing the round ligament and a portion of the broad ligament adjacent to the uterus. These sutures are carried through the vaginal flaps below the pubic arch at the side of the pelvis and tied.

Byford (38) (1896) picks up the round ligament as close to the pubic end as possible and sutures it to the uterus above its normal insertion. This is combined with suture of the fundus of the uterus to the peritoneum covering the upper portion of the bladder.

Goffe (39) (1897) first delivers the fundus. Then the round ligaments are caught with forceps at a point as far from the uterus as can be drawn to the site of origin of the ligament. This distance is usually 2.5 to 3 inches. The intervening ligament is folded into a loop the tip of which is attached to the ligament distal to the forceps. The point originally caught is then attached to the uterus at the origin of the ligament and the three segments of the ligament sutured together.

Ries (40) (1901) divides the round ligament at its uterine end and separates it from the broad ligament for 4 centimeters. He then tunnels the anterior wall of the uterus with a knife and draws the ends of the round ligaments into this tunnel from either side and fastens them with catgut.

Childs (41) (1905) folds the round ligaments upon themselves about as in the Goffe operation and also shortens the sacro-uterine ligaments.

Shurman (42) (1913) divides the round ligaments 2.5 centimeters from the uterus and separates the proximal portion from its broad ligament attachments. This is then sutured to the upper surface of the anterior vaginal mucosa.

Vaginal operations on the round ligament are for the average operator not easily performed and have not become popular except in the practice of a few men specially skillful in operating by

this route. It is difficult to get an exposure of much of the ligament and they all depend upon the outer or weakest portion of the round ligament. There would also seem to be danger of causing sufficient traumatism during the operation to produce adhesions and possible trouble during a later pregnancy and there is no opportunity to examine for and correct the pathology of other abdominal organs. Operations of this type have a limited field in obese patients in whom a laparotomy is undesirable and possibly in those for whom extensive plastic operations are required where vaginal shortening of the ligaments would decrease the time of the operation and in this way lessen the risk.

INTRA ABDOMINAL FOLDING

Wylie (43) (1889) seizes the round ligament at its middle, scarifies the inner surface, and sutures the two folds together with the loop to the outer side.

Polk (44) (1888) freshens the inner surface of each round ligament for some little distance along its middle part and sutures the raw surfaces of the two ligaments together thus making an anastomosis between the bladder and uterus. Ruggi (45) unites a point of the round ligament near the internal ring to a point near the uterus with a single catgut stitch. Bode (46) does practically the same thing, but in addition takes a stitch into the cornu of the uterus.

Mann (47) (1895) catches the ligament with two forceps dividing it into three equal parts. The point at the outer forceps is sutured under the point where the round ligament is inserted into the uterus. The ligament at the site of the other forceps is then sutured to the outer extremity of the round ligament as it leaves the abdominal wall. In his first operations he used silkworm gut sutures but later silk or catgut, and finally used several fine catgut stitches along the course of the folded ligament. In this way he has a triple fold of the round ligament.

Jonesco (48) (1897) freshens the peritoneum at each end of the ligament and sutures these two raw surfaces and the sides of the loop together with silk. The layer of the broad ligament participating in the fold is then united by means of a suture passed in the form of a U.

Morris (49) (1900) makes a small opening in the peritoneum draws out a loop of the round ligament for two or three inches, sutures the folds of the loop together tucks the loop back into the opening of the peritoneum and closes the opening.

Byford (50) (1903) folds the ligaments to the inner side and sutures the ligament one half inch from the uterine end to a point one-half inch from the internal ring. The inner edges of the loop are touched with a chemical irritant and then sewed together. The end of this fold is then touched with the irritant and stitched forward and beside the bladder about opposite and a little above the level of the external inguinal ring.

Bissell (51) (1908) splits the round ligament longitudinally into an anterior and posterior portion. The greatest portion of each half is cut away leaving three-quarters of an inch of the distal part of the anterior half and the same amount of the proximal portions of the posterior half. These stumps are sutured, one to the uterus and the other to the cut end of the corresponding part of the round ligament, then sutured together and the broad ligament repaired. This is just the opposite of the ordinary operation for lengthening tendons.

Pankow (52) (1912) divides the round ligament at its middle sutures the proximal end over the internal ring and the distal end to the uterus, and then the two loops together.

Lorents (53) (1913) in his inaugural dissertation reviews the various operations and describes what he terms the N shaped suturing of the round ligament which he states was first performed by Zarati. This is very similar to the Mann operation in which the ligament is divided into three equal parts. Two loops are sutured into the internal ring and the other two to the uterus and the three segments beneath the broad ligament in a groove which has previously been made.

The early operations of this type all depending upon seroserosal adhesions furnished the greatest number of recurrences, and for that reason have been largely abandoned. The later ones in which the edges of the round ligament are freshened or the ligaments resected as in Pankow's or Bissell's operations would seem to be difficult to perform and to have no advantages over the more recent operations of fixation of the round ligaments to the anterior abdominal wall. In addition the operations of this type all fold up or resect the intra-abdominal portion of the ligament which is generally considered to be its stronger portion and depend for support upon the distal or weaker portion. This objection may be more apparent than real. When we consider the cases of retroversion that follow incomplete involution of the uterus and ligaments it would appear that at least in these cases the fault was with the intra-abdominal rather than the extra-abdominal portion of the round ligament.

FIXATION TO THE ANTERIOR SURFACE OF THE UTERUS

Dudley (54) (1890) denudes an oval area on the anterior surface of the uterus down to the vesical fold of peritoneum and a similar area on the inner surface of the round ligament of each side. These raw surfaces are then sutured together thus fixing the round ligaments to the midline of the anterior surface of the uterus at a point near the bladder.

Menge (55) (1904) catches the ligament near its middle draws it toward the midline and stitches the folds of the ligament together and then the loop across the anterior surface of the uterus on the level of the attachment of the round ligament. The folds of the broad ligament are then attached to the anterior surface of the uterus.

Coffey (56) (1905) seizes the round ligament with its surrounding peritoneum about one and one half inches from its origin and stitches it by four or five interrupted sutures of catgut to the side and front of the uterus about the insertion of the broad ligament then fastens the next inch and one half of the round ligament back to its original insertion with interrupted catgut sutures. The folds of the round ligament are then covered by bringing the peritoneum of the broad ligament over them with a continuous suture of catgut.

Latzko (57) (1908) fixes the most external point possible of each round ligament to the middle of the fundus of the uterus forming of the redundant portion a loop on the anterior surface with the convexity down and toward the midline. The inner portions of the two loops are sutured together and to the anterior surface of the uterus. The folds in the broad ligaments are then in turn sutured to the anterior surface of the uterus to close the openings and prevent internal strangulation.

Paudom (58) scarifies the inner surface of the round ligament, folds it up and sutures it to the cornu of the uterus and to the anterior uterine wall at the level of the cornu.

Jerie (59) dissects the round ligament free for the required distance makes a tunnel in the anterior wall of the uterine cornu one centimeter long draws the loop of the round ligament into this tunnel and sutures it at each end.

Wilks (60) (1912) brings both round ligaments across the front of the uterus and sutures them together and to the anterior surface of the uterus in the middle one half inch below the apex. The folds of the broad ligament are then sutured together and to the anterior surface of the uterus

for a short distance and the suture continued taking up the folds of the broad ligaments only down to a point one half or three fourths of an inch from the bladder. Sperling (61) (1906) simply quoted by Ashe (62) (1907) and Stewart (63) (1909) describe operations that are very similar to Menge's.

Of these operations the one devised by Coffey (56) has undoubtedly been the most popular in this country. He (64) in a later article gives in more detail the principles on which the success of surgical treatment of retrodisplacements of the uterus depends. He states that the support of all the abdominal organs is by folds of peritoneum that the round ligaments are muscular structures essentially a part of the uterus that muscular tissue has only one function contraction and that under continued strain the muscle will stretch. It is therefore illogical to depend upon the round ligaments for a constant support. In the operation he describes Coffey states that the uterus is supported by the broad ligaments and the round ligaments have time to rest and an opportunity as they are fixed under the peritoneum with catgut to shorten and straighten themselves.

Alieri (2) raises the point that an essential for stability of the correction lies in placing the uterus in its normal anteversion. The more the broad ligament is tensed and the lower the round ligament is fixed to the anterior surface the greater will be the elevation and anteversion of the uterus and the less the anteversion.

This objection seems to be met by Coffey (65) who in a more recent article reports the conditions found in five patients re-operated upon for other conditions. In all these the broad ligament was found holding the uterus in perfect position. The round ligaments had regained their normal size and their normal position under the peritoneum. In this paper the author reports 272 operations by his method with two known recurrences but apparently no report had been secured from a number of the patients. Suttner (66) reports 64 cases by the Coffey method with anatomical cure but symptomatic failure in one recurrence in two and one death from conditions having no relation to the ligament operation.

Goldspohn (67) objects to Coffey's statement that the peritoneal folds are the true support of the abdominal organs. He claims that the support from the abdominal walls is an important factor as shown by the number of cases of enteroptosis in patients with relaxed or weak abdominal muscles. The peritoneal attachments of the uterus must become greatly stretched dur-

ing pregnancy and once stretched they have no power of contraction. Pregnancy is the true test of operations for retroversion and unless patients are examined after they have passed through one or more pregnancies after the operation no conclusions can be drawn as to the value of the procedure. The round ligaments are composed largely of non-striated muscle fiber and are a part of the uterus itself and as such they undergo evolution during pregnancy and involution during the puerperium. "The anatomical structure and physiological nature of these ligaments make them a really live and rather intelligent medium for the purposes here aimed at. Rest will not result in strengthening a muscle; this is accomplished by exercise. That rest will not result in shortening the round ligaments is shown by the large number of women who have worn pessaries continuously for years with cure in only two per cent.

FIXATION TO POSTERIOR SURFACE OF THE UTERUS

Menge (68) first used the round ligament as a cover for the pedicles after removing diseased adnexa, and by fixing the ligaments to the posterior wall of the uterus prevented a recurrence of the displacement.

Stolz (69) draws each round ligament up across the inner end of the corresponding tube and sutures it to the posterior surface of the uterus with several sutures of silk.

Webster (70) (1901) perforates the broad ligament below the ovarian ligament from behind forward with a haemostat, grasps the round ligament and draws the loop through the opening in the round ligament. The loop is then sutured to the posterior surface of the uterus, and the sides of the opening to the round ligament.

Baldy (71) (1902) cuts the round ligaments at the uterine end. The free end is then drawn through the broad ligament below the ovarian ligament and attached to the cornu of the uterus on its posterior aspect directly back of the original point of attachment of the normally attached round ligament. The ends of the ligaments may be cut off to secure the proper degree of shortening and the point of attachment varied to suit the requirements of the individual case.

Franke (72) (1909), without knowledge of the work of Webster and Baldy, devised a similar operation. In young women, in order to avoid interference with pregnancy after drawing a loop of the round ligament through the broad ligament he fixed it to the side of the posterior surface of the uterus. In older women the two loops

were joined together as well as fixed to the posterior surface of the uterus.

Holleman (73) after Franke's paper states that he has been using the method for some time. He suggests that if anteversion is required the opening in the broad ligament should be high, but if elevation is desired the opening should be lower. He also sutures the opening in the broad ligament to the round ligament.

Dartigues (74) (1910) describes an operation that is very similar to Baldy's. The loops of the round ligaments are sutured together behind the uterus and if it is feared that the sling may slip either up allowing the uterus to drop below or down permitting the uterus to retroflex over it, the sling may be stitched to the posterior surface of the uterus with vertical stitches in the central, least vascular portion. Soren (75) (1911) proposes to simplify the technique of the Baldy Webster operation by pulling the round ligament through the broad ligament by the use of an ordinary wire hairpin.

Alherl (3) (1911) picks up the peritoneum covering the round ligament about 1 or 4 centimeters from the uterus and cuts it with scissors for 1.5 centimeters perpendicular to the course of the ligament. Through this incision a double loop of strong silk is passed under the ligament, the ligament is raised and the peritoneum is stripped back from it for some distance, most on the distal portion. Two ligatures are made a centimeter apart on the ligament and it is cut between them. The ends of the ligatures are left long.

With a Cleveland ligature carrier the mesosalpinx is perforated about a centimeter from the uterine margin, the ligature upon the distal portion of the resected round ligament is grasped and the ligature drawn through the aperture. On the corresponding side of the posterior surface of the fundus a tunnel 2 or 3 centimeters long is made with a lance bistoury in a nearly transverse direction passing from the margin of the uterus near the perforation in the mesosalpinx almost to the middle line. By means of the ligature the ligament is drawn through this tunnel until the resected end appears at the median end of the tunnel. Two sutures are placed at each end of the tunnel. They engage the uterine wall, about a third of the thickness of the ligament, and the overlying fleshy bridge. The central stump of the round ligament is then sutured to the peripheral portion with two silk sutures and the opening in the peritoneum closed.

Schmitz (76) (1913) in order to avoid the serous adhesions of the Baldy Webster opera-

tion which is the weakest kind of intra abdominal adhesion suggests a modification which he has performed in a few cases. He makes an opening in the peritoneum over the round ligament 3 or 4 centimeters from the uterus and divides the ligament between ligatures. The distal portion of the ligament is then separated from the peritoneum for a short distance. The ligature attached to the distal end of the round ligament is then caught with a Barrett ligature carrier and carried between the layers of the broad ligament to the posterior surface of the uterus underneath its peritoneal covering. A very small perforation is then made in the peritoneum of the uterus in the midline. The ligatures one from each side are then tied uniting the two ends of the round ligament. The latter are then secured to the posterior wall of the uterus by a few interrupted sutures of fine chromic catgut. The proximal ends of the round ligament are then sutured to the distal end as in Albers' operation and the peritoneum closed.

The Baldy Webster operation as it is commonly called in this country or the sling operation of the English and French surgeons is now commonly performed according to Baldy's (1906) later technique by stitching the loop of the ligaments together and to the posterior surface of the uterus. One of the most complete reviews of the end results of this operation was that by Polak (1913). He reviewed his results in 400 operations with only 4 not seen either by himself or his assistants after operation. He thus has 396 patients from whom to draw conclusions. Polak found a rather high percentage of complications as lateral version prolapsed and cystic ovaries sigmoid and intestinal adhesions. Relapse occurred in 10 patients and 30 others were wearing pessaries. Polak concludes that this operation should not be selected for heavy uterus with the cervix in the axis of the vagina. It succeeds depends on a small uterus a cervix pointing backward equally developed ligament and a careful technique.

The operations of Albers and Schmitz would seem to be rather difficult and tedious and liable to at least a part of the complications of the others of this type.

FIXATION TO THE ANTERIOR ABDOMINAL WALL

Olbhausen (1913) first utilized the round ligament in performing ventrofixation. He passes his suture around the round ligament immediately beside the uterus and then deeply through the abdominal muscles. This is completed on each side with two or three sutures

which are then firmly tied and thus not the uterus itself but the part of it next the round and broad ligaments is fixed to the abdominal wall. In view of the subsequent development of ventrofixation it is interesting to note that Olbhausen states that it is always advisable wherever possible to limit the operation to those patients whose condition or age preclude the possibility of the occurrence of a pregnancy.

Doler (1910) sutured the round ligaments into the lower angle of the abdominal incision. In his later work (1910) he was careful not to extend his incision below a point of 1 centimeter above the symphysis. On each side of the median line opposite that portion of the linea alba which has been preserved he makes a small opening through which a loop of the round ligament is drawn and fixed to the under surface of the skin.

Ferguson (1910) seems to have been the originator of this type of operation. He in his original operation made a median incision down to the fascia then a short incision through each rectus ligating the round ligament one inch from the uterus dividing it proximal to the ligature. The proximal end was then drawn up into the wound on each side and anchored to the peritoneum and the anterior sheath by the rectus. In his later work (1910) instead of dividing the round ligament as in his former technique he used the stab wound and loop as in Gilliam's operation but also closed the opening to the outer side either by a purse string suture from the stab wound down to the bladder and up to the uterus or by suturing the redundant portion of the round ligament to the anterior abdominal wall.

Gilliam (1911) modified Ferguson's original technique by pulling a loop of the round ligament through a stab wound to the side of the median incision and suturing the loop to the upper surface of the anterior sheath of the rectus.

Simpson (1911) (1903) describes his technique as follows:

1. Operations upon the lower genital tract such as curetting repair of cervix perineum etc. are often required the suspension being but a counterpart to the correction of the other abnormalities.

2. A median abdominal incision one and one half to three inches long is made just above the symphysis.

3. Adhesions to the uterus are freed and lesions of the adnexa are given such attention as they require.

4. The wound is held wide open by one

retractor which is drawn straight up, thus making the opening vertical and permitting the operator to look far into the sides of the pelvic cavity.

5 The round ligament is grasped by a delicate forceps one inch from its uterine attachment and drawn up to the surface of the wound.

"6 A silk suture is passed through the ligament at this point in such a way as to encircle about three-fourths of its circumference and to include about an inch of that structure in its grasp.

7 The needle is taken off and both ends of the suture are passed through the eye of a carrier.

8 The peritoneum is incised just below and in front of the round ligament. The carrier is then inserted and passed directly forward immediately beneath the peritoneum of the vesico-uterine pouch, to a point on the anterior abdominal wall just above Poupart's ligament and an inch and a half to the side of the median line where it again emerges.

"9. Both ends of the suture are grasped and the carrier is withdrawn.

10 One end of the suture is then threaded on a sharply curved needle which is passed into the abdominal wall so as to grasp peritoneum, muscle and fascia again emerging into the cavity.

When the two ends of the suture are tied the ligament is drawn into and along the subperitoneal channel made by the carrier. Both round ligaments having been thus secured the conditions existing are entirely analogous to those of an awning. The uterus represents the frame, the round ligaments and sutures attached, the cords by which it is raised that part of the abdominal wall caught in the grasp of the suture represents the pulley over which the awning cord runs and finally the peritoneum of the vesico-uterine pouch represents the covering of the awning. When the cords are tightened the uterus is raised just as an awning is. The peritoneum is thus folded loosely over the round ligaments and when the sutures are tied the uterus is held in normal anteversion just as truly and securely as the frame of an awning is kept more or less straight up after it has been raised and fastened.

Simpson reports three cases in his paper. In the first two instead of burrowing beneath the peritoneum it was caught up along its course.

Noble (86) (1903) using the transverse incision through the fascia and a vertical through the recti and peritoneum locates the ligament at the internal ring by blunt dissection from the outer

end of the incision and traction on the intra-abdominal portion. The peritoneum is then separated from the round ligament to prevent the formation of a funnel when the ligament is drawn up. A loop of the ligament is then drawn out on top of the muscles and sutured to the under surface of the fascia and if long enough to the loop from the opposite side.

Montgomery (87) (1904) brings the loop of the round ligament beneath the peritoneum of the broad ligament by a suture around the ligament and a ligature carrier draws it through the fascia and fastens it with catgut to the upper surface of the fascia. In his later papers (88) (1905) and (89) (1906) he advocates the Pfannenstiel incision.

Ill (90) (1903) modified the Gilliam operation by separating the rectus muscle from its anterior sheath, piercing the rectus and peritoneum drawing out the ligament and suturing it to the under surface of the fascia.

Bardescu (91) (1904) brings the loop of the ligament through the fascia and sutures the two loops together.

Barrett (92) (1905) makes a rectus incision and puts a ligature around the round ligaments two and one-fourth to two and one-half inches from the uterus. He then passes a curved forceps between the rectus and its anterior sheath, punctures the peritoneum at the internal ring and draws a loop of the round ligament out by means of the ligature previously placed. This loop is then sutured to the under surface of the fascia and if long enough the two loops are tied together.

Morison (93) (1905) ligates and cuts the ligament close to the internal ring and frees the proximal end from its peritoneal covering. This free ligament is drawn through an opening in the fascia and peritoneum at the outer margin of the rectus, the uterus is drawn up against the abdominal wall and the two ligaments are sutured to the fascia and to each other.

C. H. Mayo (94) (1906) passes a curved forceps laterally from the lower angle of the incision beneath the aponeurosis just over the muscle to the point where the round ligament leaves the abdomen. The point of the instrument then passes over the pulley of the round ligament and along its course but beneath the peritoneum to a point from one and one-half to two and one-half inches from the uterine horn where the peritoneum is penetrated the ligament is grasped and a loop pulled back through the tunnel. The loops from each side are then sutured together and to the fascia or if not long enough to perforations in the aponeurosis. Simpson (95)

(1911) showed that this could more readily be performed by using a long forceps curved to a right angle which he introduced through a puncture in the fascia one and one half inches to the side of the median incision.

Dudley (96) (1906) by means of a very heavy needle passes a loop of the round ligament from within the abdominal cavity through the internal ring and the fascia back through the fascia rectus and peritoneum and sutures it to the peritoneum at the point of entrance and of exit.

Campbell (97) (1905) makes a median incision to the peritoneum retracts the muscle makes a transverse incision in the peritoneum on each side at the internal ring draws a loop of the round ligament through this opening and fastens it to the peritoneum and under surface of the fascia.

Freund (98) (1906) folds the ligaments on the anterior surface of the uterus and stitches them together with some of the fibers of the uterine muscle to the anterior abdominal wall. Miller (99) (1907) modifies Mayo's operation by perforating the peritoneum close to the internal ring instead of at the point where the ligament is caught. Peters (100) (1907) describes his operation which is the same as that of Simpson in his later paper except that he goes obliquely through the muscle instead of to the internal ring. Benjamin (101) (1909) punctures the fascia opposite the internal ring catches the ligament one and one half inches from the uterus draws it out and sutures it to the upper surface of the fascia. Branch (102) (1910) modifies the Gilliam operation by closing the opening to the outer side of the ligament as suggested by Ferguson and Simpson and suturing the loop of the ligament to the under surface of the fascia. Crossen (103) (1910) passes a forceps under the fascia and obliquely through the muscle to a point about one inch from the internal ring where the peritoneum is penetrated and the ligament caught about one and one half inches from the uterus. Thinnig (104) (1910) describes the method he uses which he attributes to Richardson. He divides the ligament at the internal ring punctures the fascia at the linea semilunaris pulls the cut end of ligament through this opening and sutures it to the upper surface of the fascia pulling the fundus of the uterus against the anterior abdominal wall. In addition with the continuous suture which closes the peritoneum of his median incision he catches the wall of the uterus in front of the midline. Dicken (105) (1910) modifies the Simpson technique in cases with marked relaxation of the

ligament by first suturing a loop of the ligament back to the uterus as in the first step of the Mann operation.

Strobell (106) (1912) modifies the Gilliam operation by making an additional short incision over each pubic spine. A forceps is passed through this incision just above the pubic bone and obliquely outward the ligament caught and drawn out the slack in the outer segment of the ligament taken up and the loop sutured to the upper surface of the fascia. Caballero (107) (1913) describes an operation which he has used since 1902 which seems to be exactly similar to Crossen's. Byford (108) (1914) sutures the round ligament at a point one centimeter from the internal ring back to the uterine cornu and the edges of the resulting loop together. This loop is then brought forward beneath the peritoneum as in the Mayo operation and attached to the under surface of the fascia.

Talmey (109) (1906) modifies Olshausen's operation by using two sutures on each side the nearest one encircling the round ligament about 2 centimeters from the uterine cornu. Kohlmann (110) (1910) gives Bumm's technique of drawing a loop of the ligament through an opening in the peritoneum on either side of the abdominal incision and fastening it into the muscle. Vineberg (111) (1911) modifies slightly the Olshausen technique. He fastens each round ligament to the anterior abdominal wall with two catgut sutures the outer one about 4 centimeters from the uterus and the inner one encircling the round ligament at its insertion into the uterus. In addition in many cases he catches the peritoneum of the uterus in front of the midline with a few of the stitches that close the incision in the parietal peritoneum.

McArthur (112) (1911) splits the peritoneum on the anterior surface of the round ligament one inch from its uterine end to the internal ring. The raw surface of the ligament is sutured to the parietal peritoneum from the internal ring to within an inch and a half of the median incision. Neuhoff (113) (1913) does the same thing except that he does not split the peritoneum of the round ligament.

Neel (114) (1916) gives his modification of the technique devised by Kelly. He separates the fascia from the rectus muscle 4 centimeters to the side of the incision passes a silk suture through the muscle and peritoneum picks up the peritoneum of the anterior wall to the internal ring and of the round ligament to a point one or two centimeters from the uterine cornu where the ligament is pierced the suture being then carried

back through the abdominal wall to the starting point and tied.

The first of this type of operations Ferguson and Gilliam were devised to avoid the greater objection to ventrosuspension, that is, the liability to dystocia. The advantages are that it causes no interference with pregnancy or labor it utilizes the proximal or stronger part of the ligament. It is comparatively free from recurrence and is quickly and easily performed. After the publication of these papers, the objection was made that as there were two bands across the peritoneal cavity instead of the one in ventrosuspension there was a double danger of internal strangulation. This brought out a number of papers in rather rapid succession in which the writers reported their methods designed to overcome this objection.

At the meeting of the Southern Surgical and Gynecological Association Cincinnati in 1902 the papers of Ferguson (83) Simpson (85) and Noble (86) were read. In all of which the principles involved are very similar and were thus summarized by Simpson the ligaments are to be beneath the peritoneum, are to be directed forward and the proximal or stronger part of the ligament is to be utilized. He stated at that time that the procedure he devised permitted of many modifications to suit the ideas of the different operators. How accurately he foretold the future is shown by the number of modifications devised since that time which differ only in minor details from the previous operations.

Concerning the danger of internal strangulation Gilliam (115) (1911) stated that he had never seen or heard of this accident following his operation although it had followed many hundreds of operations by many operators. This seems to be just as true today as it was then, as we have been unable to find any cases of obstruction reported. But as Simpson (85) pointed out a patient may carry a congenital hernia for a great many years without ever being aware of its presence and develop a strangulation when well advanced in life. So it would seem that this objection even though it is only theoretical should be given weight. The retroperitoneal operations can be performed just as easily and with practically no more injury to the patient, and are free from this objection. That the results of this form of operation are good is shown by Simpson's (95) results, 97 per cent of anatomical cures. As pointed out by this writer there are three classes of cases in which success of the round ligament operation alone is not likely to be uniformly obtained

- 1 When the ligaments are very delicate.
 - 2 When the congenital attachment of the bladder is low and that of the sacro-uterine ligaments is high.
 - 3 When the sacro-uterine ligaments and the base of the broad ligaments have been very much stretched giving a decided prolapse.
- Boycé (116) has repeatedly called attention to the function of the sacro-uterine ligaments as an important factor in the maintenance of the uterus in its normal position. Where descensus of the cervix is a part of the retroversion some form of shortening of the sacro-uterine ligaments is necessary and unless this is done the patient will not be symptomatically cured even if the fundus of the uterus is in its normal position.

The majority of patients requiring correction of their displacements are those in whom it has followed a previous confinement. This points to the necessity of careful supervision of patients after their delivery to secure proper involution both of the uterus and its ligaments. This applies just as forcibly to those patients who have had an operation as to those who have had no such experience.

From this review of the various operations for shortening the round ligaments we would suggest the following as the principles upon which a satisfactory operation depends

- 1 It should be quickly and easily performed. As the condition requiring operation has of itself no mortality any operation for its correction should involve the least possible risk.
- 2 It should have a minimum of recurrences.
- 3 It should not interfere with subsequent pregnancy and labor.
- 4 The ligaments should be beneath the peritoneum to avoid the at least theoretical, danger of internal strangulation.
- 5 The proximal or stronger portion of the ligament should be utilized.
- 6 The shortened ligament should be directed forward or along the normal course of the round ligament.

It should be intraperitoneal to permit exploration of the adnexa appendix, or other abdominal organs.

8 It should involve the least possible traumatism to avoid post-operative intestinal adhesions.

9 It should not overcorrect. If the fundus of the uterus is held in contact with the line of incision a suspension or fixation is liable to take place.

It will be necessary to have reports of the end results in a large series of cases before any con-

sensus of opinion will be reached as to the value of the different procedures

SURGICAL TECHNIQUE

ANÆSTHETICS

Pembrey M. E., and Shipway F. E. Observations on the Influence of Anæsthetics on the Temperature of the Body. *Proc Roy Soc Med* 9 6 1x, *Sect. Anæsthetics*

The authors make the following statement in regard to heat elimination and production but give no experimental evidence or references to support the statements. Deep anæsthesia abolishes the regulation of both the loss and production of heat so that the response of the warm-blooded animals to external heat and cold resembles that seen in cold-blooded animals. A fall of external temperature diminishes, a rise increases the production of heat. It is this fact which complicates the problem. The internal temperature of a patient may show a fall, a rise, or no change according to the conditions involved during the period of anæsthesia. A fall in the rectal temperature from 100 to 97 F is within physiological range when the whole extent of the daily variation in temperature is considered, but in the case of an anæsthetized patient subjected to an operation in a warm theater (72 to 74 F) such a fall may occur within one hour.

During short operations of slight severity the necessity for precautions against the loss of heat is not urgent for in an adult there is owing to the mass of the body, a reserve of heat which is not rapidly dissipated in a warm theater. In such cases the advantages of warm ether as compared with cold, may not be so apparent. On the other hand, in the case of long operations or an operation upon a patient possessing a low resistance, the difference may be of great practical importance.

W M BOOTHBY

Gley. The Inevitable Dangers of Chloroform Narcosis. (Sur les dangers inévitables de la chloroformisation.) *Bull Acad de Méd* Par 9 6 1 xv 608.

In discussing a report recently submitted by Reynier a proposed compulsory chloroformization for diagnostic purposes in the French army Gley calls attention to the inevitable results of chloroform anæsthesia which are quite distinct from immediate or late accidents. These inevitable results are lesions of the liver and kidneys as well as alterations in the blood and general metabolism.

The first two are well known. Regarding the

blood, different experiments have demonstrated that in the course and especially at the end of chloroform anæsthesia there is neutrophile hypoleucocytosis and some hours later neutrophile polymorphocytosis. There is a modification in the form of the red globules and a diminution in their number. Chloroform lessens the globular resistance of individuals subjected to anæsthesia.

Gley states that research has shown that chloroform causes an alteration in the organic exchanges characterized by urinary hyperacidity and an augmentation of urinary chlorides and non-oxidized sulphur etc. Analysis of the blood shows a notable bipennia accompanied by acetonaemia and often acetonuria.

Owing to these effects of chloroform intoxication the author thinks that the functioning value of the liver and kidneys should be tested before submitting a patient to the effects of chloroform and particularly when successive anæsthesias are contemplated. In fact the author thinks that the habitual use of chloroform should be renounced on account of the accidents that follow its use. W A. BERNARD.

Page 11. M. Spinal Anæsthesia. *Guy* 11 p. 623 9 6 xxx 3

For all ordinary cases inhalation anæsthesia is the method of choice, but there remain many cases in which great advantage is to be gained by the use of spinal anæsthesia by means of which either the whole or the greater part of the shock is done away with and a more complete muscular relaxation is gained. The operations in which this method may be of especial importance are those for acute bony and soft tissue lesions, particularly if septic, any prolonged bony procedure likely to be followed by shock amputations, operation on the bones of the lower extremities and certain genitourinary operations.

Seventy cases in which the anæsthetic was given in the Trendelenburg position are reported, in which position it is better to combine general anæsthetic with the spinal, the small amount necessary to keep the individual unconscious having little if any undesirable effect on the patient who escapes the discomfort of lying prone for a long period.

The infection is given with the patient lying on the side immediately after which he is turned on the back and the thighs well flexed. Fifteen minutes

after the injection of novocaine and twenty minutes after stavaine the patient is placed in the Trendelenburg position. Twelve cases were operated on without any general anesthesia. In the remaining 55 there was perfect relaxation and in 15 in the three cases of partial failure a deep inhalation

anesthesia was necessary. There was no use of interference with respiration and no patient died before recovery from the induced paralysis. Nine cases died but analysis shows that probably in none of these was the spinal anesthesia responsible.

L. K. ARMSTRONG

SURGERY OF THE HEAD AND NECK

HEAD

Don. A. Treatment of Head Injuries in a Casualty Clearing Station. L. J. C. JJ

The author notes the treatment of 100 cases of head injuries operated upon since the war began most of them in a casualty clearing station which was located in France not far from the trench fighting and the cases came under treatment soon after the receipt of the injury. Casualty clearing stations are not fully equipped for work. They lack X-ray machines — a very important essential in the management of head cases. The result given by the author were obtained in the absence of X-ray evidence and is good as the results would naturally have been far better with more complete equipment.

The experience in the present war upholds the rule of early operation in all head cases. Trauma in motor ambulances is bad for head cases especially in winter. Delay means extension of sepsis and sepsis is responsible for the large majority of deaths either immediate or remote. External scalp wounds, injuries to the cranium, dura, brain and meninges all require early attention to prevent sepsis and thus can be given with better results because earlier where the casualty stations are than later on the line of communications.

The plan followed is to cleanse the scalp of all dirt, blood and hair. The field of operation should be guarded by clean towels, the scalp and wound are next painted with tincture of iodine and the wound is then excised freely leaving a clean-cut edge which is undamaged to the eye. If there is obvious injury to the skull trephining should be promptly done. A hole three-fourths of an inch in diameter is made at the side of the opening or fissure and the dura examined. The trephine opening may be enlarged with a rongeur and if there is no blood-clot opening in the dura or other injury nothing more is necessary. If the dura is injured it is slit up and spicules of bone or blood-clot are removed. Probing with a probe, catheter or finger should be avoided unless definite evidence of the presence of spicules of bone, metal, or other foreign body is detected. It goes without saying that pressure from intracranial blood-clot should be treated in the same way.

The flap incision which was extensively used in the beginning of the war and the removal of a big piece of the skull by the de Vibiss forceps are not suitable methods to use at clearing stations since

they interfere with subsequent operations that may be deemed necessary.

Shell wounds are prone to be lacerated to the brain abscess because of hair and dirt carried to the brain. The rifle bullet wound are less apt to be lacerated to abscess or other complication. Men with head wounds do not as a rule return to the color and lodged bullet should be removed at the hospitals where brain peculiarities are to be found. It is different in cases where lodged bullet fragments are suspected. They are much more apt to induce sepsis and its complications so that when possible even at a clearing station the rule is to remove them.

An opportunity to study the results of English surgeons who believe in huge scalp flaps and large cranial openings and those of the French surgeons who practice the linear or angle incision and small trephine openings is interestingly commented upon in favor of the latter which is considered far more appropriate in casualty clearing stations where lack of adequate equipment obtains.

Indications for operation are: (1) the presence of a penetrating wound of the head; (2) the presence of patient to stand a general anesthetic; (3) the presence of a surgeon with some experience in cranial surgery.

The average operator can always remove dirt from the wound by a clean-cut incision, open the cranium wide enough for the extraction of pieces of bone pressing on the dura or sitting in the brain, to favor drainage of blood or pent up brain debris and to restore pulsation. These essentials involve but little shock, they require a minimum of time and they are attended with immediate results. When so treated head injuries are followed by primary healing in most cases and cerebral hernia is the exception.

Though gas infection is rare in head wounds, free drainage should be afforded by plenty of drainage tubes inserted wherever drainage is called for, even in the brain opening. Ample drainage precludes the possibility of dead tissue persisting in wounds and when devitalized tissue is eliminated saprophages like bacillus aerogenes capsulatus can no longer thrive.

After battles only the mild cases should be transferred to the rear. The most serious cases should be retained for some time for treatment on the lines mentioned, which will put them in a position to bear the ill effects of transport. L. A. L. GARDE.

Cushing, H. Concerning Operations for the Cranio-cerebral Wounds of Modern Warfare. *Brit. Surgeon* 9 6 xxxviii, 60

Wounds of the head and extremities form a large majority of the total injuries in the present war as shown by recent statistics. It has been clearly proved that specialization in the treatment of wounds in this war is of the greatest value in returning wounded men to active service in a condition of comparative health.

The importance of all cranial wounds, however slight, is emphasized. Roberts found that 1 series of 40 supposedly minor scalp wounds 4 5 per cent had skull fractures with more or less severe intracranial complications.

The author is strongly opposed to the routine treatment practiced at some first line hospitals, by enlargement of the wound by a crucial incision, elevation of the depressed fragments etc. and gauze drainage. He cites cases in which the results of this treatment have been satisfactory or worse. He believes that in cases of cranial wounds removal to the base hospital where proper equipment carefully planned operations, aided by the X-ray can be had, is the wisest course. He advocates a flap-incision away from the wound, thorough exploration, closure of the incision with buried gauze sutures, supplemented by cutaneous ones (to be removed on the second day) to insure primary healing with scalp protection for the denuded dura or brain. If drainage is advisable, rubber tube drains in the distant angles of the incision should be used, gauze never. Under this treatment the patient's chances are better even after a delay of several days than with an immediate operation at an ill-equipped first line hospital.

The different types of cranial wounds from projectiles are described with their characteristic symptoms. An important one is the median tangential or gutter wound (excised the vertex), involving the lateral expansions of the longitudinal sinus, causing stasis in the large cerebral veins. The symptoms are those of immediate bilateral apastic paraplegia in the severer cases — homonymous syndrome. A mild case observed by the author showed weakness and paresthesia of both legs. The milder cases, even with depressed fracture may recover without operation. In the severer cases, with cortical injury operation should be undertaken only under the most favorable circumstances, the operator being prepared to control hemorrhage from a bleeding sinus by implantation of raw muscle or vulcanized fibrin fibers. Ligation to be avoided if possible. The same principles apply to the treatment of posterior wounds involving the occipital lobes and causing central blindness.

In general, the author believes that good results follow a primary operation with closure even four or five days after the injury, poor results with death from meningitis follow in cases treated at the front in the routine way and packed with gauze.

HORACE B. ARMY

Browning, W. The Anatomical Cause of the Frequency of Hydrocephalus in Childhood. *Med. Rec.* 9 6 lxxvii, 950

In the production of hydrocephalus two complementary conditions are found: secretion and retention, both processes normal within limits. Unless there is an abnormal damming back there can be no accumulation and it is this phase that the author especially considers.

Many partial and indirect factors have some bearing on this youthful potentiality: narrower passages, softer tissues, thin bones, metabolic growth-errors, etc. But back of these is an anatomical and mechanical peculiarity which is not ordinarily appreciated.

From a mechanical standpoint there are three causes of hydrocephalus: (1) oversecretion as by a block in the vein of Galen leading to excessive production of fluid; (2) closure of the outlets from the ventricles, as at the foramen of Monro, the foramen of the three outlets from the fourth ventricle; (3) interference with the efferents from the subarachnoid space. The first two are relatively rare and may occur at any time of life. While the third form may occur at any time of life there is an anatomical peculiarity which favors its formation in the early years.

There are two general classes of these efferents from the subarachnoid space: one may be called the quadruped or animal type, the other the (postnatal) human type. There may be additional minor outlets as along or near nerves or by direct absorption through the surrounding tissues.

The animal type of discharge consists of minute channels or vessels that lead from the pial subarachnoid space along outgoing nerves to the extraspinal tissues. In them these channels persist whereas in the human they exist only up to the time of birth.

When these routes become closed there is a compensatory process which gradually relieves the situation and allows for more complete drainage of the subarachnoid space. Perforation bodies gradually develop although they do not appear in large numbers until after the twentieth year. It thus follows that the earlier years of life are especially susceptible to hydrocephalus before this compensatory process has become established and after the closure of the animal type of vessels. J. H. SKILES.

Vilbrandt, G. and Morgan, J. D. Movements of Foreign Bodies in the Brain. *Arch. Radiol. & Electrother.* 9 9 vii.

The authors report two cases in which bullets penetrated the brain subsequently wandered from their original location.

In the first case the bullet moved from the frontal lobe to the wall of the ventricle in the period of two weeks intervening between examinations.

In the second case the bullet moved from the right parietal lobe outward and downward to the occipital lobe in a period of ten days.

Both cases terminated fatally. O. W. GREEN.

Keschner M: Large Endothelioma of the Dura Compressing Both Frontal Lobes *J Am M As* 1916 14 193

Keschner here with reports a rare case of a colored woman aged thirty in whom both frontal lobes of the brain were compressed by a large endothelioma of the dura diagnosis being verified by the pathologist's report of the necropsy. In this case exophthalmos was an early symptom and a post-neuritic atrophy resulted within a period of five months in total blindness.

There was an absence of the Babinski reaction but the abdominals were present. The Wassermann test was negative and the cerebrospinal fluid was under considerable pressure. The exact location of this growth was not easy to determine as the symptoms of cerebellar tumor are closely allied to those of frontal tumors.

The author calls attention to the relative value of early and of late symptoms of brain tumor also to the symptoms of tumor of the corpus callosum. He does not believe that mental symptoms occurring in brain tumor are necessarily confined to frontal lobe involvement.

At autopsy the brain measured 13.2 x 0 cm and appeared normal with the exception of the tumor mass.

The tumor was attached to the dura in the center of the olivary process of the sphenoid for the distance of one-fourth of an inch and connected with the brain by a few vascular strands. The macroscopical diagnosis was endothelioma.

Elliott C. Royster.

Priani P: Clinical Considerations of Lesions of the Hypophysis (Considerações clinicas sobre lesões da hipófise) *Pr Med e Arg* 1916 14 4

The author discusses acromegaly and hypophyseal dystrophies. He reports three cases with a greater or less degree of hyperpituitarism, i.e. enlargement of the face particularly about the inferior maxillary region, extremities enlarged, macroglossia, sexual disturbances characterized by diminution of function or lack of development, ocular disturbances lateral or bilateral hemianopsia or complete obfuscation. The radiograph showed a tumor of the sella turcica in each case. The tumor in the first case that of a man was of long and slow evolution and was diagnosed as a simple adenoma. The other two cases which were in females, on account of the rapidity of evolution were diagnosed as adenocarcinoma. The rapid increase in these cases caused a herniation of the growth from its habitual cavity with subsequent compression symptoms.

In these two cases the disturbances of vision were marked. Both of these cases were operated upon by the endonasal method and the tumors weighing respectively 100 gr and 12 gr were removed. Both patients died.

The author thinks the cases show the necessity

for early diagnosis and treatment as in advanced cases like the above the tumor is large and while surgical intervention offers the only chance of relief yet it is impossible to completely extirpate the tumor by any method now in use. W. A. BROWN.

NECK

Barnhill J F: Some Essential Points in the Anatomy and Surgery of the Thyroid Glands. *Am J S* 1916 3

After a preamble in which he makes a plea that the otolaryngologist should perform the surgery of the head and neck, the author proceeds to the subject in hand. The points of paramount importance in the surgery of the thyroid are: (1) the large blood supply entering the gland at its upper and lower poles; (2) the outer or surgical capsule and the inner or glandular capsule between which the dissection of the gland should be undertaken; (3) the parathyroid glands, one to eight, usually four in number, which lie in the intracapsular space.

The chief dangers of thyroidectomy are the anasthenia, hemorrhage and shock, suffocation from collapse of the trachea, injury to the recurrent laryngeal nerve, an injury to or removal of one or more of the parathyroid glands. Exophthalmic goiter patients are always grave risks due to their toxic state. To avoid suffocation from collapse of the trachea, a tracheotomy tube should always be at hand to be inserted at the first sign of obstructed respiration.

In the removal of the thyroid gland the author employs the horseshoe incision through the platysma, after raising the flaps he makes a vertical incision in the midline and inserts his finger in the intracapsular space between the ribbon muscles and the gland to separate the entire anterior surface of the gland before cutting across the muscles. After the muscles are severed and turned back, the blunt dissection by finger is continued from the upper pole to the point where the inferior thyroid artery enters the gland. This artery is ligated as near the surgical capsule as possible. The author lays stress upon the fact that whereas both the inferior thyroid artery and the recurrent laryngeal nerve lie in a sheath of their own between the trachea and the esophagus, the artery alone penetrates the surgical capsule of the thyroid and gland, and if ligated within that capsule insures the safety of the nerve. He never makes a special attempt to isolate the nerve.

The inferior thyroid artery also marks the limit of safety in regard to the posterior parathyroid glands which lie in the connective tissue close to the entrance of the inferior thyroid artery. In order to avoid the removal of this important structure the author cuts across the gland substance above this point and leaves a small lobule of gland tissue in situ. He believes that the operation on thyroidectomy for simple goiter should have a mortality no higher than tonsillectomy in adults, exophthalmic

gout cases should always be handled in consultation with a competent internist, and if possible no surgical procedure should be undertaken until the pulse has reached 120 beats per minute. Hemostasis is an important factor in the safety of all operations and should be especially carefully attended to in gout operations. E. FISCHER.

Goetsch, E.: Functional Significance of Mitochondria in Toxic Thyroid Adenomas. *Bull Johns Hopkins Hosp* 96 xviii, 29

The cause of thyroid intoxication in individuals who show only the presence of circumscribed adenoma has not yet been satisfactorily explained. Pressure of the tumor on surrounding normal tissue causing an expression of normal thyroid secretion into the circulation in excessive amounts has been advocated as the explanation, as has also the theory that the tumor or foreign body acts as an excitant on normal tissue thus producing increased secretion with its train of toxic symptoms. It has long been the experience of surgeons that removal of the adenoma is followed by clinical improvement if not by cure. The author has attempted to solve this puzzling problem by a close cytological examination of the tissue removed in cases of goiter.

A typical case of toxic goiter in a middle-aged woman is cited in detail. A goiter of many years standing after various nervous and physical traumas began gradually to manifest toxic symptoms. At operation a circumscribed follicular adenoma was removed from the right lobe and the isthmus. Operation was followed by more or less immediate improvement and in one year the patient was practically

normal. The usual histological study of the excised adenoma showed nothing to account for a hyperactivity of thyroid substance. The cells lining the follicles were low cuboidal or even flattened, and nowhere was there infolding of the follicles. Colloid was fairly abundant. There was no increase in vascularity. The usual histological examination would lead one to suppose that the adenoma was functionally inactive.

The author attempted to explain the hyperactivity of this seemingly benign adenoma by a close histological study. He chose a technique which shows clearly and easily the presence of structures commonly known as mitochondria granular rods or filaments occurring in the cytoplasm of all cells being more abundant in the active stages of cell life and diminishing in number as the cell becomes inactive or senile. Therefore it seemed logical that the more active glandular cells should show more numerous mitochondria.

Applying this theory to the adenoma in question by suitable technique of staining the mitochondria were demonstrated greatly increased numbers in the cells of the adenoma. Applying the hypothesis to adenomas removed from glands which were clinically inactive, no increase in mitochondria was observed. Frank cases of Basedow's disease were also studied, and they too showed marked increase in the mitochondria in the thyroid gland tissue itself. It would therefore seem probable that the presence of mitochondria in greatly increased numbers is directly correlated with an overproduction of an otherwise normal thyroid gland secretion. E. FISCHER.

SURGERY OF THE CHEST

CHEST WALL AND BREAST

Peck, G. A.: The Early Diagnosis of Cancer of the Breast. *Am J Surg* 96 vi, 85

The author reviews the recent literature giving in abstract the attitude of various writers toward breast tumors and the symptoms which they regard as valuable in making a diagnosis of these conditions, also the important laboratory tests that have been employed as diagnostic measures.

He makes no claim to originality in the article but gives a concise and orderly presentation of the clinical symptoms of breast cancer as contrasted with benign growths and calls attention to the valuable symptoms and methods that are employed in arriving at an early diagnosis.

His conclusion is based on his review of the literature as follows:

The clinical signs and history must form the basis for a diagnosis of malignancy of the breast.

1. Serology and other general laboratory tests, as at present perfected, are not dependable for the diagnosis of these cases.

2. Repeated examinations at regular intervals, are desirable in doubtful breast tumors, but the complete clinical picture should not be waited for before operation is decided.

3. The influence of physiological development and atrophy of the breast in which a tumor is present should be kept in mind.

4. Most tumors of the female breast at or near the twentieth year are benign whereas at or near the fortieth year they are malignant.

5. Section through into the tissue of a tumor of the breast is never justifiable for the purpose of diagnosis. Well-defined growths should include surrounding tissue when removed, but ill-defined ones are best removed with one-fourth or one-half the entire mammary gland.

6. Cross-examination of the fresh specimen by well qualified pathologist at the time of operation, is safer than examination of frozen sections alone.

7. One should not be content with a partial operation in breast tumors, if there is a question of malignancy. Only the removal of the lymphatics and the entire breast can effect a cure in such cases.

Learmonth M. E. Acute Mammary Carcinoma. Canad. Med. J. 1905 403

It is estimated that acute mammary carcinoma occurs in about 1 per cent of all breast carcinomata. Of the 40 cases reported only two are living past the five year limit. The average age of onset is about 40 years. The first thing noted is usually a lump in the breast during pregnancy. The course of the disease is rapidly fatal in from one to six months unless recognized early and appropriate surgical measures undertaken. The inflammatory spread rapidly giving a massive induration. About one-fourth of the cases have retraction of the nipple. The orange skin appearance of the skin due to the blocking of the lymphatics is a marked feature.

In case surgical intervention is not initiated early in the disease death follows from metastasizing. In case of a small tumor appearing in a pregnant breast and upon its increasing size the diagnosis lies between a carcinoma and tuberculosis because of the rarity of a tuberculous infection at this time. Acute infections are usually associated with the nipples. The author advises exploration with the cautery for immediate examination of the specimen microscopically and radical removal in as it proves to be carcinoma. HARRY G. L. C.

MacCarty W. C. and Mensing E. H. The Relation Between Chronic Mastitis and Carcinoma of the Breast. N. Y. Med. J. 1905 100

From the study of 36 mammary carcinomata and 406 cases of simple chronic mastitides certain questions and their answers have been evolved: (1) Carcinoma always associated with chronic mastitis. In this series of cases the association was constant. Is chronic mastitis always associated with carcinoma. In the experience of the author it certainly is not. Are there any conditions relative to the possibility of precancerous conditions in chronic mastitis which point to a possible etiological relationship between carcinoma and chronic mastitis. There are three distinct conditions of cellular activity in this parenchyma of the mammary acinus which bring chronic mastitis and mammary carcinoma into intimate association and legitimately prohibit the consideration of the one without the consideration of the other. The microscopic pictures of the pathology of chronic mastitis is given and the authors claim the line of demarcation between the acinus and the stroma is sometimes confused thereby making it impossible to accurately state whether one is dealing with carcinoma or not.

There are three distinct histological pictures in chronic mastitis the first being characteristic of all chronic mastitis the second, characteristic of some specimens of chronic mastitis the third in its earliest stages is associated with the first and second conditions. The third condition is a recognized picture of carcinoma. The first is a benign condition, and with our present knowledge the clinical significance of the second condition is still un-

determined although it represents the precancerous histological picture.

From these facts the authors believe that there certainly is an association of chronic mastitis with carcinoma but cannot ascertain in all that chronic mastitis is an etiological factor in mammary carcinoma.

The average age of the 6 patients with carcinoma was 40 years in comparison with the average of 43 years of 406 patients with simple chronic mastitis. A discharge from the nipple is present in 4 per cent of all carcinoma and 6.6 per cent of all chronic mastitis. Trauma as a possible etiological factor in the development of chronic mastitis and cancer is greatly minimized in this series. The comparatively small percentage of patients with carcinoma recorded in the series only 6 gave a history of trauma while 44 with chronic mastitis gave similar histories. In this series 1 per cent of the patients with carcinoma and 1 per cent with simple chronic mastitis were unmarried which minimizes to a certain degree the possibility of lactation and its coincident infection.

Pathologically carcinoma is not a condition which is dependent upon the age of the subject but on some other condition of the tissues. Of all cases of chronic mastitis 3 were diagnosed correctly by the clinician the other 6 depended on fresh tissue diagnosis. In 3 of these cases of carcinoma or the breast clinical diagnosis of the glandular involvement showed that only 10 or 30 per cent actually had had it.

These errors emphasize the great value of an immediate fresh tissue diagnosis in connection with operative interference. The authors believe that practically one out of every 10 patients with cancer of the breast may be saved from operation if the surgeon has a competent surgical pathologist associated with him in his work.

From the foregoing facts the authors have emphasized the following five points:

1. Cancer of the breast is always associated with chronic mastitis.
2. The percentage of legitimate error in the clinical diagnosis of simple chronic mastitis and carcinoma is respectively 6 per cent and 3.0 per cent.
3. The percentage of legitimate error in the clinical diagnosis of the condition of axillary glands is 30 per cent.
4. There are three distinct histological pictures of chronic mastitis the one extreme in its benign condition, and the other extreme in its malignant condition. The mean which may be easily recognized is at present doubtful.

The association of the two conditions is too close to allow the consideration of one without the consideration of the other.

The authors believe that following to be the true logical plan. Conditions of the breast which are associated with clinical signs of carcinoma

should be treated radically. (3) In the doubtful cases of women near or over 35 years of age, the entire mammary gland should be removed for immediate examination. If primary or secondary hyperplasia be present nothing more should be done. If tertiary hyperplasia be present, a radical operation should be performed.

In doubtful patients, near or under thirty five years of age, a wide section of mammary gland, including the pathological condition, should be removed for examination. If primary hyperplasia be present nothing more should be done. If secondary hyperplasia be present the rest of the mammary gland should be removed and if tertiary hyperplasia be present the radical operation should be accomplished.

ERR. C. ROUSSEAU.

Lambrethsen, J. A Rare Mammary Tumor (Ein seltener Mammatumor). *Nordiskt Läk Stockholm*, 9 6, *Kirurgi* 6.

Lambrethsen describes and illustrates a mammary tumor which he classifies as a sebaceous carcinoma. The tumor showed strips of clear cells lying in a groundwork of hyaline connective tissue. He bases the diagnosis on (1) the form of these cells which have the same developmental characteristics as sebaceous glandular cells (They are polygonal with rounded angles so that they are almost oval in form.) (2) the clear appearance of the cells in which the protoplasmic granules gave at the first glance such a resemblance as to suggest the thought that the sebaceous glands formed the starting point of the tumor.

W. A. BROWN.

Pallases E. and Roubier C. Primary Tumors of the Pleura (Les tumeurs primitives de la plèvre). *Arch. Méd.* 9 6 1 43.

Primary tumors of the pleura have always been considered a rarity that existence has even been denied by some. The authors however consider the fact of their existence as indisputable as evidenced by many undeniable cases in the literature. They report three personal cases in detail. The demonstration in each case was made at autopsy. Histologically the three cases were malignant lipoma, a malignant tumor of the fibrous tissue, and a benign tumor of the fibrous tissue.

Primary tumors of the pleura may be divided into three categories: benign mixed, and malignant. Benign primary tumors are rare but some observations of lipoma, chondroma, and fibroma have been recorded. In addition purely inflammatory neoplasms have been noted (syphiloma and tuberculoma) on the pleural surface. There is a variety of fibrotuberculous pleural hypertrophy which can give rise to sessile and pediculated productions and may attain a considerable volume.

In the class of mixed tumors the authors place the recorded cases of chondrosarcoma, myxofibromatous sarcoma, myxolipomatous tumors and the like. Malignant primary tumors of the pleura, although comparatively rare are yet met

with more frequently than the two preceding classes. Pleural cancer presents itself in two forms, diffuse and circumscribed. Such tumors have been designated under a variety of appellations, i.e., sarcomatous, endothelial sarcoma, proliferating lymphangitis, etc. but all may be placed in the two classes of sarcoma and endothelioma. Sarcoma of the pleura are very similar to tumors of the same kind observed in other organs; they may be fusiform or giant-celled endothelioma occur more frequently than sarcoma. They are ordinarily diffuse accompanied by abundant hemorrhagic infarction and metastases are more often met with than in sarcoma.

Surgical intervention is or should be confined to cases where the tumor is clearly circumscribed and of considerable volume so that it shows symptoms of compression. Guyot and Parcelier in 39 collected cases of malignant tumors of the pleura found 7 surgical cases; those in which there were no metastases. The apparent operability was 37 per cent. Three were operated upon, the others which would have been fit for operation having been found at autopsy. In one of the operated cases the patient was in perfect health two years later.

Although extirpation is rarely attempted, the author thinks that prudent surgical intervention will be able to corroborate the prognosis where the tumor can not be surgically removed, particularly when there is an early diagnosis.

Goollfoud and Arcelin. Extraction of a Free Bullet from the Left Pleura After Establishment of an Artificial Pneumothorax (Extraction d'une balle mobile dans la plèvre gauche après établissement d'un pneumothorax artificiel). *L'Ann. Méd.* 9 6 1 43.

The case reported by the authors was that of a man who was found to have a movable bullet in the left pleura. Believing that extraction could be more readily accomplished by the prior establishment of an artificial pneumothorax this was done according to the Forland procedure.

One month later when the patient was accustomed to breathing with one lung a wide incision of the pleura was made, there being no appreciable respiratory trouble. The bullet being displaced a second incision was made in different intercostal space and the bullet removed.

The double intervention although it might have been avoided had the advantage of demonstrating how the patient had been accustomed by his prior pneumothorax to breathe with only one lung. The authors think that while the establishment of artificial pneumothorax is not indispensable in such cases, it is useful for the avoidance of the dangers of sudden pneumothorax during operation, although of course such total pneumothorax can be prevented in the course of operation.

Nevertheless in pleuropulmonary surgery artificial pneumothorax will find numerous indications, as in cases analogous to this.

W. A. BROWN.

Jaugens, F. Two Cases of Mediastinal Tumor Treated by Radiotherapy (*Deux cas de tumeurs médiastinales traitées par la radiothérapie*) *J de radiol t d'électrol* 9 6 li 9

Radiotherapy is the only treatment applicable to intrathoracic tumors in which on account of their volume or their localization surgical intervention is either impossible or dangerous. The situation of such tumors in a region normally very permeable to the X rays deprived of organs susceptible of being altered by repeated irradiations and allowing multiple ways of access give very favorable conditions from a technical viewpoint and permit the administration of therapeutic doses and the attainment of the limits of sensibility in the elements of the neoplasm.

The author reports the clinical data of two cases. In one a woman of 6 irradiation was begun in January 1911 so that the anterior and posterior faces of the thorax were alternately exposed to weekly treatments. The dosage was 5 H penetrability 8 B altered through a millimeter of aluminum. After seventeen treatments the woman who had been previously in a very prostrate condition had recovered sufficiently to travel to Switzerland for recuperation. On her return she had seventeen more treatments and the author reports that all objective symptoms have disappeared. He points out that while the prognosis of her condition early in 1911 was fatal in December 1915 her very satisfactory state is a very happy result of radiotherapy.

In the second case treated a child of 14 the results while not so satisfactory as in the first case still show a great amelioration. There is no notable diminution in the size of the tumor but the activity of the neoplastic elements has been checked and there is a suppression of the toxic products due to it which has brought about considerable improvement in the general condition so that the child is returned to normal health. W. A. BRENNAN

HEART AND VASCULAR SYSTEM

Ascoli and Masserini. Projectile in the Right Lobe of the Heart After Trauma of the Cava Inferiore (*Proiettile entro l'orecchietta destra del cuore pervenuto attraverso la cava inferiore*) *Cl. Ch.* 9 6 xi 377

Preliminary radiocopy of the patient reported showed a piece of shrapnel on the projection of the left iliac wing about the middle point. A second radiocopy made one month later showed the projectile in the cardiac circuit.

It was about 1 to 8 mm in diameter inside the right lobe and it moved its position rhythmically with the movements of the lobe. Although the authors judging from published cases think that operative treatment appears to offer the only ultimate hope in such a case yet they hesitated to operate in this case on account of the patient's condition.

W. A. BRENNAN

Bichat: Extraction of a Piece of Shell from the Right Ventricle (*Extraction d'un éclat d'obus du ventricule droit*) *Bull. et m. Soc. d'ch. d. Par.* 1916 xlii oo

Bichat reports the case of a soldier wounded in the neighborhood of the right lung. Radioscopy showed a foreign body in the left part of the thorax at the external and lower limit of the shadow of the pericardium and heart which followed the movements of the heart and respiration. Later examinations localized this body in the pericardium situated behind the sixth rib.

Operation performed two weeks later under chloroform consisted in incision over the sixth rib, resection of the rib, longitudinal incision of the pericardium which was found empty. The projectile was felt embedded in the lower extremity of the right ventricle. The ventricle was caught between two fingers and pulled forward incised and the piece of shell removed by forceps. Some black blood escaped but a few catgut sutures produced hemostasis. The pericardium was sutured.

There was no acceleration in the heart movements which remained at 80 until the end of the operation. The projectile weighed more than 3 gr and was 16 mm long. The condition appeared to progress satisfactorily for more than a week. On the thirteenth day after operation signs of pericarditis appeared the circuit was opened and a quantity of seropurulent fluid drawn off but ten days later there was sudden aphasia. Cheyne Stokes respiration was followed by death in a few hours.

At autopsy the lung wound was shown to be uncinatized, the trajectory contained a small fragment of bone with abundant suppuration. Bichat believes that the pericardic infection originated in the intrapulmonary infection.

This is the fourth published case of extraction of a foreign body from the heart since the war began. In only one of these cases was there a recovery. From a consideration of the general literature of the subject the author concludes that projectiles in the heart, excluding the pericardium are not well tolerated and that operative intervention has given better results on the whole than non interference and that the subject opens up a new chapter in war surgery.

PHARYNX AND ESOPHAGUS

Guttman J. and Held T. W.: Carcinoma of the Esophagus Perforating Into the Right Bronchus. *M. d. Rec.* 9 6 lxv 039

The author reports a case the interesting features of which are as follows:

The onset of the disease appeared to be at the end of September 1915 four months before the patient's death. The primary cause of the death, carcinoma of the esophagus, had probably existed for a long time without giving practically any symptoms whatever. There was no dysphagia, no vomiting, no fetor ex ore etc. up to within a short period before

his death. A fistulous communication between the esophagus and bronchus had existed for some time. As a result of this, food particles passed from the former into the latter and in the course of time gave rise to bronchiectasis.

The patient was sixty years of age and had suffered from digestive disturbances for ten years. The bronchiectasis gave rise to small pulmonary hemorrhages and to cough thus obscuring the clinical picture by simulating tuberculosis.

The absence of pain and the comparative euphoria at a fever temperature of 100 and 102 is interesting.

The choking and coughing spells when the patient attempted to drink is one of the most characteristic symptoms of esophagobronchial communication.

EDWARD L. CORRELL.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

Outland, J. H. and Glendening, L. Chylous Ascites and Chylothorax Due to Carcinoma of the Stomach. *J. Am. M. Ass.* 96 April 1835.

A man, 46 years of age, felt well up to six months before examination April 16, 1915. The onset of his illness was sudden. He had a sudden attack of dizziness and vomiting. He did not go to bed, but was weak and dizzy and continued to feel much the same way for two months. He never vomited blood. For three months previous he had been troubled with indigestion, pain after meals, belching and bloating. The bowels were constipated.

March 27, 1915 the abdomen began to swell very suddenly and in a few days was enormously distended. It was tapped April 21 and about a gallon of milky fluid was removed. April 28th it was tapped again and 2.5 gallons of asdific fluid of the same character removed.

April 27th the abdomen was tapped and over a gallon of milky fluid withdrawn. The chest was aspirated at the same time, three and a half quarts of clear straw colored fluid being removed. The fluid removed from the abdomen was milky in appearance, with a tinge of pink. It contained 90 per cent of albumin and fat and did not react to Fehling's solution. Microscopically it showed small fat globules and small specks in constant stomatic motion. Leucocytes and erythrocytes were numerous. The patient died May 31st.

When the abdomen was opened at autopsy about three quarts of milky fluid escaped. The intestines were distended and covered with a lymphatic exudate. The cecum and appendix were enormously distended. Small lymphatic channels over the surface of the intestine were greatly distended. All the glands of the mesentery were enlarged. The entire mesentery was a thick mass of glands which were soft in consistency. The liver was enlarged and oedematous. The gall-bladder was large. There were no gall stones. A tumor was present along the lesser curvature of the stomach, extending from the duodenum to well within the pylorus. The glands of the gastrophrenic mesentery were enlarged. No growth was found in the rectum.

EDWARD L. CORRELL.

Tuley H. E., and Graess, S. Chylothorax, Chylous Ascites, and Lymphosarcoma. *J. Am. M. Ass.* 96 April 1844.

A woman, aged 58, married 36 years with two children living, had five brothers and sisters, of whom one died of brain fever, one of typhoid fever and one of pneumonia, those living being in good condition. The menopause occurred seven years previous without complications. The patient had always been robust, the normal weight being 160 pounds. For several months she complained of pain in the scapular regions of both sides and could not lie on her back. For a year she had had pain and fullness in the epigastrium after eating.

The author first saw the patient October 4, 1915, for an attack of dyspnoea, the cause of which seemed apparent as the chest was full of mucus and sibilant rales and the breathing was typical of asthma.

November 2 a careful examination was made of the thorax and the presence of fluid diagnosed in the left pleural cavity. A peculiar feature of the chest findings at this time was the presence of bronchial breathing on the entire left lung, a tender and posterior with tense flatness over the left base. November 2 a thoracentesis was done through the eighth interspace and three pints of thin, milky white fluid were withdrawn. The appearance was that of pus, but an examination showed it to be free from cells and to be sterile chylous fluid. The relief from the dyspnoea was almost immediate there being very little cough following the aspiration. From then until March the total quantity of chylous fluid removed from this patient's chest was 48.5 pints.

At autopsy the head of the pancreas was involved in a tumor as described below. The tail was negative.

The lymph nodes from the neck of the pelvis, especially those lying in the posterior mediastinal and retroperitoneal spaces, were involved in an apparently primary neoplasm which was growing around the structures in those regions, but it did not infiltrate any except the head of the pancreas. The cervical, axillary, supraclavicular and infraclavicular and bronchial nodes varied in size the largest being about 1 cm. in its greatest diameter were encapsulated and moderately firm and on section pale flesh color and homogeneous except the last which were speckled with black. The posterior

mediastinal nodes were much larger reaching a maximum diameter of 4 cm but were encapsulated and sifter and paler on section. Below the level of the diaphragm the nodes seemed conglomerate in a mass larger than one fist and involved the head of the pancreas. On section this tissue was most pale homogeneous and typically like fish flesh while scattered in it could be seen lobules of pancreatic tissue. The lymph nodes along the lesser curvature of the stomach in the gastrohepatic omentum and retroperitoneal along the aorta were enlarged (those in the gastrohepatic omentum reaching a diameter of 4 cm while those about the abdominal aorta decreased in size to the region of the bifurcation where they measured about 2 cm in diameter but were of the same appearance as those described above.

In situ structures about the innominate veins were dissected primary incision being extended at right angles laterally along the left clavicle. No abnormality or rupture of the thoracic duct could be found. In the posterior mediastinum duct the esophagus and vessels were surrounded by the tumor but none of these structures were invaded macroscopically. The heart lungs trachea, esophagus aorta thoracic duct pancreas kidneys and suprarenals were removed en masse. The duct was slit open and followed to its beginning branches. Its mucosa was smooth everywhere.

The microscopic diagnosis was lymphoblastoma malignant lymphosarcoma round-cell sarcoma.

The final diagnoses were lymphoblastoma of the cervical axillary clavicular mediastinal gastrohepatic abdomino-aortic and iliac lymph nodes invading the pancreas and lung compressing other structures adjacent to them and metastasizing in the spleen chylothorax bilateral chyloous ascites gastric ulcers hemorrhage into the intestine chronic endocarditis chronic aortitis oedema of the legs fibrous pleural adhesions bilateral superficial ecchymoses a urticaria of the left leg multiple leiomyomata of the uterus senile ovaries post mortem change in the suprarenals chronic gingivitis atelectasis of the lungs.

EDWARD L. CORVELL.

Chatillon F Spontaneous Pelvic Peritonization
in Women La peritonisation spontanée du bassin
de la femme. *J gynéc et obst* 1916 xlii,
46

Several authors have from time to time shown that certain organs such as the epiploon colon etc. can among themselves form a protecting tent over the lower pelvis destined to prevent the spread of suppurative processes into the abdominal cavity.

From a study based on twenty-seven observations made by Beuttner in the Gynecological Clinic of the University of Geneva in which he studied the exact condition in which the abdomen was found on making a laparotomy he sketched certain conclusions which he recently published. Chatillon now publishes this study on the same lines based on a much larger number of cases viz 100.

Sometimes at a laparotomy the inflamed genital organs are found to be so well protected by their neighbors that they are scarcely seen the inflammatory process has been spontaneously peritonized and the diseased parts isolated from the abdominal cavity hindering propagation of the infection. The object of the author's research is therefore to find if there are any rules according to which the different organs act toward each other or how one or several diseased organs are protected by their neighbors.

The author considers this spontaneous peritonization by means of the rectum sigmoid caecum small intestine epiploon etc. He holds that spontaneous peritonization has been produced in 100 cases as follows:

21 times by 1 organ
30 times by 2 organs
26 times by 3 organs
11 times by 4 organs
5 times by 5 organs
5 times by 6 organs

While Bliessner found that the grand epiploon and small intestine were the organs most often utilized the author's research showed that the small intestine and sigmoid were the most frequent. He draws these general conclusions from his study.

1 The annexes descend into Douglas's pouch along the posterior wall of the uterus and are peritonized by adhesions which the rectum, uterus bladder etc. form around them. In this case the peritonization will be effected by the organs of the lower pelvis. It will be low peritonization.

2 If the annexes for any reason do not descend into Douglas's pouch and consequently remain in good position peritonization will be effected by the organs situated above them or in their immediate vicinity i.e. the epiploon caecum sigmoid loop or small intestine. This process the author designates as high peritonization.

3 The combination of these two methods will form a third category which comprises complicated cases where peritonization proceeds at the same time on the part of all the organs. This may be termed mixed peritonization.

Hence the general rules for spontaneous peritonization of the pelvis in woman are: (1) by means of the lower pelvic organs (2) by means of the organs of the intestinal tract (3) simultaneously by the lower pelvic organs and those of the intestinal tract.

W. A. BREWSTER.

Beach W M Some Observations on Hernia in Relation to Intestinal Stasis. *The Practitioner* Dec 1906 90 June

After reviewing the theories of Keith relative to nodal zones situated at different levels in the intestinal musculature the author makes the following observations:

1 We have tried to define intestinal stasis as a physiological or anatomical disturbance of peristalsis by an inhibiting influence through the nodal zones of

the myenterium located in the esophagogastric junction, the duodenojejunal area, the ileocecal region, and the rectum. This demonstrated in the laboratory must be verified clinically.

2. Anatomic distortions, as kinks, adhesions, ptoses, etc. lead to stasis by disturbing the ganglia controlling peristalsis.

3. Hernia is a frequent manifestation of visceral displacement concomitant with stasis.

4. Long truss wearing with great pressure tends to produce rectal disease.

GASTRO-INTESTINAL TRACT

Terry W I and Kilgore, A. R. Congenital Stenosis of the Duodenum in an Adult. *J Am Med Ass* 9 6 1914, 774.

A man aged 24, presented essentially equal to family and past history and habits. His illness began at the age of 2 with years of intermittent rather indefinite pain in the lower abdomen followed by three and a half years of freedom and then four years more of similar attacks at intervals of from three to six weeks. The pain was always below the umbilicus, extending 5 cm to either side of the midline without radiation. There was no definite relation to food. It was relieved by hot drinks and occasionally by defecation. It was usually worse at night.

He had had a definite pain for six years but four years ago vomiting had begun and had grown progressively worse, usually coming after the evening meal, sometimes after other meals. There had never been hematemesis or melena.

The abdomen was scaphoid except for prominence about the umbilicus (distended stomach) over which there was marked peristalsis from left to right. The lower border of the stomach was seen and percussed midway between the umbilicus and the symphysis.

At operation the stomach was found to be much dilated and lying in the abdomen. There were some old adhesions across both the anterior and the posterior aspects of the stomach toward the pylorus but none about the duodenum except two very thin strands between the pylorus and gall bladder. The pyloric ring was much dilated. The first portion of the duodenum was dilated the upper portion forming a definite pouch. Just distal to this dilated portion at about the junction of the first and second portions of the duodenum and above the entrance of the common duct the intestine was evenly constricted to one-third or less of its normal diameter for about 5 cm. There was no thickening of the wall and no scars could be found. No abnormalities of the peritoneum to account for the constriction.

A posterior gastro-enterostomy was done and while the stomach was cut into marked thickening of the wall was noted in spite of the dilatation of the organ, indicating long-standing obstruction.

The patient vomited during the first forty-eight

hours following the operation the vomitus containing considerable blood. Following this he was desirous much of the time and on this account was given occasional nasal feedings. On the fifth day he was apparently much improved and took considerable nourishment but vomited small amounts twice during the afternoon. Quite suddenly in the evening the pulse rate increased and respirations became shallow and rapid and he gradually sank into coma and died six hours.

At necropsy there was found to be marked dilatation of the stomach with partial breaking down of the gastro-enterostomy wound leakage of stomach contents into the peritoneal cavity and beginning peritonitis. The constriction of the duodenum presented the appearance of an obstructing fold of the duodenal wall rather than of a narrow tube 5 mm long as it had appeared before fixation. Grossly and microscopically the constriction was covered with normal mucous membrane and careful search failed to reveal any scar tissue or other evidence of old ulceration. EDWARD L. CORCORAN.

Cooke, J V, Rodenbaugh, F H and Whipple G H. Intestinal Obstruction: a Study of Non-coagulable Nitrogen in the Blood. *J Exp Med* 9 6 1914, 7.

This communication deals with analyses of the blood in intestinal obstruction, intestinal closed loops, and other acute intoxications. The tables give figures for non-coagulable nitrogen, urea nitrogen and in some instances the total nitrogen partition in the blood. The authors interest in this study of the blood was aroused by a communication of Tilden and Comfort who in a large series of human cases reported three cases of intestinal obstruction with very high non-coagulable nitrogen. Since that time they have studied the blood of various animals which were being observed in connection with other experimental work.

They found that most cases of intestinal obstruction especially with signs of acute intoxication showed high non-coagulable blood nitrogen and it seemed to them that this factor might be of value in diagnosis and especially prognosis of acute abdominal conditions. They believe that this non-coagulable nitrogen determination is of value in various acute intoxications. If the reading is high, may assume a dangerous grade of intoxication, but on the contrary it may not assume that a low reading gives evidence of slight intoxication, because a fatal outcome may be associated with a low reading. It is of considerable value to know that the non-coagulable nitrogen of the blood may show high readings in other conditions besides renal disease.

On the other hand, determinations of the blood urea alone are of somewhat less value in studying the retention products in the blood in these conditions. In their experimental animals the blood urea has varied from less than 30 per cent to more than 80 per cent of the total non-coagulable nitrogen, and,

while a high urea reading is the rule the variations in the urea curve and the curves of the other non-coagulable nitrogenous substances are so great that the urea reading is a somewhat unreliable index of the extent to which non-coagulable nitrogenous substances have accumulated. The authors work seems to establish the following facts:

1. Intestinal obstruction as a rule is associated with an increasing amount of non-coagulable nitrogen in the blood. With acute intoxication the rise in non-coagulable nitrogen may be rapid and reach as high as three or even ten times the normal amount. With more chronic intoxication there may be little or no rise in the blood non-coagulable nitrogen. Closed intestinal loops show exactly the same picture and when combined with obstruction may give very high nitrogen readings.

2. Acute proteose intoxication due to injection of a pure proteose will show a prompt rise in blood non-coagulable nitrogen even an increase of 100 per cent within three or four hours. These intoxications also show a high blood content of creatinin and urea. The residual or undetermined nitrogen may be very high.

3. A human case of intestinal obstruction with autopsy presents blood findings exactly similar to those observed in many animal experiments. Clinically the non-coagulable nitrogen of the blood may give information of value in intestinal obstruction. A high reading means a grave intoxication but a low reading may be observed in some fatal cases and gives no assurance that a fatal intoxication may not supervene. The kidneys in practically all these experiments are normal in all respects.

It is possible that protein or tissue destruction rather than impaired eliminative function is responsible for the rise in non-coagulable nitrogen of the blood in these acute intoxications. Transfusions of dextrose solutions often benefit intestinal obstructions and may depress the level of the non-coagulable nitrogen in the blood. Some cases show no change in non-coagulable nitrogen following transfusions and diuretics, and as a rule such cases present the most severe intoxication.

GEORGE E. BRIDY

Power D.: A Clinical Lecture on Volvulus. *Am. J. S. G.* 916 xxx 78

Power defines volvulus and states that the exact mechanism of its production is unknown but that two necessary factors are (1) congenital or acquired defect in the intestinal attachment allowing free mobility and (2) a condition producing an artificial pedicle. He cites seven cases from which he concludes that volvulus is one of the causes of acute intestinal obstruction and that it may appear in newborn children although this is rare. He believes that volvulus requires for its production a loop of bowel lying less securely packed than usual in the abdominal cavity, a loaded bowel and irregular peristalsis. Frequently there is a twist of one or two turns in the loop upon itself usually the mesentery is long in these cases.

The onset of volvulus is sudden and painful and occurs in persons who have had no reason to believe they were not in their ordinary health; it may occur without any known cause or it may follow an injury to the abdomen. Generally the pain is persistent or is characterized by exacerbation. The position of the volvulus determines the time of the appearance of the signs of intestinal obstruction. When the sigmoid is involved the signs appear early when the caecum is twisted there may be a delay till the larger intestine has emptied itself or it may be masked by a discharge of flatus generated in the great bowel. The onset of vomiting may be delayed or in some cases may be entirely absent but usually it is a marked feature of the condition. At first the temperature and pulse are not altered.

Abdominal distention is limited early to the portion of bowel involved. In its inception there is no rigidity of the abdominal wall, local tenderness over the actual seat of the volvulus is present but is not very marked until the onset of peritonitis.

Strangulated hernia, acute perforation of the stomach or duodenum, biliary and renal colic, acute intestinal obstruction due to strangulation by a band, hamorrhagic pancreatitis, thrombosis and embolism of the mesenteric vessels and appendicitis must each and all be considered in the diagnosis.

The prognosis at the present time is extremely unfavorable, the improvement in this regard depends entirely upon the early recognition and early operation. In looking up the records in his hospital from 1899 to 1915 the author finds that there were 25 cases of volvulus, 14 men and 11 women. Twen-

ty-one of these patients died. In the after treatment of volvulus the author believes that nothing should be given by mouth for the first twelve hours after the operation though the mouth may be rinsed out with warm water from time to time if thirst is distressing. Three or four doses of purgative extract may be given hourly by injecting 0.5 to 1 ccm into the muscles, in the hope of causing contraction of the involuntary muscles of the body, thereby stimulating the unstriated muscles of the intestine. The rectal tube should be passed every four hours if the distention is very great.

In general the after treatment is directed toward the reduction in the tympanites as he recognizes that the tympanites is a measure of intestinal paresis and that as this is reduced the patient will improve. EAST C. ROBERTS.

Abbott A. W.: The Early Diagnosis of Intussusception in Children Under Three Years of Age. *J. La et G. N. Y.* 39

The author gives a series of statistical observations made upon twelve cases of intussusception in infants under three years of age. The diagnosis was made before operation in all but two and the intussusception was found to be fecocolic in all cases.

In 100 per cent of the cases the attack began by a sudden violent abdominal pain accompanied by re-

gurgitation of stomach contents the child being otherwise well. This pain is recurrent varies in intensity but is regular in periodicity. With the pain the child assumes peculiar positions, generally prone. In 5 per cent of the cases, collapse quickly occurred and the pains were then merely indicated by moans and drawing up of the limbs.

In 93 per cent an abdominal tumor could be made out in the course of the colon.

In 9 per cent there were 0 faces in the stools. In 83 per cent of these mucus was the chief constituent of the stools. In 77 per cent of the cases, blood was present in the stools only after the second day.

In nearly all cases the abdomen was not distended, flaccid, and scaphoid.

In exceptional cases vomiting was absent and in 81 per cent of the series it only occurred after the second day.

Positive identification of the intussusception by rectal examination is pathognomonic and was demonstrated in only 55 per cent of the cases.

The virulence of the disease and its mortality depend not so much upon the time elapsing before operation as upon the intensity of the strangulation of the mesenteric circulation. However the earliest possible diagnosis and immediate operation is imperative.

In the series, 8 recovered and 4 died. In those in which collapse quickly followed the onset all died. While in those in which collapse was absent 8 recovered and one died. P. M. CHASE

Sweet, J. E., Peet, M. M., and Hendrix, B. M.
High Intestinal Stenosis. *Ann Surg Phila* 9 6
1911, 730

The authors carried out a series of experiments to determine the cause of death in high intestinal obstruction, the clinical picture of which suggests grave constitutional disturbance of toxic nature. Draper's idea that the toxin is a normal product of the duodenum which under normal conditions is neutralized or detoxified by the junction is supported. The authors began with the admitted clinical fact that the symptoms of acute pancreatitis and acute high obstruction are so much alike, if not identical, that a differential diagnosis can be made only at operation and this suggested that the fatal agent might in some way be connected with the pancreatic juice.

It is believed that high intestinal obstruction is due to the highly toxic properties that have been found in the proteose stage of protein digestion. The normal ferments of the stomach and the normal ferments of the pancreas break a protein down to this stage normally. It is supposed that the gastric digestion carries the proteins of the food to the peptone stage, from which the digestion is carried to the amino-acid stage by the ferments of the pancreas and the intestine. The intestinal juice is not supposed to contain any proteolytic ferment except the ferment erepsin which can digest the pro-

tein casein, but no others, while its chief function is to digest the proteoses to the amino-acids. But either gastric or pancreatic ferment is capable of producing a toxic proteose. In addition, many bacteria can digest the protein building-stones to the highly toxic amine compounds. Further the substance fecitbin can, by the action of the fat splitting ferment lipase be broken down with the formation of the choline bases, some of which such as choline and neurine, are highly toxic.

Whipple has demonstrated that the toxic body found in their high loops is a proteose and that this purified proteose would exactly reproduce the symptoms of high obstruction when injected into a normal animal.

Two outstanding features of the authors' experimental work are (1) the added demonstration of the fact that a gastro-enterostomy opening does not function in the presence of a normal pylorus (2) the explanation of the similarity between acute pancreatitis and acute high obstruction: they are alike because they are both essentially the same thing—an intoxication with the toxic products of protein cleavage. In pancreatitis certainly due to the proteolytic ferment of the pancreas in high obstruction not necessarily perhaps, but in their opinion in all probability the same toxin, produced by the same ferment. In pancreatitis the escape of the products of the digestion of the pancreas into the tissue permits the intoxication. In obstruction the conditions of obstruction permit the absorption of toxic products, which under normal conditions would either not be formed, or if formed, would be immediately broken down to non-toxic products.

The authors refer to the failure to find any definite poison in conditions of stasis of the large intestine and draw attention to the fact that in stools of the colon the head of the pancreas is dragged across the transverse colon, producing as has been reported a dilated duodenum. Removal of the colon would relieve this drag and the authors predict the idea that it would be well to consider the chronic absorption of such a poison.

C. G. HERTZ

Fowler, R. H. Complete Congenital Atresia of the Ileum. *Med Rec* 9 6 1911 39.

The author reports the case of a baby whose delivery was normal and easy, no fears being used the weight at birth being about seven pounds. Vomiting commenced about fifteen minutes after birth. The vomitus was green, frothy and thick without special odor. The vomiting continued at intervals during the night and the following day. The abdomen was slightly distended and tense. There was no visible peristalsis and no masses were seen or felt. There were no external congenital anomalies. The rectum easily admitted the little finger, no blood escaped or appeared on the gloved finger. No masses or obstruction were felt. The genitalia were normal.

At operation a right rectus incision was made.

A large amount of thin serous fluid escaped on opening the peritoneum. The small intestine presented. It was of dark color and distended six times the diameter of the neighboring loops. This distended loop of gut literally popped into the wound. It was blind and free without fibrous cord connection. The mesentery down to its root was also lacking at this point. The gut above this point was less dilated than the blind pouch. The bladder was full and the stomach distended. No stenosis or change in the pylorus was noted. The duodenum was dilated slightly more than the commencing jejunum. In a hurried search the lower end of the ileum was not found. The appendix was normal. There was no persistence of the embryonal type of cecum. The latter was firmly attached to the posterior abdominal wall. The intestines were moderately congested. The upper free end of the small intestine was sutured to the abdominal wall and the abdominal wall closed in layers about the protruding gut. Enterostomy was then performed by the thermocautery. The patient died five days later.

At autopsy it was found that the total length of the small intestine was 56 inches. The ileum ended in a small blind pouch 23 5 inches from the ileocecal valve one half inch in diameter. The wall of this was thickened and bulbous for a distance of three-eighths of an inch. It was slightly curled upon itself. The segment distal to this cul-de-sac was patent. There was a defect in the mesentery at a point opposite the atresia of the ileum. The upper blind pouch ended at a point 33 5 inches from the pylorus. It was very much dilated for a distance of six inches. The widest diameter of this portion was 1 75 inches. The duodenum had no mesentery. The cecum was located in the right iliac fossa; there fore rotation of the intestine had occurred. The ileocecal valve and the pyloric sphincter showed no change. The liver, gall bladder and ducts and stomach were apparently normal. There was an accessory spleen.

EDWARD L. CORNELL.

Huggins, R. R.: Absence of Muscular Tone an Important Etiological Factor in Post-operative Ileus. *Tr Am Ass Obst & Gynec* Indianapolis 19 6 Sept.

Distention and stasis, to a varying degree follow most laparotomies. This is usually considered a temporary paralysis a reflex action through the plexus of Auerbach and Meissner as a result of manipulation and trauma to the visceral peritoneum. Aside from the paralysis accompanying peritonitis there are occasional cases where infection can be excluded in which the patients die from paralytic ileus. This may occur when least expected and where there has been very little intra abdominal exposure and manipulation. The comparative frequency with which it has occurred with vaginal hysterectomy is significant because there is very little exposure and handling of intestines in this procedure. Careful pre-operative operative and

post-operative treatment is important in lessening post-operative paresis, but occasionally in spite of this an aggravated form of the above condition occurs and death ensues after exhaustion of all known methods of relief. When there is evidence of chronic fatigue with poor muscle tone after chronic infection or long continued strain there is always greater difficulty in dealing with this post-operative distention. The author believes that in certain instances where death occurs from so-called paralytic ileus, it is primarily due to lack of muscular strength in the walls of the stomach and intestines. As a result of observation of various degrees of distention in routine abdominal surgery we find that this depends largely on the general muscular tone in the individual previous to operation and the amount of exhaustion incident to the operative procedure and the effects of the anesthetic.

Keith has recently called attention to the presence of nodal tissue in the bowel similar to that in the heart. This is located at various points in the intestinal tract and acts as pacemaker for that particular portion. It is neuromuscular in character and suggests the intimate relation that exists between the muscular and nervous system, and the disturbances that may arise if either is below the normal in efficiency. A block may occur as in the heart at any point where one rhythmical zone passes into another. Bayliss and Starling demonstrated the intrinsic beat in intestinal muscle. Magnus demonstrated that the strips beat more actively when removed from a normally fed animal than from one that was not digesting. The intestinal tract has an intrinsic tone regulated by extrinsic nerves. Tonic contraction and rhythmical peristalsis disappear when there is general bodily weakness, and when the depleted central nervous system fails to deliver the necessary tonic impulses. Post-operative distention varies in direct proportion to the strength and tone of the general muscular system. Patients with poor general muscular tone require more careful preparation and greater efforts to minimize exhaustion from anesthetic and operative effects.

Moschowitz, E.: The Pathological Diagnosis of Diseases of the Appendix. *Ann Surg Phil*, 1916 1111 697

Moschowitz believes that in 90 per cent of cases the diagnosis of a present or previous appendicitis may be easily recognized by the naked eye. He holds that the conventional method of longitudinally slitting the organ to see if the appendix is diseased and to what extent is wrong. In acute appendicitis the longitudinal method is not so apt to lead to mistakes. The author advises simple transverse incisions made at various levels. By such incisions it is possible to tell accurately the quantity and topography of the exudate, the width and conformation of the lumen and the evidence of a lumen, the relation of the mucosa to the muscularis. Emphasis is placed upon the observation that a local peri-

tonitis is always present in the early stages of disease, and that the absence, even grossly, of a localized appendicular peritonitis practically excludes an acute appendicitis. Acute perforations are, in the opinion of the author, due to the direct destructive action of the bacteria upon the wall of the appendix associated with extensive tension upon the exudate within the lumen. Thrombosis of the mesenteric lumen plays a small part in the etiology of perforations.

The pathological anatomy of acute appendicitis is summarized as follows: (1) The infection is always enterogenic as evidenced by the invariable origin of the lesion from the mucosa. (2) The lesion of acute appendicitis is not a catarrhal inflammation as understood in the pathological sense. (3) The infection starts in the crypts of the mucous membrane. Additional weight is lent to this contention by the fact that approximately nine-tenths of the lesions of acute appendicitis occur at the tip of the appendix where stagnation is most apt to occur. This fact makes untenable the contention that appendicitis is occasionally due to a caecitis or lesions of the so-called Gerlach's valve by interfering with the drainage of the organ. (4) The pathological lesion fairly corresponds to the duration of the illness. (5) The essential pathological lesion of acute appendicitis is a membranous inflammation, a so-called diphtheritic inflammation.

In healing appendicitis the course of events is as follows: The exudate or membrane breaks down, becomes necrotic, and leaves an ulcer which gives birth to granulation tissue. The extent of this granulation tissue depends upon the extent of the destruction of the mucosa. If the mucosa has been completely destroyed, no regeneration of epithelium is possible and the ensuing organization of the tissue results in complete obliteration. If the mucosa has not been completely destroyed, the epithelial lumen is restored, a stricture is formed the size of which is obviously in inverse ratio to the extent of the mucosal destruction. At the same time the formation of new connective tissue in the muscular coats leads to the changes of deformity and separation of the fibers by newly formed connective tissue. In the peritoneal coat the formation of the new connective tissue and destruction of the surface epithelium also lead to two changes: thickening and formation of adhesions. The histological characteristics of a healed or chronic appendicitis are therefore the following: (1) a narrow lumen (stricture) (2) complete obliteration of the lumen by new connective tissue (3) the absence of mucosal crypts. (This absence indicates, except in cases where the lumen

of the appendix has been dilated from other causes, that a previous acute suppurative inflammation has taken place. This phenomenon is important in differential diagnosis in cases where there is question as to whether the lumen of the appendix is narrower than normal.) (4) the widening of the submucous connective-tissue zone (5) the attenuation and diminution (or even complete disappearance) of the lymphoid tissue (6) the infiltration of

the muscular coats by new connective tissue and consequent deformity (7) the thickening, increased density and deformity of the peritoneal coat.

As a result of the author's observations it is stated that an acute appendicitis always gives rise to permanent pathological changes and secondly that a normal appendix never has been the seat of an acute attack. Of the diagnostic characters of healed or chronic appendicitis great emphasis is laid upon (1) stricture (2) obliteration, (3) disappearance of crypts (4) widening of submucosa. The appearance of petechial spots scattered throughout the mucosa is considered to be due to operative trauma. Diverticulism of the appendix has always been associated with but inflammation.

In regard to carcinoma of the appendix the author calls attention to certain curious features of the disease. Carcinoma of the appendix differs from carcinoma of other organs and especially of the intestinal tract in number of features: (1) It occurs as a rule in the younger individuals, most commonly in the second and third decades. Two of the author's cases exemplify this. (2) Carcinoma of the appendix, both pathologically and clinically, is of very low grade of malignancy. Appendix carcinoma resembles other carcinomas only in the histological structure and the epithelial type of cell. In other respects they differ histologically from other carcinomas. The cells are smaller and less atypical, the nuclei show little variation in size and shape and are less rich in chromatin, and comparatively free from mitotic figures. Finally there is less tendency to invasion of neighboring organic structures and practically no tendency to metastasis. Indeed the author finds these pathological data brought out by clinical experience. Carcinoma of the appendix has by far the best prognosis of any cancer in the human frame. The author believes the reports of fatal cases are rare. Perhaps one of the reasons for the favorable prognosis is the early diagnosis of appendicular pain, due to the prompt interference with the drainage of the narrow lumen of the organ by the growth of the tumor. (3) The vast majority of carcinomas of the appendix are of the solid type, whereas carcinomas of the intestine are of the glandular type.

After a consideration of the subject as a whole the author arrives at the following conclusions:

1. The pathological lesion of acute appendicitis represents a suppurative process from the very beginning. The earliest lesion is a pathognomonic as the primary lesion of typhoid and all the subsequent stages of the disease within the organ are directly traceable to the spread and development of this lesion. There is no pathological evidence that an acute catarrhal inflammation of the appendix occurs.

The changes associated under the name chronic appendicitis (stricture, obliteration, etc.) are pathogenetically the healed products of the acute lesion. According to this interpretation, chronic appendicitis is not a continuous progressive

inflammation, but an end product. There is no pathological evidence of "involution" of the appendix, or of chronic catarrhal inflammation of the appendix.

3 The only justifiable classification of inflammation of the appendix, therefore is the following: (1) Acute appendicitis. (2) Healing of subacute appendicitis. (3) Healed or chronic appendicitis. (4) An acute localized peritonitis with the formation of fibrin and limited to the site of the lesion is always present in acute appendicitis as early as twelve hours after the onset (and perhaps earlier) so that the absence grossly of a localized peritonitis in suspected cases, is *eo ipso* evidence of absence of acute appendicitis. (5) In addition to obliteration and stricture, attention is called to two new easily recognizable, constant, and pathognomonic signs of chronic appendicitis namely: (a) absence of mucosal crypts (b) marked widening of the submucous connective tissue zone. The latter sign is especially easy to determine upon cross-section of the organ, and is recommended as the simplest way to determine the presence or absence of a chronic appendicitis. (6) Cross-section of the appendix at various levels is far preferable to longitudinal section to determine pathological changes.

C. G. HERR

Valdez, G.: Morphine as an Early Diagnostic Element in Certain Forms of Acute Appendicitis (*La morfina como elemento de diagnóstico precoz en ciertas formas de apendicitis aguda*) *Pres. méd. Argent.* 19 6 14, 430.

Valdez uses morphine in the diagnosis of various acute abdominal processes especially in those of an appendicular nature believing that this method may be applied in those cases in which the diagnosis is doubtful. In effect by making an injection of morphine in such cases the reflex defensive phenomena disappear (contracture of the abdominal muscles) which allows a much better abdominal examination, as at the end of an hour after the injection the pain can be localized with great exactness.

Valdez thinks that morphine can be usefully employed in some cases of difficult diagnosis.

W. A. BUCKMAN

Robinson, J. E.: The Leucocyte Count of Appendicitis. *N. Y. M. J.* 19 6 173

A report is given of 200 appendices removed at operation at the King's Daughters Hospital Temple Texas, in the last two years in which sections were made of the appendices and records made of the blood-counts only blood-counts made before operation being considered.

Reports are also given of the blood-counts in 200 cases in which records were kept of the blood counts but no sections made of the appendix.

Fifty two cases, or 21 per cent were diagnosed as active inflammatory by both the surgeon and the pathologist the average leucocyte count being 18 000 and the polymorphonuclears 82 8 per cent

Sixty five cases, or 32 5 per cent were diagnosed as chronic by both the surgeon and the pathologist the average leucocyte count being 10 161 and the polymorphonuclears 76 per cent.

In 40 cases, or 20 per cent the appendices were removed while operations were being performed for non inflammatory conditions in the abdomen. In these cases which both the surgeon and the pathologist reported normal the average leucocyte count was 8,400 and polymorphonuclears 67 5 per cent.

It will be seen that the surgeon's report made with the history and appendix before him corresponded with the laboratory report 157 times or in 78 5 per cent of the cases.

Fourteen cases were diagnosed as active appendicitis by the surgeon and as normal by the pathologist and in these cases the average leucocyte count was 11 900 and polymorphonuclears 72 1 per cent.

Twenty-four cases diagnosed as chronic appendicitis by the surgeon and as normal by the pathologist gave an average leucocyte count of 8 000 and a polymorphonuclear of 65 8 per cent.

In 5 cases reported as active appendicitis by the surgeon and as chronic by the pathologist the average leucocyte count was 7,450 and the polymorphonuclears 62 5 per cent.

Presuming that the findings are correct and that the work is that of surgeons of average ability it will be seen that the surgeon is incorrect in his conception of the pathology of the appendix in 21 5 per cent of the cases. Twelve per cent of the normal appendices were diagnosed as chronically inflamed. Seven per cent of chronic cases were diagnosed as active and 2 5 per cent of normal appendices were diagnosed as acutely inflamed. There is one redeeming feature of the surgeon's report in no instance was an inflamed appendix diagnosed as normal and his efficiency along this line is easily 100 per cent.

In the second series of 200 cases in which sections were not made 93 were diagnosed as actively inflamed and 55 showed pus either in or around the appendix these gave an average leucocyte count of 20 000 and a polymorphonuclear of 84.6 per cent. The highest leucocyte count was 98,000 with 83 per cent polymorphonuclears. The lowest count was 10,000 leucocyte with 86 per cent polymorphonuclears.

Thirty-eight cases diagnosed as active appendicitis showing no pus gave an average leucocyte count of 18,000 polymorphonuclears 83 3 per cent.

Six cases in this series gave a leucocyte count as low as 12,000 with an average of 83 per cent polymorphonuclears. In 107 cases diagnosed as chronic appendicitis the average leucocyte count was 10,000, polymorphonuclears 70 2 per cent.

It will be noticed here that the cases showing pus gave a leucocyte count of 11 000 and a polymorphonuclear count of 18 per cent higher than those in the series which were sectioned and pronounced to be actively inflamed, while the cases showing no pus gave practically the same count as the series

sectioned, namely 18,000 in the sectioned series and 18,500 in the series not sectioned with a difference of only 0.4 per cent in the polymorphonuclears.

EDWARD L. CORNWELL.

Leigh S. Treatment of Suppurative Appendicitis.

South. M. J. 961:53

As soon as appendicitis is suspected, the head of the patient should be immediately elevated and the patient kept on the right side. In such position if rupture takes place, the septic fluids will either remain at the site of the appendix and become walled off or gravitate into the pelvis where they may be more safely taken care of by the serous membrane, be more conveniently reached at the time of operation, and the dangerous region of the upper abdomen will be thus safeguarded.

The question of transportation is most important, the patient's shoulders being well propped up and inclined to the right side. This must be strictly done in all carriages, wagons, trains and ambulances used for the sick. The last named should always be equipped with an elevating stretcher.

When a case of suspected suppurative appendicitis reaches the hospital, he should be immediately placed on an elevated bed, on the right side with an ice bag applied. Except in desperate cases, a low turpentine enema should be given.

The anesthetic is of major importance. The author has used nitrous oxide-oxygen in 1,000 cases, not only without mortality but without any bad effects, either direct or indirect. It is especially helpful in severe appendicitis, doing practically nothing to the abcess, producing no irritation of the lungs or kidneys, and accompanied either by no nausea or a minimum amount.

The location of the incision in cases of suspected suppurative appendicitis is important. Drainage through the old longit. diast. incision leaves a very weak spot which need by always requires operation to close. For several years the author has employed the transverse incision. The abcess is opened after walling off. The pus is drained and the appendix sought in most cases. The cavity is wiped dry and gauze rubber tube drains inserted.

In suppurative appendicitis, in which the abcess has not been walled off by adhesions, and in consequence of the general peritoneal cavity has become infected, the transverse incision must be stretched to allow free access to the peritoneal cavity. Incisions are preceded by injecting novocaine solution to produce nerve-blocking. The greatest possible gentleness is exercised in the handling of the tissues.

No irrigation should be used, but the pus should be wiped out carefully with sponges. After all the pus which is accessible is thus cleaned out pads are cautiously inserted and the appendix searched for and removed a pad being packed into the site of the appendix, which is usually quite solid. The pelvis is often found full of pus, which should be removed by suction.

EDWARD L. CORNWELL.

Shaw H. A. The Treatment of the Retrocecal Appendix. *Ann. Surg. Phila.* 961:117:5

The author refers to the simple clean, bloodless technique for the removal of retrocecal appendix by mobilization of the cecum and colon. In the etiology of a retrocecal appendix the following factors are emphasized: (1) the influence of peritoneal adhesions established during the descent of the cecum from its subhepatic position to the iliac fossa; (2) the inherent curve of the fecal pouch; (3) the unequal development of the pouch.

The author suggests the diagnostic points necessary to determine the position of aberrant appendices: careful survey of the cecum (with the embryology thereof in mind) noting the relative size and position of the terminal sacculi; its topographical peritoneal relations; careful palpation. The technique emphasizes the mobilization of the cecum and portion of the colon necessary for exposure, and after exposure separation of adhesions and delivery of the appendix. After removal of the appendix the cecum is replaced and the incision line in the peritoneum closed by sutures. The stump of the appendix is treated after the accepted manner.

C. G. HERTZ

Frazier C. H. and Post M. M. Experimental Colonic Stenosis. *Ann. Surg. Phila.* 961:117:759

The authors believed that a maximum amount of stasis without partial obstruction could be secured by a simple reversal of the large intestine and carried out their experiment by the reversal of the colon for a length of four to six inches above the sigmoid. Two sets of experiments were carried out, as follows:

With reversals of the colon *per se* the stools were soft and well formed and all the dogs gained weight. The following substances were demonstrated by qualitative tests in the urine: methylamine, trimethylamine, tetramethylamine, pentamethylamine, paroxyphenylthylamine. From the presence of the last, it was inferred that phenylethylamine was present. Methylguanidine, diamethylguanidine, and imidazoethylamine were not demonstrable. The urine of these dogs as well as the substances obtained after chemical isolation of the mixed bases was injected intravenously but no noticeable toxicity could be established; no did the curve of blood pressure differ from that to be noted following the injection of normal canine urine.

The results of reversal of the colon in dogs with Eck fistula. A heavy silk ligature was tied around the portal vein close to its entrance into the liver thus forcing all of the portal circulation into the vena cava. In these experiments the stools were well formed and no toxic symptoms were observed. The chemical examination of the urine was the same as before, both qualitatively and quantitatively, showing that the liver had not removed or changed the substance absorbed from the colon.

The authors' conclusions were that mere stagnation of feces in the colon of the dog, when in a nor-

mal mixed diet does not lead to the formation of toxic substances of note, at least in the presence of the normal flora of the canine colon.

The fact that these dogs remained in perfect health and gained in weight indicates that simple colonic stasis in the dog is harmless and certainly suggests that the dire effects attributed to colonic stasis in man are in part at least due to some other cause than the absorption of the products usually formed in simple fecal stagnation. C G HENY

McArdle J S: Alternatives to the Operation of Colotomy *Practitioner* Lond. 1916 xcvl, 578.

The after-effects of so unsurgical an operation as colotomy are very distressing to the patient. The author believes that every effort should be made to substitute some more finished procedure for this crude method and suggests that either of the four following operations should be carried out according to the conditions found on exploration.

1 The sigmoid above the stricture can be joined to the sound lower part of the rectum.

2 If the sigmoid is fixed so that it cannot be brought down the transverse colon if low may be anastomosed to the rectum and to the descending colon above the stricture.

3 If this is not feasible the caecum may be joined to the rectum and the ileum joined to the colon above the stricture.

4 The lowermost coil of the ileum may be joined to the rectum and by a lateral anastomosis to the descending colon above the obstruction.

The difficulty in all these procedures is the application of the usual suture methods because of the difficulty in commanding the rectum through an abdominal incision.

The author has devised a means whereby these operations are rendered comparatively easy. In whatever segment the upper opening is made the small female end of a Hildebrand button is inserted and fixed with a purse-string suture. By means of an especially devised forceps the larger male end is passed through the rectum and made to project upward so that a small incision may be made over the central part which then protrudes allowing the bowel wall to slide down so close to the spring that no suture is needed. The two halves of the button are then clamped. The result is a passage for fecal matter into the rectum instead of outward on the abdomen or through the lumbar region while drainage of the large intestine is possible through this route. E. K. ARMSTRONG.

Axtell W H: Acute Angulation and Flexure of the Sigmoid a Causal Factor in Epilepsy. *Tr Am Neurol Soc* Detroit 1916 Ju c.

In December 1910 the author published his first list of 31 cases, 8 private and 23 a clinic cases. In August 1911 a further report was made on 10 private cases with 3 recoveries. This included 3 additional a clinic and 2 private cases making in all 36 cases. The 3 reported cures have remained so

for a period of over four years. One additional case of the original list of 10 private cases has had no return of the convulsions since ceasing treatment two years ago. The treatment seemed at the time to increase the limitation as reported.

Since the last report Axtell has had 9 additional cases with 4 of them remaining free from seizures for from one to two and a half years making in all 45 cases reported with 8 recoveries to date.

From his observations the author is convinced that those who acquire epilepsy after the fifteenth year are more amenable to successful treatment than when the trouble commences earlier in life. In his judgment surgery can give but little relief except where there is a definite history of inflammatory adhesions holding the angulations and flexures in fact the condition of fecal stasis precludes surgery of the colon until the condition is first relieved which when so relieved eliminates a prime factor in the production of the trouble. A new and undescribed cause of the intestinal stasis which is so generally present in these cases is the separation of the recti muscles which are so essential to a thorough evacuation of the colon and for the support of the abdominal organs.

The essential failure of treatment of these conditions lies in the fact that so few recognize the true condition, and if the condition is recognized there is not sufficient persistence in relieving the condition or an ignorance as to the amount of material the colon holds and as to when it is well emptied. As the result of failure to recognize the true condition mutilating surgery is resorted to without getting results commensurate to the gravity of the surgery resorted to the first intimation of the true condition being found upon opening the abdomen then details are carried out which should have been used in the first instance and which would have rendered surgery unnecessary.

Hawley D C: Position for Sigmoidoscope Work. *Tr Am Proctol Soc* Detroit 1916 June.

A majority of writers express a preference for the knee-chest position while a minority prefer some other such as the Hanes Sims or the exaggerated lithotomy position.

Before the days of the pneumatic sigmoidoscope the position was of necessity such as would admit of inflation by atmospheric pressure. Here the knee-chest position was undoubtedly the most satisfactory.

The knee-chest position is trying and disagreeable for the patient and not easy nor always convenient for the operator. Its use is frequently attended with embarrassment and fear on the part of the patient.

With the pneumatic tube the older method may be discarded. The author favors the following method.

The patient is placed in the left lateral position with the left arm drawn out behind the back, the patient lying well over on the left chest not

stomach, the knees flexed the right more than the left and placed above and well over and beyond the left on the table and with the back concaved as much as possible. In this position the abdominal muscles are relaxed, while in the knee-chest position they are apt to be contracted. In a majority of cases the instrument may be passed easily and quickly over the brim of the pelvis and into the sigmoid colon as far as required or to its full length.

This method is not advocated exclusively but a more thorough trial is urged.

Hanes, G. S.: Some Important Pathological Conditions About the Rectal Outlet. *T. Am. P. and Sec.*, Detroit, 9 June.

Tubercular ulcerations do not occur as frequently in the mucosa of the rectum and sigmoid as is generally believed. Amoebic and various types of bacterial ulceration produce dysenteric symptoms that often lead to emaciation and exhaustion. Active tubercular ulceration is always accompanied by a decided increase in the temperature and pulse rate. These are not characteristics in other types of ulceration. In tubercular ulceration there is a history of constant and progressive symptoms while in amoebic there is usually a history of improvement and relapses. Tubercular ulceration involving the rectum and sigmoid seldom yield to treatment. Amoebic ulceration in this climate can be cured by one method or another.

Bacterial types of ulceration are usually very difficult to treat. Within the last two years Hanes has found cauterization with the high tension electric spark to be a most valuable means of treatment.

Tubercular abscesses often occur about the rectum when patients otherwise show no evidence of tuberculosis. The abscesses and subsequent fistulae are characteristic in that there is a great tendency to undermine the skin. The external openings are therefore large with a livid appearance of the surrounding cutaneous structures. They point to impending trouble which may be precipitated months or years hence. This being true it is of great importance that direct the habits, hygiene, etc., of individuals thus afflicted.

Fistulae of long standing with one or more very small external openings with a history of an extensive abscess are very difficult to cure. From external evidences they appear to be very simple. Usually the finger when introduced well into the rectum will be able to detect by careful palpation the hard indurated sinuses which often extend surprisingly high up by the rectum.

Internal fistulous openings rarely if ever perforate the rectal wall unless there is some pathology primarily in the rectal mucosa whereby its resistance is impaired. The internal openings of the fistulae are usually in the anal canal. The anal tissues are almost always diseased before the abscess is formed, therefore it is reasonable to suppose that the infection passes out through the diseased anal structures and is responsible for the abscess.

There are occasional fistulous tracts that extend up by the rectum to considerable heights and are very tortuous. It is difficult to follow these sinuses to their terminations when operating. When the wound heals and a small opening remains it is fairly certain that some part of the original fistula was not reached. It is then advisable to inject bismuth paste which will often effect a cure.

Furunculosis and is undoubtedly a local infection. The focus of the disease is below the pectinate line and at the anal margin. It has been the author's practice to remove the diseased tissues at the margin of the anus and from the emulsion of these diseased tracts res bacteria are cultivated and an autogenous vaccine administered to the patient. The operation with a toxigenous vaccine obtained in this manner gives decidedly the best results.

Krouse, L. J.: Spasmodic Stricture of the Rectum. *T. Am. P. and Sec. D. Trust*, 9 June.

Spasmodic stricture of the rectum is often called phantom stricture on account of its imaginary existence. Krouse states that in the early part of the last century it was more frequently diagnosed than later on. At the present time the opinion regarding the existence of such an affection is equally divided between those who are firm believers and those who doubt its existence.

After quoting the statement of various authors well versed in rectal pathology he expresses his own opinion as to its existence and reports several cases. He agrees with few writers who believe that spasmodic stricture is often the forerunner of the more serious disease of benign stricture of the rectum. He reports several cases.

Krouse claims that spasmodic stricture is not a disease but only a symptom of some other disease located in the rectum or in an adjoining organ. His conclusions are:

1. It is not a common affection.
2. It is easily detected on digital examination.
3. It often terminates in an annular fibrous stricture.
4. It involves the lower Houston valve.
5. A rectal ulcer is the most important etiological factor.
6. Curing the ulcer in its early stage lessens the chances of the development of an annular fibrous stricture.

Syphilia, regarded as a contagious disease as other exanthemata, is characterized by its chronicity and virulence. The only exception to its point of inoculation being confined to tissues covered by squamous epithelium, is within the rectum.

Its frequency in the rectum and anus is not realized and, consequently, is not recognized by the profession. Its relationship to fistulae and stricture is emphasized, and the importance of tuberculous in these two conditions minimized. The careless treatment of fistulae is proverbial. The possibility of stricture resulting from secondaries later in life is suggested.

Drueck, C. J.: How to Examine the Rectum. *Chicago M Recorder* 1916 xxxviii 280

A very careful clinical history should precede all examinations. The author includes an outline which he has found serviceable and which allows for a detailed history.

The examination comprises inspection, digital and instrumental examination.

Inspection reveals many points which might otherwise escape notice. Digital examination is the most important of all and should not be painful when properly executed. A careful method should be followed in making the digital examination so that no false interpretation may result.

Instrumental examination is made by boogies and specula. The former are dangerous to use and are not recommended. An ordinary bivalve speculum is usually satisfactory for an examination of the lower part of the rectum. A long conical speculum with an artificial light gives the best results in the examination of the upper rectum and sigmoid.

J. H. SKILZ.

Yeomans, F. C.: Malignant Transformation of Benign Growths. *T Am Proctol Soc Detroit* 9: 14

The benign tumors of the colon and rectum considered were of the polypoid type, solitary polyp, multiple polyposis, multiple adenomata, and villous tumor. All originate from the intestinal mucosa, are of the same histologic structure but differ in number, size, form, and the relative amounts of glandular and fibrous tissue present.

The author cites the theories of origin of multiple adenomata as advanced by Meyer, Liebert, and Schwab, and (Häuser and H. C. Ross's views on the formation of benign growths. Yeomans thinks these tumors inflammatory in character and notes the frequent history of colitis or dysentery in these cases. Intestinal parasites as causal in others, and the positive evidence of the rôle of irritation as furnished by therapy—colonoclavage or colostomy, and irrigation benefiting some patients and curing others. He reports a case of multiple adenomata in a man aged 30, colostomized in 1913 with marked benefit. Many tumors have disappeared, the remainder have retrogressed and the patient is working. There is no evidence of malignant change.

That benign growths become malignant is beyond question but the cause involves the same enigma as the cause of cancer itself. The author cites the work on neoplasms of Waldeyer, Adams, Cathart, and others, as well as modern research on the transplantation of tumors and the parasitic theory of their origin. He concludes: "All that can be stated positively is that cancer begins as a small local process—that it excites no reaction in the blood, whereby a diagnosis can be made that the individual cancer-cell is the parasite of cancer and whatever eventually explains the origin of cancer will also explain the transformation of a benign into a malignant growth."

Yeomans reports the transformation of a simple adenoma into an adenocarcinoma in a man aged 76 who had rectal bleeding of 8 years' duration, progressive constipation, and a tumor that in recent years could not be reduced within the rectum. The tumor 3.5 by 2 inches was attached just within the anal verge. It was removed under local anesthesia and both clinically and histologically was proved to be adenocarcinoma.

Villous tumor or adenoma tends to recur in malignant form so should be extirpated early, thoroughly and radically.

Multiple adenomata constitute the most important and serious type of benign growth of the intestine. Their usual site is the lower colon and rectum. Clinically they are malignant from diarrhea, hemorrhage, etc. and if neglected over 40 per cent become actually malignant. Improper local treatment as snaring, curettage and cauterization is followed by malignant recurrence in a large proportion of cases.

The curative operative procedure indicated is enterotomy either in the colon above the growths or in the terminal ileum when the entire colon is affected. If the tumors disappear the enterotomy may be closed. If they persist after prolonged irrigation and the patient's general condition warrants it, partial or total colectomy is indicated with implantation of the ileum low down into the sigmoid, the operation being performed either in one or preferably two stages.

Gaut, S. G.: Anorectal Injuries. *T Am Proctol Soc Detroit* 1916 June

While the rectum is protected by the buttocks and bony structures, it is frequently injured by external trauma, expulsion of hardened feces, and by foreign bodies swallowed or introduced through the anus. Such wounds being contused, lacerated, incised or perforated.

Laceration of one or all of the rectal coats results from careless examinations, introduction of imperfect syringe nozzles, bougies, proctoscopes, or other instruments.

Perforating wounds are caused by bollets, knife thrusts and pointed objects that have been swallowed or introduced into the rectum except when due to specific ulcers or cancer.

Recently many pneumatic rectal ruptures, the result of compressed air introduced through the anus to a spirit of fun, have been reported.

The infection of carbolic acid into hemorrhoids is responsible for extensive anorectal injuries.

The chief manifestations of superficial anorectal injuries are bleeding, sphincter spasm, frequent micturition and painful defecation, symptoms that are exaggerated when the wounds are extensive.

Infected wounds are characterized by a chill, temperature, throbbing pain, swelling and a thick yellow discharge.

In extensive injuries of the upper rectum, hemorrhage is profuse. The shock the patient ex-

lapses and soon exhibits symptoms of peritonitis, when the peritoneum is involved.

The diagnosis of anorectal injuries is easy when the nature of the accident is known, the degree of hæmorrhage, bruising and swelling noted and the buttocks, anus, and rectum inspected and digitally and proctoscopically examined.

As to the treatment minor injuries take care of themselves, while extensive injuries may require simple or complicated treatment.

Incised wounds are sutured under aseptic conditions.

Contused, lacerated and pneumatic injuries are drained at one or more points, followed by irrigation, and the ragged edges and necrotic tissue removed. Subsequently they are treated by drainage and topical applications, as fistula wounds.

Injuries of the bladder and urethra are immediately closed when feasible but if not the bladder is drained, and the wounds here and in the rectum are permitted to heal by granulation.

Small rectovesical rents are sutured, but where the rectum or sigmoid is extensively injured, the bowel is resected, or an artificial anus is established.

Rectovaginal tears are repaired by suturing the vaginal before the rectal side of the wound is closed.

Barnea, R. H. Observation on Fissure in Ano. *T. Am. Pract. Soc. Detroit*, 9 June.

The author considers fissure as an ulcer and believes that traumatic causes are of true etiological factors in the production of this trouble but that it is necessary that the tissues become inflamed and hence frail and easily torn in order that fissure be formed. He believes that catarrhal inflammatory conditions are frequently the result of an excessive carbohydrate diet and sometimes an excessive fat diet.

In the treatment of fissure he recommends palliative treatment by correcting the diet with reference to the excesses of carbohydrates and fats and placing the patient on a proctoid diet for a time. When operation is necessary, he believes that the object should be drainage rather than paralyzing the muscular fibers. He also advocates the use of a small enema before defecation in order to avoid irritation from the stool. It is very important to keep the wound clean by hot salt baths and the hot enema, in order that any foreign substance may not lodge in the wound.

Hill, T. C. Prolapsus Ani in Adults. *T. Am. Pract. Soc. Detroit*, 9 June.

The theory is advanced that all cases of procidentia recti are the result of neglect and improper treatment of what was in the beginning a simple form of mucous membrane prolapse. Correction of the condition early may prevent serious infirmity later in life.

He describes at length an operation modified after that of Goodall of London. In this opera-

tion he employs a multiple suture. He advises removing the excess of tissue distal to the ligature.

The operation is performed under local anesthesia and is advised for patients of all ages. It is particularly suitable for use in prolapse of the aged.

The author claims that the operation is painless, short and easily performed. There is absence of hæmorrhage and the end-results are satisfactory.

Terrell, E. H. The Treatment of Hæmorrhoids by New Method. *T. Am. Pract. Soc. Detroit*, 9 June.

The author presents a simple, safe and efficient method of curing selected cases of hæmorrhoids by the injection of quinine and urea solution. During the past two years 7 patients have been treated by this method with only one recognized failure. Injection of quinine and urea in solutions of from 5 to 20 per cent strength produces starvation and atrophy of the hæmorrhoids. The series reported includes only uncomplicated internal hæmorrhoids. The results of the treatment of these patients justify the author's conclusion that the method is simple, safe, and effective in properly selected cases.

LIVER, PANCREAS, AND SPLEEN

Einhorn, M. The Duodenal Tube as a Factor in the Diagnosis and Treatment of Gall Bladder Disease. *J. Am. Med. Ass.* 9 June, 1908.

The duodenal tube has made possible the obtaining of secretions direct from the papilla of Vater and the instilling of fluids in its vicinity. Einhorn has diagnosed probable cholecystitis by direct examination of the bile in forty cases. He concludes that in the majority of cases in which turbid bile is found in the duodenum in the fasting condition, cholecystitis with gall-stones exists. Turbid bile is occasionally found without gall-bladder disease, when the liver is seriously involved (neoplasms, or echinococcus, cirrhosis) or in stricture of the duodenum below the papilla. Exceptionally clear bile is associated with biliary calculi, either the gall bladder not being inflamed, regardless of the presence of stones, or the gall-bladder is entirely filled with calculi no bile entering the organ.

The macroscopic appearance of the bile is important: a clear yellow bile denoting a normal function of the liver and gall bladder while a turbid, greenish, or dark brown bile usually means a diseased state of one or both of these organs.

In a number of cases of cholecystitis an attempt was made to instill either a weak solution of argyrol or of ichthyol just above the ampulla. This treatment is based on the idea that astringents will exert a beneficial effect on the bile ducts. Infections of 20 to 30 ccm. of a 0.25 per cent solution of argyrol may be given every other day. The improvement is often striking, benefiting not only the digestive disorders but the gall-bladder condition. The author believes that duodenal alimentation finds an appro-

prate place in some forms of cholecystitis, particularly when complicated with ulcers of the stomach or duodenum.

E. K. ARMSTRONG

Denver J B: Recurrence of Symptoms After Operation for Gall-Stone Disease. *Illness* M J 19 6 xxix 419

During the period from January 1, 1910 to Jan. 1, 1916 1,031 operations upon the gall bladder or biliary passages were performed at the German Hospital with a total mortality of 7.18 per cent.

The type of operation and the mortality of each is shown by the following table

	Operations	Deaths
Cholecystectomy	360	26
Cholecystectomy and choledochostomy	14	4
Cholecystostomy	437	
Cholecystostomy and choledochostomy	23	4
Cholecystostomy, choledochostomy and pancreatostomy		
Cholecystostomy and choledochostomy	35	4
Cholecystostomy	63	12
Cholecystostomy and choledochostomy		
Cholecystostomy	23	7

Mortality 7.18 per cent

During the same period and included in the above were 42 cases that had been operated upon previously for the same disease. Of these 5 had had two previous operations and one had been operated upon 3 times without relief. In all 50 operations were performed upon these 42 cases. The operative mortality in this group was exactly 8 per cent. The 4 fatalities were due in one case to uncontrollable hemorrhage. In another to the same cause plus leakage from a cholecystododenostomy. In the third from toxemia and exhaustion, and in the fourth which was the case mentioned as having had 4 operations death was due to acute pancreatitis and carcinoma of the head of the pancreas.

It would appear that gall-stones are the most common cause of the recurrence or persistence of symptoms after operation. They make their presence known within a year and often within a few days or weeks. They are usually stones that have been overlooked or out of reach but if the gall bladder has been left the possibility of reformation of stones cannot be disregarded.

In 8 cases the cause of later trouble was either failure to dislodge infection or a re-infection of the biliary passages and pancreas. Chronic and acute cholecystitis without stones was found in 3 instances and chronic pancreatitis in 5.

The author feels that the percentage of failures from these sources would have been much higher had he not laid great stress upon free and long continued drainage of either the gall bladder or common duct or both in all operations upon the biliary passages. The use of maximum sized tubes which are allowed to remain until they practically fall out has been his rule. Operative biliary fistula always close if there is no obstruction to the normal passages and the physiological rest afforded by free drainage is of the utmost value in allowing the tissues to clear away the lurking infection.

Structure of the common duct was met with in 6 instances. In 2 they could fairly be attributed to surgical treatment since in one the duct was accidentally injured during cholecystectomy and in another a severe local infection caused sloughing of a portion of the duct itself. In the other 4 cases the condition was secondary to extensive and long continued disease of the duct such as suppurative and ulcerative cholangitis and might have been obviated by earlier operation.

In 4 cases the only lesion that could be found to account for the symptoms was the presence of adhesions. It must be said however that adhesions often extensive and dense were present in all of the cases. They are part and parcel of the healing process. It is a difficult matter to say just what part adhesions play in the production of symptoms. Where they produce definite kinks or obstructions of the stomach, duodenum or intestines it is not so difficult to correlate the mechanical conditions with clinical effects. The author does not disturb adhesions when operating unless they are in the way. As a rule they cause no trouble and if disturbed, they are sure to reform and probably more densely than before.

More recurrences took place after simple drainage of the gall bladder than when it was removed. Thus in half of the stone cases recurrence was due to calculi left or re-formed in the gall bladder. In one case stones were impacted in the cystic duct and would have been removed by cholecystectomy. When stones are overlooked in the common or hepatic duct it is, of course, clear that the treatment of the gall bladder is of no moment so far as subsequent obstructive symptoms are concerned. It is better to remove the diseased gall bladder when complicated by pancreatitis.

The causes of recurrent symptoms following operation for gall stone disease are the following:

Late operation and extensive pathology

Type of operation not adapted to the lesion

Overlooking stones in the gall bladder or ducts.

Reformation of stones

Persistence or recurrence of infection of gall bladder, ducts or pancreas

Insufficient drainage.

Adhesions, especially adherent duodenum pylorus or stomach

Internal biliary fistula.

External biliary fistula.

Contraction of papilla of Vater

Stricture of the common duct

Stricture of the hepatic duct

Stricture of the cystic duct

Chronic pancreatitis, pancreatic lymphangitis and interstitial pancreatitis.

The type of operation done must necessarily influence the result, for example draining the gall bladder when it should be removed or vice versa, draining the gall bladder externally when it should be drained into the duodenum, failure to drain when there is present a cholangitis, pancreatic lymphangitis.

4 Recent surgical experiences in young children afford clinical basis for such hopes.

5 In view of the otherwise hopeless nature of the case the biliary tract should be explored as soon as the diagnosis is sufficiently established and if the anatomical relations permit—16 per cent of published cases—an artificial passage to the bile to the duodenum should be made. When for any reason, this cannot be done at the time of exploration, an external outlet for the bile should be provided. A repair operation may be attempted at a later date. Meanwhile the child's nutrition should be maintained by the administration if necessary of bile or bile salts.

EDWARD L. CORNWELL.

MISCELLANEOUS

Davis, J. D. S. Value of Pain, Jaundice and Tumor Mass in the Differential Diagnosis of Diseases of the Right Upper Quadrant of Abdomen. *T. 4: 4 Oct & Gyac Indianapolis 9 6 Sept.*

The usual symptoms of peptic ulcer are pain, vomiting and hemorrhage the most important of which is pain.

Pain is the earliest definite symptom. It is usually aggravated by large amounts of food and often relieved by small amounts. Pain may come on during ingestion of food but more frequently comes on a few hours after meals and at night. Gastric ulcers are often characterized by periods of long remission intermittency occurring for long periods of time during which the patient often believes himself well.

The X-ray examination will often be a helpful aid in determining the presence of peptic ulcer. Much valuable information may be secured by the roentgenologists, many of whom claim to diagnose 75 per cent of ulcers.

Peptic ulcer diagnosis is usually based upon the presence of localized pain, followed by vomiting, frequent presence of occult blood in gastric contents or stools, hypersecretion, increased amount of gastric contents, reliable findings with the X-ray and often history of an old irritant dyspepsia.

If hemorrhagic pancreatitis is sudden and violent in onset is characterized by excruciating deep-seated pain usually in the epigastrium or between the xiphoid and umbilicus associated with severe nausea and vomiting, hiccough, constipation, and albuminuria frequently results.

Acute suppurative pancreatitis usually begins suddenly with severe epigastric pain, vomiting, hiccough, chills, and an irregular pyrexial temperature and progressive tympanitis.

In pancreatic calculi paroxysms of pain may be due to the impaction of stone. The pain advances along the lower left costal border to the back rather than to the right side. Detection of free fat in stools or glycosuria may markedly aid in the

diagnosis. Characteristic calculi found in the stool is confirmatory. Jaundice rarely appears in pancreatic lithiasis unless the stone passes into the common duct and becomes lodged. If this takes place or if pressure is made upon the common duct by inflammatory swelling jaundice may occur.

In cholecystitis pain may or may not be very severe, depending largely upon the amount of obstruction produced by the swelling of the ducts.

Epigastric pain with local soreness beneath the right rib margin is usually followed by nausea and vomiting. When the common bile-duct is occluded jaundice with chills and high temperature may result.

Renal calculus is accompanied with severe pain when the stone gets into the kidney pelvis or ureter in its position and blocks the flow of urine. The pain radiates from the loin obliquely downward into the right iliac region—the front of the thigh, bladder or genital organs. Symptoms from renal stone depend upon the size, character and location of the stone. The pain may appear suddenly and is of an agonizing character associated with marked muscular rigidity or spasm. If the stone passes, pain may suddenly cease leaving the bladder more or less irritated. If the stone is rough it may produce much uricæmia and hemorrhage. If the ureter remains long blocked by a stone hydronephrosis marked by tumor mass beneath the costal region may be found. When suppuration occurs in connection with stone pyelonephrosis results and pus, blood, cast and albumin may be found in the urine, and severe symptoms may result.

The liver when enlarged from hepatic abscess may extend several inches below the rib border. When distended by other infections, dull aching pains are present all over the abdomen. The pain is most acute during the night or early morning. Indigestion, headache, lividitate coated tongue and a foul breath may be present. Loss of appetite, weight, and sleep may take place and at times yellow skin, chills, and rigors at times occur with pain and tenderness over the liver. If the abscess swelling is sufficient to press on the bile radicles the jaundice is slight but if the pressure is sufficient to obstruct the common or hepatic duct there will be marked jaundice.

Flloating kidney pain is not so severe as that from renal stone and is localized in the right side of the abdomen. If the ureter is elevated or pressed upon by the descent of the kidney, pain will result. If a band of fascia or blood vessel is abnormally located so as to drag across the ureter in the kidney descent in a manner to obstruct the ureter the patient may suffer pain in the loin which may be projected down along the ureter. When the attachments are loose enough to admit free mobility of the kidney the ureter is not liable to kink and the kidney remains symptomless.

Nephromata or hypernephromata cannot often be distinguished from floating kidney. It is usually

tender to pressure but unaccompanied by pain. Nephromata may or may not be associated with sex abnormalities.

In appendicitis the pain in a large number of cases occurs at the epigastrium and then is diffused over the abdomen and generally localizes at or near McBurney's point. If the appendix is long enough to extend into the region of the gall bladder and ducts its inflammation may excite symptoms of cholecystitis or choledochitis and the pain may be at the rib border. If located behind the cæcum pain may be referred to the loin or to the right rib margin. If in contact with the ureter the pain may simulate that of renal stone. Regardless of its location it is often the cause of gastro-intestinal disturbances—pylorospasm, hyperchlorhydria, and general intestinal irritation. Appendicitis is usually accompanied by temperature, high or low. In fact in acute attacks elevation of temperature is the rule. Its existence is often doubted when other symptoms are unaccompanied by temperature. Nausea and vomiting are usually present in all of these conditions but are not significant or especially characteristic.

Jaundice is a valuable diagnostic sign. It appears in appendicitis and renal disease only as a result of sepsis.

Obstructive œdema due to a duodenal ulcer near the ampulla of Vater sometimes results in a closure of the common bile-duct and may cause pancreatitis and jaundice.

Choledochitis and cholelithiasis are accompanied by slight or marked jaundice which may be of an intermittent or transient type. It may be so slight that an examination of the conjunctiva or a chemical examination of the urine is necessary to detect it.

Pressure by pyloric cancer upon the common duct may give rise to jaundice of a constant progressive intense type.

Peptic ulcers both of the stomach and duodenum are at times so infiltrated as to cause a tumor mass that may be felt in the median line or beneath the right rectus muscle which is at times very tender to touch. Pyloric cancer produces a tumor that at times is freely movable upon full inspiration and is separated from the costal margin by a distinct depression. They are usually far advanced when palpable—firm irregular often painless and not very tender to pressure.

When the gall bladder is disturbed from obstruction to the cystic or common duct it produces a pear shaped tumor mass at the margin of the liver movable synchronously with the diaphragm and presenting no depression between the rib margin and the tumor mass.

Appendiceal tumors may be located anywhere in the abdomen. They are sometimes six or more inches long and may become attached to any other abdominal organ. When inflamed they may become fixed by adhesions to some surrounding tissue.

Floating kidney tumors are usually marked by smooth, sharp outlines and mobility. They are usually free from pain and tenderness unless obstruction results from ureteral pressure.

A hydronephrotic or pyonephrotic kidney is usually stationary or fixed well back into the loin and does not move with the diaphragm. The hydronephrotic kidney usually presents no urinary findings while the pyonephrotic kidney is usually accompanied by septic symptoms the urine showing blood, pus, albumin, and casts.

Pain is the most prominent symptom in all conditions of the right upper quadrant and is of great value in a differential diagnosis if the peculiarities and characteristics of pain common to each condition is kept in mind.

Regardless of every aid in diagnosis it is often difficult to differentiate and instead of waiting months or years for the trouble to clear up an exploratory diagnosis under nitrous oxide gas-oxygen or novocaine should be made.

Peak, J. H. Visceroptosis. *I ter at J Surg* 916
xix 193

The author's principal aim in this paper is to show the development of operative procedures for the relief of visceroptosis. In so far as the morbid entity and what might be termed the medicinal treatment may be concerned every physician ought to be perfectly familiar with these features therefore, the author deals briefly with the surgical phase of the subject in concluding his paper.

The extent and character of the existing ptosis will necessarily determine the surgery to be undertaken. The rule the author follows if the patient is a relatively good surgical risk, is to first perform nephropexy then place the patient on the back and open the abdomen in the median line above the umbilicus abrade the upper surface of the liver with a gauze sponge shorten the round ligament of the liver plicate the gastrosplenic ligament and anchor the colon by attaching the greater omentum where it comes off the colon to the abdominal wall at about the normal level of the colonic position. (This last procedure the author has performed many times during the last ten or fifteen years.)

Following the operation the patient is placed in bed with the foot elevated ten or twelve inches. This position is necessary in order that adhesions may form properly about the kidney and liver. An exceedingly light diet is maintained and the bowels kept open by enemas rather than purgatives. The patient should be maintained in this position for twenty-one days but can be shifted slightly from side to side to change the center of gravity and thereby give the parts rest. At the end of the third week the foot of the bed may be lowered to the normal level and the patient will be able to leave the hospital at the end of the fourth week.

EDWARD L. CORNWELL.

SURGERY OF THE EXTREMITIES

DISEASES OF THE BONES, JOINTS, MUSCLES
TENDONS. CONDITIONS COMMONLY
FOUND IN THE EXTREMITIES

Cunningham, S. P. Regeneration of Long Bones
Following Infection. *Trans St. J. Med.* 9 6
xli 5

The author considers the methods of treatment which have been of most value in treating infected long bones resulting from compound amputated fractures. The principles to be kept in mind are (1) the general condition of the patient (2) the injured member should be placed in as nearly a normal position as can be maintained without interference with the blood supply by band bags and extension (3) when infection is severe but not too extensive should be made to the part to promote drainage and a splint applied under the limb to facilitate the changing of dressings. Probing manipulation, and irrigation should be avoided. After infection is controlled the author uses the Moorhead wax to dry fill the cavity. He has reached the conclusion that bone regeneration is the result of the combined action of the periosteum and blood-clot. Two cases are reported. J. W. W. SCOT.

Cameron, H. G. Osteogenesis Imperfecta. *Proc. Roy. Soc. Med.* 19 6 ix, Sect. D. Child 43

A case is reported of this rather rare bone condition in a child aged five years.

The author makes these three observations (1) Osteogenesis Imperfecta is a condition characterized not only by deficient ossification and fragility of the long bones, but also by a typical and peculiar formation of the skull which consists of bulging the temporal region sufficient to displace the upper part of the ear (2) The shortening of the limbs is more marked in the proximal than in the distal portions of the limbs. Characteristic expansion and the tortuous, sinuous outline of the shaft of the long bones are noted. J. W. W. SCOT.

Remy, C. E. Bl. Sclerotics Their Relation to Multiple Fractures in Childhood. *Am. J. C. M.* xlii 9 6 xli, 33

The author traces the heredity of blue sclerotics or osteopathylous, and finds that with an exception the condition of fragile bones was transmitted by the females and occurred only in the males. He also finds that in addition to the fragility of the bones and the blue sclerotics, in all cases presenting blue sclerotics, there is an accompanying flat foot and a peculiar tendency of the lower eyelid to cover the lower portion of the iris. He thinks the condition is due to a congenital deficiency of the matter furnishing the bones their elasticity.

J. R. M. A. T. M.

Wilcox, H. W. Osteo-arthritis. *Colo. Med.* 1916
xlii 53

The author uses the classification of G. L. H. Walte and gives a review of the present-day beliefs concerning the etiology and treatment of osteo-arthritis. Some of his conclusions are as follows:

Any inflamed joint should be put as far as possible in a condition of absolute rest. This relieves pain and tends to arrest changes going on in the joint tissues thus preventing deformity and possibly ankylosis.

If the focus of infection is known and is accessible to removal it should be gotten rid of.

If there are deformities which can be corrected, either in the diseased joint or in another joint closely related to it, any such defect should be corrected and the joint held in normal position by whatever means necessary.

A terminal emolument seems not to influence the reparative process greatly. R. B. CORLISS.

M. Mahall, H. W. A Case of Multiple Cartilaginous Exostoses. *Am. J. Orth. S.* 19 6 xi 336.

The author reports a typical case of multiple osteochondromatosis. X-ray plates demonstrate abnormal growths in the cervical, dorsal, and lumbosacral regions of the spine, on the right scapula and both ulna bones, femora, tibiae, fibulae, left humerus, right humerus, ulna, and first metacarpal bone of the right hand. A small tumor on the fifth cervical vertebra was followed by relief from slight distress previously complained of locally in the neck and head. Microscopic sections of the excised mass indicate its benign character and show an irregular grouping of hyaline cartilage and bone trabeculae surrounding the bone marrow.

The history in the author's case tends to confirm the opinion as to the importance of congenital developmental defect as causes and their transmission from mother to offspring, also the location and size of abnormal growths indicate that continuous mechanical trauma or repeated mechanical irritations may accelerate the growth. PHILIP LEWIS.

Griegel, D. M. A Case of Symmetrical Pressure Fibromatosis. *Edinb. Med. J.* 9 6 xi 444

The clinical findings in this case were hard movable growths, with fascial attachment, just posterior to each great trochanter of the femur and over each ischial tuberosity. The tumors of the trochanters were removed and on examination were found to be composed of a dense fibrous material in the center of which were found tubercles with the accompanying lymphoid and giant cells but no demonstrable tubercle bacilli. The author was inclined to believe that the growths were either desmoidal or basal in origin and were result of irritation. J. R. M. A. T. M.

Moore J. E.: Osteomyelitis Involving the Hip-Joint. *Ann Surg* Phila. 1916 14:11 473

Eighteen years ago the author denounced the use of the term epiphyseitis as applied by most writers to an acute inflammation of the hip-joint. He believed then that the condition was one of acute osteomyelitis and subsequent observation has confirmed his opinion that the condition does not arise in the epiphysis, but on the shaft side of the bone. The term epiphyseitis was suggested by Macnamara because of the rarity of osteomyelitis in this location and the absence of a diagnosis until the epiphysis had become separated. The name osteomyelitis as applied by the author is not strictly correct as the neck of the femur has no medulla but the process resembles osteomyelitis in every other particular and demands the same prompt treatment. When the diagnosis is made very early before the joint is involved an incision should be made over the greater trochanter and an opening drilled through the trochanter and the center of the neck of the femur in its long axis until the seat of the infection is reached. When the diagnosis is not made until the joint is involved it is better to open directly into the joint from the front. When a late operation is done, a formal excision should not be made unless the neck is completely necrotic, but as much as possible of the neck should be preserved for future use.

Four cases are cited as proof of the correctness of the author's contentions. All of them occurred in children under twelve and all involved the neck some with and others without joint involvement. He suggests that it might be well to revive the old term "acute osteitis of growing bone." GARRWOOD

FRACTURES AND DISLOCATIONS

Campbell W. F.: Colles Fracture. *Med Times* 1916 33: 161

The author gives a detailed discussion of Colles fracture. He contends that the reasons for imperfect reduction of these fractures are largely a lack of appreciation of the fact that the fractured fragment are locked impacted and must be disengaged before they can be normally replaced. In order to accomplish this anesthesia for securing complete relaxation is essential. Colles fracture is not an "off fracture" it is a hospital fracture and if the fragments are accurately reduced retention is easily accomplished with almost any kind of splint. R. B. CORFID

Serafini C.: Isolated Fractures of Head of the Radius (Sulla frattura isolata del capitulo del r.). *C. R.* 1916 24: 1

Pure isolated fractures of the radius are comparatively rare. The author gives a short historical review of the subject from Veracelli's memoir in 1851 down to the present time. He divides the traumatic lesions of the head of the radius into the three following classes:

1. Fractures which involve the head alone either complete or incomplete

2. Fractures which involve both the head and neck of the radius in which the direction of the line of fracture injures the mass of the head for a much greater extent than the neck complete and incomplete. These are fractures of the head radiating to the neck

3. Fractures associated with the head and neck, so-called explosive fractures. In which the fractured diaphysis at the level of the neck supplemented by the continuation of the traumatizing action in directly in the head of the radius which is broken into several fragments. In this variety fracture of the neck is primary and of the head secondary

The author gives short histories of 57 cases gathered from the literature and adds fuller details of 7 personal cases which he has observed in five years. In 22 cases the injury was caused by a fall on the palm of the hand with the forearm in flexion. In 28 cases the injury was due either to a fall on the elbow or to the elbow striking some hard object.

Generally such fractures are more frequently due to direct than to indirect trauma. The etiology, mechanism, pathologic anatomy, symptoms, diagnosis, surgical and non-surgical treatment as well as the results are discussed.

Clinically such fractures are recognized by the tumefaction and the pain localized to the external part of the elbow under the epicondyle by the limitation of movements especially of pronation and supination and by the dislocation and malposition of the fragments. Clinical examination should invariably be supplemented by radiography of the elbow in different positions.

Mobilization and massage may give good results but if there are free articular fragments and the head is badly dislocated early operative intervention is called for. The latter gives excellent results and is preferable to late intervention. It is indicated generally when callus formation is noted. The ultimate results as to functional value cannot be stated until at least a year has passed after the injury. With free fragments the ultimate prognosis may be grave. W. A. BRENNAN

Jones R.: Malunited and Ununited Fractures. *B. M. J.*, 1916 1: 809

The author states that conditions to which the terms delayed union and non union are applied may be difficult to distinguish because there is often found even after months osteogenic changes leading to consolidation in a fracture considered to be permanently united. There may be several weeks of apparent inactivity in callus formation and then consolidation occurs quite rapidly. Delayed union is the most common in the middle of the femur in the humerus at the junction of the middle and upper third and in the tibia and fibula at their lower third.

A fundamental principle in the treatment of fractures is to secure and maintain good length and good alignment and in securing these ends care

should be taken that the circulation of the limb should be in no way impaired.

If a case of delayed union is first seen in the seventh or eighth week it is necessary to do no more than make quite sure of good alignment, length and circulation.

For old cases Jones recommends the "percussion and damming" of H. O. Thomas which consists of breaking down the soft fibrous callus, turning the fractured ends toward the skin and beating them with a mallet. A pulley is then applied to the limb and extension produced. A Thomas knee-splint is adjusted and the external maintained. Two pieces of rubber tubing are tied around the limb, one three or four inches above the fracture, the other an equal distance below. At first they are kept on twenty minutes each day, later on several hours at a time. They should be tight enough to cause considerable swelling and stasis.

In aseptic compound comminuted fractures Jones strongly recommends that the pieces be saved. If the pieces are quite loose they should be taken out, laid in alcohol and carefully replaced in position or around the site of fracture.

Weak union can be diagnosed by the signs:
(1) tenderness on pressure over the site of fracture
(2) exuberant callus formation.

The causes of malunion of a fracture are:

1. Inefficient reduction of fracture
2. Errors in method of maintaining the fracture in position
3. Errors in after-treatment. PHILIP LANE

Carr W. F. The Treatment of Fractures. *Lancet Clin.* 96 civ 493

On the basis of twenty years experience in the Emergency Hospital in Washington, and having treated more than 7,000 fractures of nearly every bone and variety Carr contends that we are retrograding if the proper treatment of fracture instead of advancing. He believes that many surgeons are too prone to impute too ready to operate and too apt to use fully methods of operating.

The methods of Lane and Milne of England are condemned since the use of plaster breaks some of the most important fundamental laws governing the treatment of fractures, such as:

1. Continued pressure upon bone causes its rapid absorption.
2. Large foreign bodies embedded in bone frequently cause, without apparent infection, a rarefying osteitis.
3. Cutting off the blood supply of part of the periosteum by pressure is equivalent in effect to removal of this periosteum.

Other important laws laid down in this paper are:

- (1) It is impossible to hold two fragments of bone, tending to slide apart from muscular action, by putting compresses over it. (2) Any incision through muscle playing over a bone down to the bone, may produce scar tissue binding the muscles to the bone at that point and interfering more seriously

seriously with motion. (3) Continued irritation of muscle and tendons at the seat of fracture often produces thickening and contraction of these muscles or tendons, and such contractions may seriously impair the motion of the joint. (4) Infection at the site of fracture almost always interferes seriously with union. (5) Inflamed and infected wounds are far more liable to infection than clean cut incisions.

These laws are fixed and immutable and the ignoring of some of them has led to pernicious methods of treating fractures that have come into common use and the sanction of high authority. Short fragments may be held in place by wiring. No appliance, however, should be fastened directly to the broken ends of long bones for the purpose of keeping the fragment in alignment but only to prevent shortening. The alignment must be maintained by splints, casts or extension—never by metal plates or any appliance encircling the bone or by a wire passed through and through the broken ends.

R. B. CORLETT.

Nathan P. W. Choice of Method in the Treatment of Fractures. *Am J S & G* 96 84

Nathan deplors the percentage of poor results in fractures handled by the average practitioner and says that the average practitioner has not been taught the application of ordinary mechanical methods. The essential fault is that the splint so often does not overcome the muscular spasm which is the primary cause of overriding fragments and that when used the plaster of Paris is not properly applied nor retained until consolidation takes place.

In fractures of the shaft of the femur the fragments are the best exposed and greatest muscular relaxation is gained by a position of semiflexion of the limb. The additional advantage of continuous extension is readily acquired by a simple apparatus of gas-pipe adjusted to fit in any bed and capable of maintaining an extension frame at any angle desired.

In fractures of the surgical neck of the humerus the arm should be abducted and externally rotated. In fractures of the femoral neck, the Thomas hip splint may be modified to keep the limb in abduction.

The best method in fracture treatment is that which requires the least skill to carry out rather than the fine elaboration of surgical technique.

R. G. P. CLEARD

Elliot J. M. Treatment of Fractures by Methods of Suspension and Extension. *J Surg Phila.* 96 i ii 64

Special attention is called to the use of extension when combined with suspension in fracture treatment. It is necessary in this kind of treatment that there be some sort of iron frame firmly attached to the head and foot of the bed and five feet above the surface to give movable points of support with adjustable pulleys. With proper adjustment the best methods are easily determined for suspension of simple fractures, of doing painless dressings, of such cases as a compound fracture of the el-

bow or for complex appliances for badly complicated fractures. The addition of a spring in the line of pull as a shock absorber is a wonderful source of relief to the patient.

In fractures of the humerus the extension can be vertical, horizontal or angular and in cases just above the elbow this angle of the arm and forearm can be varied several times during the day to avoid ankylosis formation, and meanwhile the patient can sit, lie or sleep.

Suspension of the lower extremity is variously used. In fractures in good position hammocks may be used allowing the patient to rotate the limb. For tibial and fibular fractures requiring extension and for supracondylar fractures the railway splint with the self-contained extension apparatus may be used so-called because the lower fragment rides upon a carriage that tracks on the main part of the splint while countertraction is obtained by adhesive plaster over the upper fragment attached by a helical spring to the splint. Subtrochanteric cases need the Hodgen splint. Fractures of the femoral neck require the Hodgen splint with foot extension.

R. G. PACKARD

SURGERY OF THE BONES, JOINTS ETC.

Harrison, F. C. A Splint for Drop-Wrist. *Canad. Pract. & Rev.*, 916 xii, 191.

The author describes an easily constructed splint by Southerland to be used in the treatment of injuries to the musculospiral or median nerves from which drop-wrist results.

A posterior splint for the hand and arm is made of several layers of plaster of Paris bandage three or four inches wide with a thin piece of board, one and one half inches in width, running longitudinally nearly the length of the plaster. Three more layers of plaster bandage are applied above the board and then strips of flannel are placed across the splint for the purpose of fastening it to the hand and forearm. Two more layers of plaster bandage are then applied to secure the flannel strips. The whole is then moulded to the back of the hand and forearm extending from the base of the fingers almost to the elbow. It is allowed to dry and is then cut across at a point corresponding with the wrist joint and hinged the board embedded in the plaster holding the screws firmly. A spring is then attached by metal uprights to the hand and the forearm pieces. In this way the wrist is held in a position of dorsal flexion. Flexion can take place to the extent of allowing the hand and forearm to come into line.

R. B. CORLIFF

Rich, E. A. The Treatment of Abscesses in the Course of Tuberculous Disease of Joints and Bones. *Verh. d. Med.* 1916, iv 237.

The author pleads against unnecessary and dangerous incision of tuberculous abscesses pointing out the harmlessness of the collection and the possibility of back pressure having a real function.

In his opinion, the only indication for any operative procedure is such an increase of abscess pressure as to cause intolerable pain and then the only procedure that is justifiable is aspiration under the most rigorous asepsis. Aspiration is indicated to relieve pressure and not to evacuate the cavity and in old chronic cases where the disease itself has subsided. Aspiration should be done with a No. 13 or 14 wire needle and not with a trocar. The author has had small success with the use of Beck's paste.

H. W. METERING

Ridlon, J. As to the Necessity for Operation in Joint Tuberculosis. *Chicago M. Recorder* 916 xxxviii 256.

The author reports two cases of tuberculosis of the knee joint treated by conservative methods. The first was an adult female whose right knee-joint following a fall upon it, became tuberculous and was excised with a resulting ankylosis.

Subsequently the left knee became inflamed and was examined by six eminent surgeons all of whom diagnosed it as tuberculous. Conservative treatment by immobilization, for three years resulted in a cure with a normal range of motion.

The second case was in a girl five and one-half years old. The left knee was seen after being inflamed for a year and was treated by the application of a brace. During the course of the treatment five sinuses opened up and discharged for many months. In three years the knee was cured in a straight position and in four years the knee could be completely flexed and the patient walked and ran without limping.

Excision should never be done in children. In adults it is a time-saving measure but one half such cases require amputation later on. H. W. WILCOX.

Belot and Filhouland: Osseous Repair and Proliferation (Sur la réparation et la prolifération osseuses). *J. de radiol. et d'électrol.* 1916, ii, 87.

Radiologic study of osseous traumatism of war shows that apart from those which cover spontaneously there are many with a different evolution. There may be an exaggerated osteoperiosteal proliferation. The neoformation may take the form of a voluminous callus surrounding or immobilizing a joint or involving the muscles, and the functional importance engendered may be such as to require surgical removal of the excrescence.

The callus formations observed in peace are quite different from those observed in war. The latter are large extensive rich in elements rapid in ossification often proliferating at quite a distance from the point of fracture. This is accounted for by the fact that the subjects are young and in full cellular activity. There is an abundant production of fragments more or less grouped and disseminated and almost always accompanied by debris of periosteum and thus latter constitutes the reparatory nucleus. These periosteal fragments scattered here and there even in the neighboring muscles continue

to live and proliferate, and multiplying their elements not only forms a voluminous callus but even an exaggerated one with distant osseous trabeculae.

Traumatized bone ordinarily shows a marvelous tendency to reparation: the tendency of separated bone and periosteal fragments to live exists even when radiographically they appear deprived of all relation with the body of the bone. The author thinks that a certain amount of reserve should be exercised in the removal of all bone fragments shown by the radiograph. Only those which are manifestly incapable of living should be the object of an immediate removal. These will comprise fragments without periosteum, infected fragments, fragments very distant from the injury etc. As regards other fragments the later clinical and radiographic manifestations will suggest what must be removed.

While it goes without saying that infective phenomena will necessitate an immediate wide cleansing of the wound it should be borne in mind that it is necessary to allow the bone sufficient elements to permit of reparation. Frequently absence of consolidation results from a too radical removal of bony débris.

It is more important to remove the fragments at a distance which are useless for reparation and which can act as foci giving birth to osseous formations.

The authors call particular attention to the value of radiologic examination not only in the diagnosis and study of fractures but for the determination of the physiotherapeutic treatment for the restoration of function. Clinical observation alone cannot always give sufficiently accurate information as to the nature of the obstacles opposing restoration of function, but radiography can detect them as well as the imperfection of consolidation.

W. A. BROWN.

Delagenière H. Osteoperiosteal Grafts Taken from the Tibia to Serve in the Reconstruction of Bone or in the Repair of Loss of Osseous Substance (Des greffes ostéopériostiques prises à la tibia pour servir à la réparation des pertes de substance osseuse) *Bull. et Mém. Soc. d'Chir. d'Par.* 9 6 xlii, 1918.

Delagenière gives details of 41 operations in military service in which tibial grafts have been used with good results. In his civil practice before the war the poor results which he had obtained from osseous grafts, properly so-called, forced him to renounce them in favor of osteoperiosteal grafts taken from the tibia. The tibia is easily accessible, and its internal face is large and extensive so that there is ample material for a graft. Moreover repair of the osseous wound left after removal of a graft is facile even if the graft is thick and the medullary cavity of the bone open.

He finds that autografts are best and therefore confines his practice to grafts taken from the patient's tibia and generally for the following class of cases: (1) pseudoarthroses of the arm, forearm, or tibia, (2) for the stoppage of loss of bony substance and (3) in anoplastic operations of the nose.

The result of such grafts is uniformly good. The technique of cutting the graft and applying it in the different classes of cases is described fully. The evolution of the graft is different in infected and non-infected cases. In a septic or purulating wound the phenomena are rather complex. The periosteum grafts in this condition but the osseous parts die and become necrotic. Fatulae are established which heal only when the elimination of the necrotic osseous parts is complete. At this time the graft can be radioscopically observed to be transparent, but by degrees it becomes opaque and thenceforth behaves as in the evolution of a so-called septic graft, except that in this case the evolution is much slower.

The author draws attention to the efficacy of this species of graft in cranial injuries where there is a very extensive loss of substance. Many of the cases reported are of this class. On account of its simplicity and efficacy he thinks it is indicated in all cases of important loss of cranial bone and even in minor losses when the subject shows signs of meningeal irritation.

W. A. BROWN.

Brown, W. L., and Brown, C. P. Important Points in Bone-Transplantation. *Trans. St. J. Med. Soc.* 9 6 xlii, 3.

The authors report their conclusions reached from experimental work done with bone and periosteal transplants, their result agreeing with those of the majority of investigators. They were unable to reproduce bone from periosteal transplants, either free or left attached, except from a bone where trauma was necessary to its removal, that is, only bone and bone-cells reproduce bone. Bone transplanted free into the tissues, either with or without periosteum, is always absorbed.

Bone when transplanted must be in such a position that it has a function to perform, must have sufficient contact with living bone and sufficient immobilization to secure primary union.

Clinically the graft should not be too large should be planted within the old periosteum, if possible, should be required to maintain but little mechanical support, and there should be complete immobilization for several weeks. The graft in locations in which there is continued liability to displacement, requires additional internal mechanical support.

All the periosteum at the point of contact should be preserved. The technique of the bone work should be faultless.

H. W. WINCOW.

Lyle, H. H. M. The Aperiosteal Stump and Its Care. *J. Surg. Pathol.* 9 6 xliii, 674.

In amputations there are four methods of treating the bone: osteoplastic, tendinoplastic, periosteal, and aperiosteal. The latter while the simplest and most practical is the only method most likely to give an end-bearing stump. The technique consists in removing thoroughly a small cuff of periosteum, 0.5 cm. in depth, and spooning out the mar-

row cavity for a like distance. If shreds are allowed to remain they are liable to produce painful bony spikes.

The stump should be quickly put to use. As soon as healing is accomplished massage is instituted twice daily and a 2 per cent solution of salicylic acid in olive oil is rubbed in. The stump should then be pressed against a box in the bed five to ten minutes, three times a day and this period rapidly increased. Standing exercises are soon begun and at the end of two weeks the patient should be able to wear a peg leg.

R. G. PACKARD

ORTHOPEDICS IN GENERAL

Henderson, M. S.: The Intraperitoneal Inoculation of Animals: Its Diagnostic Value in Orthopedic Surgery. *Am J Orth Surg* 1916 xiv 329.

In a series of 143 patients tested by the author guinea pigs were used in the majority of cases. As the guinea pig is rather resistant to the bovine type of tuberculosis while the rabbit is not Henderson recommends that where the patient is a child there fore more likely suffering from a bovine type of infection the rabbit or both rabbit and guinea pig should be injected.

He concludes as follows:

1. As a test the intraperitoneal inoculation is practicable and requires no special laboratory facilities. The test has been of great value in doubtful cases, and in instances in which it is possible to obtain the material for inoculation it has become a routine procedure.

2. A positive bacteriologic test in obscure lesions makes the diagnosis certain.

3. The value of negative tests increases with the number made.

4. Antiformin digestion of tissue acts on the tubercle bacilli either to kill them or to reduce their virulence so that the low resistance of the guinea pig will be sufficient to overcome them. It greatly reduces the value of the test and should not be used.

PHILIP LEWIS

Vulpus, O.: Experience with the Albee Operation for Spondylitis Tuberculosis (Erfahrungen mit der Albeeschen Operation bei Spondylitis tuberculosa). *Munchen. med. Wchnsch.* 1916 lviil 546.

Vulpus gives the results from his orthopedic clinic in Heidelberg of the Albee operation for tuberculous spondylitis. The operation so far at least as end results are concerned is little known to German orthopedists. He has re-examined 24 operated patients and reports have been received of 6 others who were operated upon. About two and one half years have elapsed between operation and the re-examination. The ages of the patients varied from 3 to 45 years the majority being under 10 years. The typical Albee technique was used.

In all cases there was easy and uneventful recovery except in 3 cases where some bony splinters had to

be removed. After the operation there was a remarkably prompt cessation of subjective phenomena. Pain ceased after a while and the patients could easily move about. Anatomic preparations made a year after operation are instructive and show that there has been a firm union around the graft and that the graft has been absorbed. All the subsequently examined patients may be considered to be clinically cured. One child died after a year of tuberculous meningitis and this was the only death. No case complicated with paralysis was operated upon and Vulpus has seen no paralysis develop after an Albee operation. In 7 cases in which there was a psoas abscess before operation this process was resorbed. As a result of his experience Vulpus strongly recommends the operation.

W. A. BREKMAN

Wallace, C.: The Operative Treatment for the Disabilities and Deformities Following Anterior Poliomyelitis. *Am J Orth Surg* 1916 xiv 400.

The author bases his article on a study of the operations at the Hospital for Ruptured and Crippled Children during the past three years.

He states that the attempt to secure ankylosis of the hip in children by doing an arthrodesis has been hopeless.

He thinks that nearly one third of the operations performed in the series would have been unnecessary if the patients had received proper brace attention.

The Scutter operations for contractures about the hip are most beneficial.

The transplantation of an active hamstring tendon when both were normal, to the attachment of the paralyzed quadriceps extensor tendon so improved the power about the knee that braces have been discarded.

Arthrodesis for paralytic deformities in children has been of little value.

The grooving of the tibialis anterior tendon into the anterior surface of the tibia and transplanting the extensor proprius hallucis tendon to the calcaneoscapoid ligament for equinovarus deformity has been helpful.

He found the typical Whitman operation the most satisfactory for calcaneus calcaneovalgus and dangle foot deformity.

PHILIP LEWIS

Davis, G. G.: Stability of The Lower Extremity in Paralysis. *Am J Orth Surg* 1916 xiv 391.

The author states that in treating paralysis the prime object is to secure support and secondarily to promote propulsion to the greatest extent possible. Stability is therefore the first consideration. Intimately associated with stability is the question of balance. Stability has largely to do with bones and ligaments but balance is largely controlled by the muscles.

If what the author calls the sub-tarsal joint is the only involved part the stability is often not marked and there are a number of ways to tal

it. In the order of efficiency he names arthrodesis, fixation of tendons, tendon-transplantation, and silk ligaments.

The ankle-joint is close to the subastragalar joint and the paralysis most frequently produces toe-drop or less often a calcaneus. Even a well-laced shoe may prevent a slight toe-drop from being troublesome. If the case is more severe the foot may be held up by fastening the extensor tendons or the peroneal and anterior tibial to the anterior part of the tibia. In the cases of calcaneus usually associated with cavus, Gill buries the tendons into the tibia posteriorly. Still the problems of the foot are comparatively easily solved without the use of apparatus.

If a little lower extremity is to be obtained one must for the assumption of the knee and hip joint of hyperextension. He can secure a little back knee by fixation of the ankle joint plus an elevated heel.

When the muscles controlling the hip and running from the trunk to the femur, especially the gluteus maximus, are paralyzed the difficulties are greatly increased. If the gluteus maximus is active then even if the quadriceps femoris is paralyzed, the gluteus will pull the femur back and frequently fix the knee, but in hip paralysis the disability is often extreme.

Where extreme external rotation is present it can be controlled by the operation of sewing the fascia lata firmly to the posterior edge of the greater trochanter while the foot is held in firm internal rotation.

PHILIP LEWIS

Willard D. P. Subastragalar Arthrodesis in Lateral Deformities of Paralytic Feet. *Am J Orth Surg* 9 6 15

The operation recommended by the author consists of an arthrodesis of not only the astragaloscaphoid, but also of the astragalocalcaneal articulations, and in severe cases of cavus perhaps the calcaneocuboid joint as well. It is more than arthrodesis; it is the welding together of the adjoining surfaces of three bones, the astragalus, scaphoid, and calcaneus. There is no careful dissection of the cartilaginous joint surfaces. Instead there is a rough digging and gouging of both the articular areas, and also the bony surface between them, with no attempt at removal of the fragments that are torn loose.

The astragalus, scaphoid, and calcaneus become one solid bony mass, movable in the anteroposterior directions but immobile for side movements. No shifting of the foot occurs. A rigid point of attachment is given to the unparalyzed muscles. No foreign substance is left in the tissues.

Two incisions are recommended: one on the inner side of the foot about a fingerbreadth below and in front of the internal malleolus on the level of the sustentaculum tali, the other on the outer side immediately below the external malleolus.

The foot is fixed in plaster at right angles to the leg. The patient is allowed to walk in the cast at the

end of four weeks, and the cast is removed four weeks later. Unless the paralysis of the other portions of the leg demand it, no braces are applied.

PHILIP LEWIS

Orr H. W. A Critique of Present Methods in the Treatment of Infantile Paralysis. *Am J Orth Surg* 9 6 336

The author is opposed to the application of braces except as a final step in the treatment of these conditions and where they have been improved to the fullest extent by the usual methods. In other words, not until the best result has been obtained which follows spontaneous recovery combined with those measures by which the patient's resources have been carefully safeguarded. This involves splinting and encasement under the direction of the best orthopedist available and for a sufficient length of time bringing the patient to the point where he is ready for results obtainable by modern methods of surgery.

Orr objects to the use of braces either as splints or as aids to locomotion except for those patients whose disability is definitely established as permanent or for those whom no other methods of improvement are possible or feasible.

PHILIP LEWIS

Rogers M. H. Operative Treatment of Infantile Paralysis. *Am J Orth Surg* 9 6 219-23

The author bases his study on 30 cases, 79 of which were over years of age and 51 under 12 years. The general policy was conservative. The author believes in operative interference in any case where a light brace is not sufficient and especially where there is developing or increasing deformity in spite of the brace. The type of case that needs attention is not always the flail foot with complete paralysis, but the case that shows a paralysis of one group of muscles and a powerful antagonistic group. Rogers does not believe in silk ligament fixation can permanently oppose constant pull from a healthy muscle. Tendon-transplantation is more satisfactory.

In the cases of arthrodesis there were 50 per cent failures.

There has been noted at the Massachusetts General Hospital a gradual change of view away from arthrodesis toward astragalectomy. Each case presents a problem in itself and must be worked out individually.

PHILIP LEWIS

Taylor R. F. Operative Treatment of Infantile Paralysis. *Am J Orth Surg* 9 6 394

It is the author's belief that tendon sutured to tendon is not so efficacious as tendon sutured to peroneum or bone preferably than the insertion of the paralyzed tendon if it is to replace. A muscle to be transplanted and to functionate most successfully must have its tendon pulled in as straight a line as possible from its origin to its new insertion.

No silk extension is comparable in result to plan-

ning and effecting an operative procedure so that there is ample tendon to reach to the new insertion.

Adhesions in the transplanted tendon are to be avoided by carrying it through subcutaneous adipose tissue through the sheaths of tendons that are to be replaced or through septa in which non-closable foramina have been made by plastic flaps and by early electrical stimulation to prevent adhesions from forming. Several small skin incisions are preferable to two large ones. Subcuticular silver stitches are less likely to lead to adhesions.

The question of time when weight bearing is to be permitted depends upon the severity of the original deformity, the strength of the transplanted tendon and the security of the mechanical fixation by sutures, the possibility of early muscle training in active exercises, electricity, massage, etc. Weight bearing should not be permitted sooner than 30 days and then with some support.

Fine intestinal silk is preferable to catgut, kangaroo tendon or heavy or paraffin-coated silk in suturing the tendon accurately to the peroneum in the bone groove.

PHILIP LEWIN

Ryerson E. W.: *Methods of Stabilizing the Flail Foot in Infantile Paralysis*. *Am. J. Orth. S.* 1916 xlv 337.

The author advises more frequent resort to astraglectomy in the feet which are very weak and in addition a fixation of the tendons by the Gallie operation slightly modified.

Whitman's operation of astraglectomy and backward displacement of the foot is of great value in the treatment of calcaneus deformities. Arthrodesis has a distinct field of usefulness in patients over fourteen years of age.

Silk ligament suspensions may have to be removed or the foot may relapse and it is extremely difficult to control lateral deviations of the foot by this means.

Ryerson was unable to get good results with the autogenous bone peg or dowel driven through the lower end of the tibia and through the astragalus and os calcis. For six months he used the Gallie method of inlaying the tendon in the groove gouged in the bone and in addition to this drilled a hole through the bone at the upper end of the groove. He then dissected up the proximal portion of the tendon cut off as high as possible, passed it through the hole and brought it down in loop-fashion to be sewed side by side to the portion lying in the groove.

PHILIP LEWIN

Anderson W. L.: *New Methods Used in the Study of Flat Foot at Yale*. *Med. Times* 1916 xli 144.

Methods of diagnosing static foot troubles and their correction as carried out at Yale University are given by the examiner, the author.

There has been added to the equipment of the medical office the most modern form of apparatus for making a diagnosis of faulty foot conditions.

This apparatus consists of a wooden table 36 inches high with a top surface 20 x 26 x 2 inches in which is sunk a 13 x 13 x 25 inch plate glass section. Seven inches below and fastened by hinges to the rear legs of the table is a 13 x 22 inch German silver reflecting mirror which can be adjusted at varying angles from 30 to 45 degrees to the plate glass in the top of the table. Clutches on either side of the frame holding the mirror enable it to be fixed at any one of these angles which adds to the comfort of the examining physician. On the sides and fastened to the diagonally opposite legs are electric lights with 15 watt frosted globes set in aluminum lined reflectors so arranged that their rays are thrown directly upon the glass top. At a convenient distance in front of the table a long mirror 20 x 54 inches, which is also adjustable is placed so that the patient is able to see the bottom of his own feet as he stands upon the glass-topped table. In this way the physician as well as the patient has an exact picture of the actual degree of foot fault while the feet are maintaining the weight of the body and photographs of the foot condition can be taken if desired.

R. B. CORFIELD

Jones, R.: *The Soldier's Foot and the Treatment of Common Deformities of the Foot*. *Brit. J. J.* 1916 l 783.

In the treatment of hammer toe the author advises against amputation particularly if the affected toe is as is usually the case the second toe for this removal is likely to cause the development of hallux valgus. Arthroplasty is not advised. The operation advised is a wedge-shaped excision removing the articular cartilage on both sides of the joint so as to definitely ankylose the joint in extension. An oval piece of skin, including the usually present corn, is excised and the flexor tendon is cut and the toe put up in extension on a little splint. This splint is worn for some weeks to insure ankylosis in the extended position.

In displacement of the little toe the displacement is similar to that of hallux valgus. Amputation is the treatment advised. A good-sized flap is necessary to overcome subsequent contracture. If a callus is present over the head of the metatarsal walking with a shoe is not permitted until the callus has softened up and the skin becomes more nearly normal. Only very exceptionally should the head of the metatarsal be removed also for this forms one of the points in supporting the foot on which a soldier's marching power depends.

Metatarsalgia is a peculiarly painful disability of the foot associated with flattening of the transverse arch. Immediate relief Jones says, can nearly always be given by removing the pressure of the body weight off the heads of the metatarsal bones by a bar behind them placed transversely across the sole of the shoe bringing the weight bearing on the neck of the metatarsals. The inner side of the heel of the shoe should be raised one-third of an inch and a band of strapping placed around the

transverse arch of the foot. In cases of longer standing not responding to this treatment the head of the metatarsal, usually the fourth, should be removed. The same type of shoe should be employed as after-treatment.

Painful conditions about the heel may be due to (1) injuries or strains about the insertion of the tendo achillis, (2) spurs of bone and adventitious bursae under the os calcis, (3) osteitis and peritonitis from direct injury of the os calcis.

For Group 2 the method of pin-firing used by the farrier is advised in the more obstinate cases where rest and elevation of the heel three-fourths of

an inch does not relieve. This condition may be due to inflammation of the bursa or strain of the insertion, but in both cases the treatment outlined in the article of band of strapping placed just above the malleolus is beneficial.

In Group 3 Jones advises an incision along the inner margin of the heel and the removal of the pus and the adventitious bursae.

In Group 4 the osteitis and peritonitis may be slight and rest usually cures these, but if they are associated with a gross fracture of the os calcis or astragalus of any severity the patient will not again be fit for service. M. S. H. 1908, 40.

SURGERY OF THE SPINAL COLUMN AND CORD

Graves J. C., Jr.: Backache from the Viewpoint of the Orthopedist. *Verh. d. M. d. G. S. 1908, 166.*

The author presents some definite suggestions as to the various causes of backache. They are coming to be understood by the orthopedic surgeon.

A atomic peculiarities of form together with imperfect adjustment of the parts result in the most important factors in backache. There also definite pathological conditions which may be present separately or in conjunction with the variations of form or adjustment, such as the hyperostrophic form of arthritis which is apparently due to disturbance of the metabolism, the localization of the symptoms being due to the localization of the infectious arthritis is another reason. In many cases of disease frequently associated with backache, apparently any of the infectious organisms may at times lead to joint symptoms. K. B. Curtis.

Elmer W. G.: The Handling of Children with Tuberculosis of the Spine While They Are Under the Influence of an Anesthetic. *J. N. Surg. Phila.* 1908, 131, 34.

The author cites two cases from his own experience which show how important the self-protection offered by the muscular system is in cases of tuberculosis of the spine. In children, especially the relaxation of the patient under a general anesthetic makes it very easy by slight torsion by stretching or by increasing the kyphosis to do great permanent damage. In one of the author's cases he believes that tuberculous material was forced into the spinal canal. In the second case in attempting to push the child further down on the table the spine was buckled like a hinge.

Since it has been shown that children bear bone-grafting into the spine very well, and that the results are very satisfactory, great care should be taken to prevent such accidents as the above, as very little violence is required in this type of case. The author suggests the application of a cast on the day preceding the operation. This cast is split on both sides in the midaxillary line and the following day

the child may be placed upon the table and the anterior half removed. After it is thoroughly anesthetized it may be turned to the prone position, without danger of injury to the spine and the posterior part of the cast removed. At the end of the operation the cast may be reapplied very quickly and fastened with strips of adhesive plaster. (L. W. H. 1908, 131, 34.)

Hatch F. G.: The Treatment of Scoliosis. *South M. J.* 1908, 67.

The thoracic scoliosis is the most difficult to treat. Those cases due to empysem, rib-ribs, or marked structural scoliosis without bone pathological lesions give poor prognosis.

The author believes Abbott's treatment has now taken the recognized method of scoliosis and that it is one of the greatest advances in mechanical surgery ever presented.

The conclusions reached are as follows:

The Abbott method of treatment gives far better results than any other method used either in the past or the present.

1. The technique is a complicated one and there are very few men who put on the jacket as Abbott teaches even though they use his frame.

2. It takes from three to six corrective jackets to effect a cure. Each jacket holds the spine about seven weeks or as long as one can further correct the position by the application of the felt pads.

3. While we strive to overcorrect our cases it is not always possible to do so, but in practically every case the children can be placed in a nearly normal position.

4. After the patients are corrected, exercises are used daily for many months. These must at first be given by a competent instructor and later carried on at home. If the patients do not carry out the exercise treatment they will gradually relapse.

5. In a warm climate it is often wise to put on a thin extension jacket for the summer and start the correction from that point again in the fall.

H. W. Stevenson.

MISCELLANEOUS

CLINICAL ENTITIES—TUMORS, ULCERS
ABSCESES, ETC

Hazen H H: Cases Illustrating the Faulty Treatment of Superficial Malignancy *J Am M A* 1916 Lvi 1829

During the past three years the author has been consulted by 32 private patients for malignant conditions of either the skin or mucous membrane of the mouth. Of this number only 6 consulted him for early untreated stages of cancer. One of these had a cancer on the under surface of the tongue while the remainder had cancer of the face.

The faults in handling the other cases naturally group themselves under three headings: (1) neglect on the part of the patient; (2) faulty diagnosis on the part of the physician; and (3) improper or insufficient treatment by either physicians or quacks. In 9 instances patients had neglected themselves without seeking medical advice. In this series there were 6 cases that had been wrongly diagnosed by the attending physicians and 12 cases were either improperly or insufficiently treated after a correct diagnosis was made. In several instances more than one faulty method of treatment was employed. 4 cases had been treated by caustics; 5 patients had operations performed from which rapid recurrences took place. One small basal-cell lesion of the cheek had been treated by fulguration with a recurrence in nine months, the recurrence being both deep and wide. 1 of the patients had been treated by small livid doses of roentgen rays. (The new method of single dose therapy had been in use such a short time that we have not as yet had a chance to study recurrences after it, although some will doubtless occur.)

Special interest attaches to a series of 4 cases which were treated by the much vaunted radium. All of the patients being made much worse. The conclusion is:

1. The public is not yet sufficiently educated as to the importance of attending to superficial forces that will not heal.

While it must be admitted that some cases of superficial malignancy are difficult to diagnose still entirely too many of them are mistaken for other affections even by experienced physician. All suspicious growths should be positively diagnosed at once.

2. Many cases are not treated radically enough. It should always be remembered that in sufficient treatment of whatever kind is the worst possible thing for a patient suffering from a malignant condition.

3. Radium even in large dose and when administered in its greatest advocates' hands is of no value in the superficial cases that it is believed to cure.

McCouch G P., and Ludlum S D W: Is Myopathy Related to Disorders of Internal Secretions? *Med Rec* 1916 Lxxix 1042

Myotonia congenita and myasthenia are frequently associated with muscular dystrophy. Amyotonia congenita is said to have occurred in connection with muscular dystrophy and may be identical with one form of it. There is some evidence suggesting that thyro-parathyroid deficiency may bear an etiological relation to myotonia. Myasthenia is frequently associated with hyperthyroidism, hypo-adrenalism and probably with hyperactivity of the thymus. Hypothyroidism and pathological findings suggesting both hypo- and hyperactivity of the thymus are sometimes found in amyotonia. Myopathy is found in association with many disorders of internal secretion perhaps most frequently with hypopituitarism. The case reported by the authors combines the adiposity, the deficient development of both primary and secondary sexual characteristics, the small hands with tapering fingers and the enlarged sella turcica of dysraphia adiposa genitalis with the distribution of atrophy and pseudohypertrophy, proportional muscular weakness, diminution and in some cases total loss of tendon reflexes and the diminished response to electrical stimuli without reactions of degeneration characteristic of the facio-scapulo-humeral type of progressive muscular dystrophy.

Alberghini tests on a series of four cases of myopathy, one case that may be either myopathy or spinal muscular atrophy, one case of neuritic muscular atrophy (peroneal type) and two cases of muscular atrophy from syphilitic root neuritis showed hyperactivity of thyroid, thymus and adrenal in the first three conditions. In the peroneal case hyperactivity of the testis was also noted. The tests on the syphilitic cases were negative. Thyroid and thymus hyperfunction are frequently observed in hypopituitarism.

Whether the glandular disorders bear an etiological relation to myopathy or are secondary to it or whether both are due to a common cause is uncertain, but the combination is too frequent to be regarded as a mere coincidence.

SERA VACCINES AND FERMENTS

For H H: Vaccine Therapy and Other Treatment in Acne Vulgaris and Furunculosis *J Am M A* 1916 Lvi 24

A study of the examination records of the entering student at Cornell University showed that 30.2 per cent of the freshmen had suffered from acne vulgaris. Of this proportion the distribution of the lesions was as follows: 10 per cent had comedones, 10 per cent had pustules, 10 per cent had cysts, 10 per cent had nodules, 10 per cent had scars.

In order to ascertain just what results could be expected from the different forms of therapeutics, and more especially to try out the efficacy of vaccine therapy an analysis of 100 u selected cases of these two forms of pyrogenic dermatoses was undertaken.

The cases were all considered chronic, in that they were all of six months duration and no case was included in which the eruption could possibly be ascribed to drugs or occupation or to syphilis. An attempt was made to study the bacterial etiology of either condition except in so far as was necessary for the preparation of the autogenous vaccines, since that has been so well worked out by previous investigators and also because ordinarily the stock vaccines are prescribed on the basis of a clinical diagnosis.

All the patients studied were instructed, before beginning treatment, to avoid such foods as seemed to disagree with them, not to eat to excess, to eat slowly and at regular intervals, to drink plenty of water especially on rising in the morning, to see that the organs of elimination were functioning normally, or if they were not to consult the physician to change before resorting to medical correctives. Locally they were to remove the comedones by gentle massage after first having relaxed the skin by applications of towels wrung out of hot water. Following the removal of the blackheads, they were to apply to the face towels wrung out of cold water in order to tone up the skin and cause a diminution in the size of the pores.

In the tables given the most striking point and one not generally brought out by writers on the subject was the fact that in the 74 cases of acne treated not one of the cases developed in a student engaged in athletics. The author does not mean to imply that acne has never occurred in athletes, but he wishes to point out that the table shows the great part athletics plays in the prevention of acne. On the other hand, however, nine cases of furunculosis, out of a total of 36 occurred among students engaged in athletics. These cases were due to direct infection and without exception occurred among the wrestler and crew men, the location of the lesion being typical of the cause of the trouble.

Dietetic errors and digestive disturbances accounted for from one-third to one-half the cases in each group. Comedones were not found so frequently as many writers would lead one to expect. A majority of the cases in each group were sporadic but of those influenced by seasonal variation the larger number of cases occurred in the summer. The cases of acne also showed longer a average duration than the cases of furunculosis, the period of duration being from three to four years of acne for furunculosis six months to one year. It is interesting to note that although of the entire freshman class the larger percentage of the cases of acne were of general distribution over twice the number of students who applied for treatment did so for the facial type of acne.

Under the heading local treatment were included all applications made directly to the eruptions. In some instances the means of treatments or lotions in others particularly the coarse putter type and especially in furunculosis local treatment included evacuating the pus by free incisions and application of a dressing. Combined treatment included those cases in which the patient received the vaccines in conjunction with the local treatment. Medical treatment included cases in which the patient was treated only by medicinal treatment usually such as a lead sulphide and oil ointment.

A study of the patient results as shown shows that not one patient with severe acne cured by more after evacuation of the acne was cured by autogenous vaccine on the other hand autogenous vaccines were resorted to in the group in improvement in 5 per cent in stock vaccines in 18 per cent of the cases. The worse type of acne comprised cases in which the treatment of the majority of the lesions exceeded six months, 2.8 per cent of these patients were permanently improved, 2.8 per cent cured. The type of those in which the majority of the lesions were 1/2 inch or less in diameter exhibited by 55 per cent of the patients improved none cured.

The conclusion would seem to demonstrate first the important part played by personal hygiene in the cure prevention and treatment of acne vulgaris and furunculosis second the superiority of well known therapeutic measures or vaccine therapy to the additions made and third the value of following the case to ascertain the number of permanent improvement experienced has shown that the value attained during the time of treatment is no criteria of the changes to be seen in the results later date.

LOW & L. C. VILL

BLOOD

Barlett W M. A Method for the Determination of the Alkali Reserve of the Blood Plasma. *J Biol Med* 9 6 1924.

It must be pointed out that bicarbonates, alkali protein compounds, and small quantities of alkali phosphates together constitute the alkali reserve of the blood plasma and that under normal conditions these substances are present in very constant quantities. A diminution in the alkali reserve known as acidosis and may be recognized by a variety of clinical symptoms and by characteristic alterations in the composition of the blood urine and alveolar air.

The alkali reserve maintains the plasma at a constant slightly alkaline reaction despite the fact that all products of metabolism are continually being poured into the blood. Chief among these products so far as total quantity concerned is carbonic acid. This, as carbon dioxide enters the plasma circulating through the tissues and is taken up partly in combination and partly as dissolved carbonic

acid. An almost infinitesimal change in reaction in the direction of acidity occurs. The slight change is sufficient to stimulate the respiratory center. The resultant pulmonary ventilation removes the excess of carbon dioxide and the plasma reaction returns to its original point. An excessive production of carbon dioxide in the tissues results in a greater change in the reaction of the plasma with a consequent increased stimulation of the respiratory center and increased pulmonary ventilation. This tends to accomplish the removal of the extra carbonic acid. No depletion of the alkali reserve occurs.

The author carried out a series of experiments on a large number of normal individuals and the method he employed consisted in dialyzing serum or whole blood against salt solution in order to remove coloring matters and proteins. The hydrogen ion concentration of the dialysate was determined by means of the indicator phenolsulphonophthalein phosphate solutions of known hydrogen ion concentration being used as standards for comparison. At the outset of this work it was realized that the actual hydrogen ion concentration was not determined the results however coincided closely with those obtained by the electrical method. In severe acidosis variations in the direction of acidity were encountered. The method seemed to indicate variations in the hydrogen ion concentration although the variations observed were probably greater than those actually occurring.

Also a series of cases exhibiting clinical or laboratory evidences of acidosis was studied. These cases included nephritis and diabetes in adults and nephritis recurrent and idiopathic acetoneuria and severe diarrhoea in children and the results are recorded in detail.

Briefly Marriott summarizes his paper as follows:

1. Acidosis implies a diminution of the alkali reserve of the blood plasma though not necessarily a change in its hydrogen ion concentration.

2. A simple and rapid method for the measurement of the alkali reserve is described. It is a modification of the indicator dialysis method for the determination of hydrogen ion concentration but is more accurate and gives more information than that method.

3. The method serves for the detection and accurate quantitative estimation of the degree of acidosis.

The results obtained in twenty five cases of acidosis are reported.

GROVER E. BELLAMY

Leopold J S and Bernhard, A.: The Non Protein Nitrogenous Constituents of the Blood and the Phenolsulphonophthalein Test in Children
Am J Dis Child 1916, xl 432

The authors report the results of the examination of the blood of 50 children free from renal disease and of 16 children suffering from renal disease.

In every instance the amount of the total non-protein nitrogen of the urea nitrogen, of the uric

acid, and of the creatinin was determined. In the children free from renal disease the average of the total non protein nitrogen was 28 mg per 100 ccm of blood the average of the urea was 12 mg per 100 ccm. the uric acid average was 1.3 mg per 100 ccm. the creatinin average was 1.5 mg per 100 ccm. and the average phenolsulphonophthalein excretion was 70 per cent.

Cases suffering from some renal affection were divided into four groups: acute nephritis, chronic nephritis, passive congestion and one case of sarcoma. The phenolsulphonophthalein excretion was diminished in each condition while the non protein nitrogen constituents were increased only in chronic nephritis being within normal limits in acute nephritis and in passive congestion. In the case of sarcoma of the kidney the non protein constituents were normal with the exception of the uric acid which was increased.

From a study of their findings the authors concluded (1) that in children the blood content of the non protein nitrogenous constituents is normally practically identical with that of the adult (2) that the variations under conditions of kidney affections correspond with those changes observed in adults under similar conditions and (3) that the determination of the non protein nitrogen in the blood of children will prove as valuable a help in diagnosis and prognosis in children as it has in adults.

J W TURNER.

Goodman C. and Bernstein E. P.: Prescille Gangrene-Thrombo-Angiitis Obliterans. V F
Am J 1916 xl, 1073

The authors who believe the etiological factor of thrombo-angiitis obliterans to be an infectious agent, report 21 cases in which serological studies were made with regard to typhus fever.

They call attention to the fact that thrombo-angiitis obliterans is more prevalent in those countries where typhus fever is epidemic and they suggest the possibility of the specific micro-organism of typhus fever being the etiological factor of thrombo-angiitis obliterans.

The agglutination reactions and complement fixation tests upon the 21 cases were made according to the methods described by Orlitzky. In 18 cases the reactions were negative in 3 cases the reactions were marked one showing almost complete agglutination in a dilution of 1:200 and two in a dilution of 1:400.

The positive reactions were given great weight because 102 controlled cases gave a negative reaction and because in many instances the serological reactions of typhus patients may become negative within so short a period as five months from the termination of the disease.

EXPERIMENTAL SURGERY AND SURGICAL ANATOMY

Dubois, E. P.: Metabolism in Exophthalmic Goiter. *Arch. Int. Med.* 1916 xvii, 915

In contrast with the symptoms on the part of the nervous system, the heart and eye symptoms which vary greatly in this disease, an increased basal metabolism was found by Dubois with great regularity in exophthalmic goiter which in severe cases he states reaches a level found in no other condition. On the other hand, in cretinism and myxoedema he found the metabolism lower than in any other diseases. The administration of thyroid extract particularly in myxoedema, raises the heat production. All other diseases in which metabolism is increased are easily distinguishable from exophthalmic goiter and they never approach the extremes found in this condition. The basal metabolism is higher than normal in youth, in fever, in lymphatic leukemia, and in pernicious anemia, in severe cardiac disease and in some cases of severe diabetes and cancer. It is lower than normal in old age and in some wasting diseases and perhaps in some cases of obesity. Diseases of the ductless glands other than thyroid show in some cases an increase in some a decrease but these are comparatively small.

From the author's experiments and observations in a large series of cases he was able to make the following summary of his work.

The metabolism in exophthalmic goiter has been studied for the first time in a respiratory apparatus which is also a calorimeter. Thirty-seven observations were made on eleven patients with this disease and six experiments were made on a cretin. With some of the patients the nitrogen balance was also studied.

The measurement of the heat production gives the best index of the severity of the diseases and of the effect of treatment. Very severe cases show an increase of 75 per cent or more above the normal average severe cases 50 per cent or more and moderately severe and mild cases less than 50 per cent while a few mild and several atypical cases or those in which operation has been performed may be within normal limits. In severe cases the warmth of the skin and sweating can be accounted for entirely by the necessity for the increased elimination of heat. At least a part of the tachycardia is due to the increased metabolism, and perhaps it might be possible to reproduce the extreme tachycardia, the cardiac enlargement emaciation, and mental irritability if it were possible to stimulate the metabolism of normal men for twenty-four hours a day over a period of months or years.

The specific dynamic action of protein and of glucose is within normal limits and there is no consistent difference between the effects of protein in meat and an equal amount in milk and eggs. One patient was able to derive 89 per cent of his calories from carbohydrate in an experiment when he was

showing an alimentary glycosuria. There is evidently no interference with the oxydation of carbohydrates.

The methods of direct and indirect calorimetry agree very closely when the technical difficulties are considered. The method of direct calorimetry gave results which were slightly lower than the indirect the total difference being 2.9 per cent the average difference in the individual being 4.1 per cent. This and the absence of abnormal respiratory quotients show that the law of the conservation of energy holds good in exophthalmic goiter and that there is no profound disturbance of the intermediary metabolism.

The average water elimination through the skin and lungs in the severe and moderately severe cases of hyperthyroidism is 39.9 grams per hour. The increase above the normal is closely proportional to the increase in heat production 25.7 per cent of the calories are dissipated through vaporization in goiter patients whereas the mean normal is almost the same 23.9 per cent.

The level of the heat production was used as an index of the effect of medical treatment. Rest in bed for a week or more caused a drop of more than 10 per cent. The effects of treatment with Beebe's serum, thyroid residue, ergotin, and quinine hydrobromate was less marked, each being tested on one patient. Ligation of the thyroid arteries with three out of the four patients studied caused a distinct rise in metabolism the duration of which was uncertain. There is as yet no proof the author states that any conservative form of treatment causes a greater reduction of metabolism than mental and physical rest.

One small cretin 36 years old produced about half the calories eliminated by children of his size. As estimated by the surface area, his metabolism was about 20 per cent below the normal adult level. Three and a half days treatment with thyroid extract raised his heat production to normal.

GEORGE E. BEILBY

Dewey K.: Experimental Hypercholesterolemia. *Arch. Int. Med.* 1916 xvii, 737

The author has made use of a watery colloid emulsion of cholesterol for intraperitoneal injections in rabbits and guinea pigs. Instead of Merck's pure cholesterol he used a preparation obtained from gall-stones by extraction with ether in the Soxhlet apparatus. For the separation of all saponifiable substances from this ether extract, a method was employed which is based largely on Kumagawa and Suto. Five grams of the dried ether extract were dissolved in 350 to 400 ccm of petroleum ether to this 70 ccm of a 1 per cent absolute alcoholic solution of potassium hydroxide and 30 ccm of distilled water were added. The mixture was shaken and the ether solution of cholesterol separated from the alcoholic solution of soaps in the separating funnel. The petroleum ether was evaporated and the dry cholesterol treated in the same manner.

ficial vein by means of a Brewer or Pope tube. The time during which the blood was permitted to flow has varied greatly depending upon the size of the tube used, the donor's blood-pressure, his heart rate, the physical condition of the recipient and the symptoms which developed during the procedure.

The hemoglobin of the patients has been frequently recorded during the process of the transfusion and has been found to increase from 0 to 40 per cent while they were on the table. If a subsequent bleeding occurs the hemoglobin is generally from 5 to 30 per cent higher on the following day.

In none of this series has any of the surgical accidents occurred, such as embolus, local infection, hemolysis or over-transfusion with its train of symptoms, or cardiac dilatation, edema of the lungs, tender tense abdomen, enlargement of the liver and spleen, and rupture of the abdominal viscera. In 3 cases, immediately after transfusion the patient developed a severe chill and high temperature. The temperature however subsided in about twelve hours.

Where the time would permit, the examination of donors consisted in taking the history, physical examination, Wassermann reaction, hemolytic tests and blood examination, with particular reference to leucocytosis, lymphocytosis, eosinophilia, parasites, etc. It was not possible to make all of these examinations in nine of the emergency cases. Under these conditions relatives of the patients were always used as donors and no harmful results were observed from the transfusions. In one case the blood transfused was from the patient's son, and had previously been tested in the ordinary way yet this patient developed the most marked reaction in the form of a chill and fever of any of the series.

The cases transfused to minimize surgical risk were quite satisfactory. The cases transfused for diseases of the blood, although showing slight benefit, were on the whole unsatisfactory. Cases transfused for shock demonstrated the value of this procedure.

The author believes that there is no excuse for a surgeon permitting his patient to die from shock or hemorrhage without giving him the advantages of transfusion. Transfusion should be looked upon not only as a method for reviving moribund cases with hemorrhage and shock, but also as the best prophylactic in preventing these conditions in individuals who are anemic, depleted, and weakened by disease. Many after transfusion are enabled to withstand major surgery. ALBERT EISENBRAND.

BLOOD AND LYMPH VESSELS

Vinavencio. Treatment of Accessible Arterial Aneurysms (Nota sobre el tratamiento de los aneurismas arteriales accesibles). *Gac. med. d. Caracas* 9, 6, 1911, 64.

The author discusses the comparative merits of ligation and radical extirpation. He refers to six cases which he operated upon. Two cases of aneur-

ism of the carotid treated by ligation and 4 cases of aneurysms in the limbs treated by extirpation, i.e., one of the superficial femoral, one of the popliteal, one inguinal and one axillar.

The two carotid aneurysms recovered perfectly without complication. In the femoral aneurysms, gangrene developed and the patient died. The other three limb aneurysms recovered perfectly but complete and radical extirpation of the aneurism alone was extremely difficult on account of adhesions, etc.

The author believes that the radical cure of accessible arterial aneurysms ought always to be the method of choice, unless there are special contraindications. W. A. BARNHART.

SURGICAL DIAGNOSIS, PATHOLOGY AND THERAPEUTICS

Sibley W. K. The Treatment of Scars. *Practitioner* Lond. 9, 6, 1914, 637.

The most frequent causes of scars are injuries, surgical operations, burns, tuberculous and other ulcerating skin diseases, acne, and variola. Scar tissue, because of its avascularity is not affected by drugs taken internally, but may be locally influenced by physical and electrical agents.

Hyperemia with Bier's suction cups will improve depressed, irregular and adherent scars and tend to convert avascular into vascular tissue. Scarring from both acne and smallpox is benefited by this treatment. Other methods of increasing hyperemia are the use of radiant heat, moist or dry hot air and hot or cold compresses, all of which are serviceable for the relief of pain and for the production of hyperemia.

Massage is most useful in freeing adherent scars from deeper structures.

3. Desquamating agents, such as salicylic acid or resorcin from 5 to 30 per cent strength, may be used to smooth down raised scars.

4. Electrical treatments, of which there are several forms, often give satisfactory results. By means of ionization soluble drugs are driven into the scar tissue. Sodium chloride, sodium salicylate, and iodine are the drugs used. Small repeated doses of X-rays may be cautiously used on hypertrophic scars, especially if they are keloid in nature. Radium also causes scars to become smooth and movable and relieves pain. High-frequency currents may be given locally or generally. Galvanism restores the tone of adjacent muscles and thus increases movement of the parts.

5. Of drugs used locally there are two: (1) fibrolysin, which consists of a 15 per cent solution of combined thiosulphate and sodium salicylate, 40 minims of which may be injected every two or three days into the gluteal region or around the affected tissue and (2) dicatrine (thiosulphate and antipyrine) which is stated to be non-toxic and non-irritating, the dose for injection being from 8 to 17 minims. E. K. ARMSTRONG.

EXPERIMENTAL SURGERY AND SURGICAL ANATOMY

Dubois E. F.: Metabolism in Exophthalmic Goiter. *Arch Int Med* 1916 xvii 915

In contrast with the symptoms on the part of the nervous system the heart and eye symptoms which vary greatly in this disease an increased basal metabolism was found by Dubois with great regularity in exophthalmic goiter which in severe cases, he states reaches a level found in no other condition. On the other hand, in cretinism and myxedema he found the metabolism lower than in any other diseases. The administration of thyroid extract, particularly in myxedema, raises the heat production. All other diseases in which metabolism is increased are easily distinguishable from exophthalmic goiter and they never approach the extremes found in this condition. The basal metabolism is higher than normal in youth, in fever in lymphatic leukemia, and in pernicious anemia, in severe cardiac disease and in some cases of severe diabetes and cancer. It is lower than normal in old age and in some wasting diseases and perhaps in some cases of obesity. Diseases of the ductless glands other than thyroid show in some cases an increase, in some a decrease but these are comparatively small.

From the author's experiments and observations in a large series of cases he was able to make the following summary of his work.

The metabolism in exophthalmic goiter has been studied for the first time in a respiratory apparatus which is also a calorimeter. Thirty-seven observations were made on eleven patients with this disease and six experiments were made on a cretin. With some of the patients the nitrogen balance was also studied.

The measurement of the heat production gives the best index of the severity of the diseases, and of the effect of treatment. Very severe cases show an increase of 75 per cent or more above the normal average severe cases 50 per cent or more, and moderately severe and mild cases less than 50 per cent while a few mild and several atypical cases or those in which operation has been performed may be within normal limits. In severe cases the warmth of the skin and sweating can be accounted for entirely by the necessity for the increased elimination of heat. At least a part of the tachycardia is due to the increased metabolism and perhaps it might be possible to reproduce the extreme tachycardia, the cardiac enlargement emaciation and mental irritability if it were possible to stimulate the metabolism of normal men for twenty-four hours a day over a period of months or years.

The specific dynamic action of protein and of glucose is within normal limits and there is no consistent difference between the effects of protein in meat and an equal amount in milk and eggs. One patient was able to derive 89 per cent of his calories from carbohydrate in an experiment when he was

showing an alimentary glycosuria. There is evidently no interference with the oxydation of carbohydrates.

The methods of direct and indirect calorimetry agree very closely when the technical difficulties are considered. The method of direct calorimetry gave results which were slightly lower than the indirect the total difference being 2.9 per cent the average difference in the individual being 4.1 per cent. This and the absence of abnormal respiratory quotients show that the law of the conservation of energy holds good in exophthalmic goiter and that there is no profound disturbance of the intermediary metabolism.

The average water elimination through the skin and lungs in the severe and moderately severe cases of hyperthyroidism is 39.0 grams per hour. The increase above the normal is closely proportional to the increase in heat production 25.7 per cent of the calories are dissipated through vaporization in goiter patients whereas the mean normal is almost the same 23.9 per cent.

The level of the heat production was used as an index of the effect of medical treatment. Rest in bed for a week or more caused a drop of more than 10 per cent. The effects of treatment with Beebe's serum thyroid residue, ergotin, and quinine hydrobromate was less marked each being tested on one patient. Ligation of the thyroid arteries with three out of the four patients studied caused a distinct rise in metabolism, the duration of which was uncertain. There is as yet no proof the author states, that any conservative form of treatment causes a greater reduction of metabolism than mental and physical rest.

One small cretin 36 years old produced about half the calories eliminated by children of his size. As estimated by the surface area his metabolism was about 30 per cent below the normal adult level. Three and a half days treatment with thyroid extract raised his heat production to normal.

GEORGE E. DEILBY

Dewey K.: Experimental Hypercholesterolemia. *Arch Int Med*, 1916 xvii 737

The author has made use of a watery colloidal emulsion of cholesterol for intraperitoneal injections in rabbits and guinea pigs. Instead of Merck's pure cholesterol he used a preparation obtained from gall-stones by extraction with ether in the Soxhlet apparatus. For the separation of all saponifiable substances from this ether extract a method was employed which is based largely on Kumagawa and Saito. Five grams of the dried ether extract were dissolved in 350 to 400 ccm. of petroleum ether to this 0.0 ccm. of a 1 per cent absolute alcoholic solution of potassium hydroxide and 30 ccm. of distilled water were added. The mixture was shaken and the ether solution of cholesterol separated from the alcoholic solution of soaps in the separating funnel. The petroleum ether was evaporated and the dry cholesterol treated in the same manner a

all these problems await further investigations. Nevertheless it is believed that certain conclusions may safely be drawn from his observations. They furnish a further corroboration of what may now be accepted as a fact that there is in the words of Bayliss a complete chemical regulation of the cardiovascular system which may act independently from the central nervous system. It has been shown in this paper that it is not only the blood circulating in the blood vessels that takes part in the regulation of their functions, but that the chemical conditions of the tissues and fluids surrounding the blood vessels also exercise an important influence. It appears furthermore that it is not only the products of the internal secretions which are concerned in this but that common acids and alkalies the specific metabolites of the tissues and cells besides a number of neutral salts, under ordinary circumstances for eign to the organism, may exercise a controlling influence. Strong acids act like alkali in compelling vessels to contract. It is true that such extreme chemical changes as have been presented in this paper are not ordinarily likely to occur. Rowntree and his associates estimate the hydrogen ion concentration of normal human blood-plasma as varying from $pH=7.4-7.6$ of the blood serum from $pH=7.6-7.8$. In clinical acidosis $pH=7.3-7.1$ and in dogs just before death from experimental acidosis $pH=6.9$. Henderson has shown that the blood is able to dispose of considerable quantities of alkali or acid without much change in its reaction. There must necessarily however be a limit to this, and one may conclude from the observations recorded by the author that besides the chemical and physical reactions of the blood itself there are other chemical and physical factors which, when once a certain limit has been overstepped, may lead to grave disturbances of circulation, and one can easily conceive of certain pathological processes such as inflammations, thromboses, necroses, and other local, possibly even systemic, affections originating in this manner.

GEORGE E. HEILAY

Auer, J., and Gates, F. L.: The Absorption of Adrenalin After Intratracheal Injection. *J. Exp. Med.* 1916 xxiii, 757.

In order to subject a living organism to the systematic action of any soluble substance it is obvious that the substance must first reach the circulating fluids of this organism, from the lymph and blood streams the drug may then pass into the tissues and exert its effect. The main routes available for bringing any substance into contact with the tissues are as follows: (1) by introduction into the gastrointestinal canal (2) by subcutaneous intramuscular intravenous, or intraspinal injection (3) by incision through the skin, and (4) through the respiratory tract.

Auer and Gates purpose in this paper has been to test the possibilities of the respiratory route and they have submitted evidence of an experimental nature which shows that a simple intratracheal in-

jection of a solution in a normally breathing rabbit penetrates within a few seconds to the alveoli chiefly those of the left lower lobe that absorption is rapid and well maintained and that the procedure may be repeated effectively a number of times even with a substance like adrenalin which decreases absorption. It was also shown that absorption of adrenalin from the lung could be obtained at a time when double the dose given intramuscularly exerted no blood-pressure effect whatever and that absorption could still take place after the development of pulmonary edema, when there was an undoubted dilution of the injection solution with a serum-containing liquid and when a diminution of the absorptive field had occurred.

The solution injected after reaching the alveoli is probably largely taken up by the capillaries of the pulmonary veins. This is indicated by the great rapidity with which an intratracheal injection of adrenalin may cause a rise of blood-pressure. In numerous instances for example the pressure began to rise less than five seconds after the completion of an injection, equaling, and even surpassing in rapidity of effect intramuscular injection. Absorption by the lymphatics probably plays a secondary part, an assumption rendered all the more likely when it is considered that lymph nodes are interpolated in the lymphatic pulmonary path, where the bed of the lymph stream becomes greatly widened and the current slowed.

Injection into the lungs, however offers another advantage due to the vascular arrangement of the absorbing field which could be of value therapeutically. Absorption of liquids injected into the lung probably takes place largely through the capillaries of the pulmonary veins to a slight extent possibly through the capillaries of the bronchial veins which empty partly into the pulmonary veins, partly into the azygos veins, and probably some absorption occurs also through the lymphatics. By far the larger portion of the absorbed material will thus be rapidly delivered to the left auricle and then to the left ventricle. At each succeeding systole, as long as absorption continues a fraction of the drug will be driven into the coronary arteries and be able to affect the musculature of the cardiac pump. This fact the authors state, ought to render the procedure of intratracheal injection a valuable method when it becomes imperative to stimulate a suddenly failing heart as promptly as possible by drugs of the digitalis group.

Intratracheal injection is perhaps better under the conditions mentioned than the intravenous route for the surface veins cannot always be entered with promptness and certainty even under fairly normal conditions and in cases of cardiac weakness the difficulties will be measurable increased while an intratracheal injection can be carried out with ease. Moreover the authors state it is legitimate to expect that some absorption will take place from the lung alveoli as long as the heart lung circulation persists no matter how feebly and that thus some

all these problems await further investigations. Nevertheless it is believed that certain conclusions may safely be drawn from his observations. They furnish a further corroboration of what may now be accepted as a fact that there is in the words of Bayliss, a complete chemical regulation of the cardiovascular system which may act independently from the central nervous system." It has been shown in this paper that it is not only the blood circulating in the blood vessels that takes part in the regulation of their functions, but that the chemical conditions of the tissues and fluids surrounding the blood vessels also exercise an important influence. It appears furthermore that it is not only the products of the internal secretions which are concerned in this, but that common acids and alkalies, the specific metabolites of the tissues and cells besides a number of neutral salts under ordinary circumstances for eign to the organism may exercise a controlling influence. Strong acids act like alkali in compelling vessels to contract. It is true that such extreme chemical changes as have been presented in this paper are not ordinarily likely to occur. Rowen and his associates estimate the hydrogen-ion concentration of normal human blood plasma as varying from $pH=7.4$ to 7.6 of the blood serum from $pH=7.6$ to 7.8 . GEORGE E. BAILEY

Auer J. and Gates, F. L.: The Absorption of Adrenalin After Intratracheal Injection. *J. Exp. Med.* 1916 **xxiii** 757

In order to subject a living organism to the systematic action of any soluble substance, it is obvious that the substance must first reach the circulating fluids of this organism from the lymph and blood streams the drug may then pass into the tissues and exert its effect. The main routes available for bringing any substance into contact with the tissues are as follows: (1) by introduction into the gastrointestinal canal (2) by subcutaneous intramuscular intravenous or intratracheal injection (3) by incision through the skin, and (4) through the respiratory tract.

Auer and Gates purpose in this paper has been to test the possibilities of the respiratory route and they have submitted evidence of an experimental nature which shows that a simple intratracheal in-

jection of a solution in a normally breathing rabbit penetrates within a few seconds to the alveoli chiefly those of the left lower lobe that absorption is rapid and well maintained and that the procedure may be repeated effectively a number of times even with a substance like adrenalin which decreases absorption. It was also shown that absorption of adrenalin from the lung could be obtained at a time when double the dose given intramuscularly exerted no blood pressure effect whatever and that absorption could still take place after the development of pulmonary edema when there was an undoubted dilution of the injection solution with a serum-containing fluid and when a diminution of the absorptive field had occurred.

The solution injected after reaching the alveoli is probably largely taken up by the capillaries of the pulmonary veins. This is indicated by the great rapidity with which an intratracheal injection of adrenalin may cause a rise of blood pressure. In numerous instances for example the pressure began to rise less than five seconds after the completion of an injection, equalling and even surpassing in rapidity of effect intramuscular injection. Absorption by the lymphatics probably plays a secondary part, an assumption rendered all the more likely when it is considered that lymph nodes are interpolated in the lymphatic pulmonary path, where the bed of the lymph stream becomes greatly widened and the current slowed.

Injection into the lungs, however offers another advantage due to the vascular arrangement of the absorbing field which could be of value therapeutically. Absorption of liquids injected into the lung probably takes place largely through the capillaries of the pulmonary veins to a slight extent possibly through the capillaries of the bronchial veins which empty partly into the pulmonary veins, partly into the azygos veins, and probably some absorption occurs also through the lymphatics. By far the larger portion of the absorbed material will thus be rapidly delivered to the left auricle and then to the left ventricle. At each succeeding systole, as long as absorption continues, a fraction of the drug will be driven into the coronary arteries and be able to affect the musculature of the cardiac pump. This fact the authors state, ought to render the procedure of intratracheal injection a valuable method when it becomes imperative to stimulate a suddenly failing heart as promptly as possible by drugs of the digitalis group.

Intratracheal injection is perhaps better under the conditions mentioned than the intravenous route, for the surface veins cannot always be entered with promptness and certainty even under fairly normal conditions and in cases of cardiac weakness the difficulties will be measurably increased while an intratracheal injection can be carried out with ease. Moreover the authors state it is legitimate to expect that some absorption will take place from the lung alveoli as long as the heart lung circulation persists no matter how feeble and that thus some

tissue cultures had been obtained from this animal. During the present experiments 31 animals were used and a total of 50 operations were performed. The process of wound healing was studied at various stages both in the living animals and in the preserved material.

The experiments reported in the present paper demonstrate that in wounds made in the skin of adult frogs there occurs as has previously been shown to be the case in living cultures of adult frog tissues, a direct transformation of the fibrin-clot into a new fibrous tissue without any intracellular action. This newly formed fibrous tissue which fills the wound space is apparently identical in appearance, structure, function, and staining reactions with regularly formed permanent connective tissue. It differs from adult connective tissue in the kind of the frog in its reaction with pancreatin digestion. No ever this test as well as all others that have so far been tried, fails to differentiate between the new fibrous tissue and young connective tissue found in diploles of various ages.

In experimental wounds made by removing various sized pieces of skin from the frog the rapid coagulation of the blood plasma and lymph to form a coagulation tissue which fills the wound cavity.

Observations on living animals show that the coagulation tissue becomes more and more resistant and is generally of sufficient strength to hold the edges of the wound in place and to maintain position in the wound cavity. It serves, at least temporarily as a connective tissue and as a base for the epithelial cells which rapidly move in from all the cut edges and cover the wound.

The study of the prepared sections of wound tissue show that at first the coagulation tissue formed as a result of the clotting of blood and lymph a typical fibrin net is present in the wound. Later this fibrin net is transformed into a new fibrous tissue containing bundles of wavy fibers in which in many instances the individual fibrils can be noted. This transformation of the clot and the formation of the new fibrous tissue takes place before the tissue-cells wander into the coagulation tissue and therefore cannot be due to an intracellular action. It is a direct transformation of the fibrin-clot and is identical with the process which was previously found to take place in the fibrin-clots in living cultures of adult frog tissues.

The tissue cells, which later migrate into the new fibrous tissue in large numbers from the surrounding area, do not digest the fibrin but apparently by their movements, cause a disintegration of the large bundles into smaller ones. These cells when they first appear in the fibrous tissue are rounded, but later they assume the typical elongated spindle shape of fibroblast cells. The preparations do not show any connection between these spindle-shaped cells and the fibers which had already formed, nor is there any evidence of a later attempt by them to form new fibers intracellularly.

The staining reactions of the new fibrous tissue appear to be identical with the staining reactions of the connective tissue in frog skin. However, the new tissue can be digested in pancreatin and in this reaction it differs from the connective tissue in the skin of the adult frog. On the other hand, it stains identically with pancreatin on embryonic but fully formed connective tissue obtained from the tail and skin of tadpoles of various ages, showing that pancreatin will digest it just as it does the newly formed fibrous tissue. (GEORGE E. BATES)

After 1. Some Reaction of Blood Vessels to Certain Chemicals. *J. Pharmacol. & Exp. Therap.* 9: 6, 11, 107

Aside from the fact that the various tissues and organs of the body receive from the circulating blood such material they require for their nutrition and for their growth, on the other hand must necessarily discharge some of the products of their metabolism into the interstitial tissue and its lymph-spaces. The blood vessels are therefore likely to be steeped in media more or less unstable, their chemical composition and arising widely in different regions of the body and must be assumed a priori that the vascular system reacts in certain definite ways to the physical and chemical changes that are more or less continuously taking place around about it. The study of the effects of chemical reagents of the products of glandular secretion on the action of drugs upon the heart and the blood vessels, especially upon the arteries has been mainly carried out by methods of perfusion. The direct observation of the living vessels under varying mechanical, thermal, electrical, and chemical conditions has received comparatively little attention.

The study of the reaction of the vessels was done mainly on the frog, using principally the mesentery and the reagent employed were dissolved in a 0.75 per cent saline solution and applied by means of a small glass tube holding rubber bulb at one end and the other drawn out into a moderately fine capillary. He presents a detailed description of the reaction observed by the use of alkalies and of acid solutions.

Summing up his results the author seems to be fully conscious that there still remain sufficient problems that have not been solved and discrepancies that have not been reconciled. The curiously uneven and apparently irregular contraction of the vascular walls, which they call beading demands further investigation and explanation, he believes. The fact that cleansing the mesentery with filter or lint paper in one instance causes no disturbance

however and that again violent constrictions may follow the same manipulation, though suggesting several plausible hypotheses, has not attained a precise explanation in his opinion. Similarly it has often been observed that acid solutions (alkaline not so frequently) had apparently no effect until the mesentery was washed with normal saline when the constrictions promptly appeared. Here again, he states, several explanations suggest themselves, but

all these problems await further investigations. Nevertheless it is believed that certain conclusions may safely be drawn from his observations. They furnish a further corroboration of what may now be accepted as a fact that there is in the words of Bayliss a complete chemical regulation of the cardiovascular system which may act independently from the central nervous system. It has been shown in this paper that it is not only the blood circulating in the blood vessels that takes part in the regulation of their functions, but that the chemical conditions of the tissues and fluids surrounding the blood vessels also exercise an important influence. It appears furthermore that it is not only the products of the internal secretions which are concerned in this, but that common acids and alkalies, the specific metabolites of the tissues and cells besides a number of neutral salts under ordinary circumstances for elga to the organism, may exercise a controlling influence. Strong acids act like alkali in compelling vessels to contract. It is true that such extreme chemical changes as have been presented in this paper are not ordinarily likely to occur. Rowntree and his associates estimate the hydrogen-ion concentration of normal human blood plasma as varying from $\text{pH} = 7.4$ to 7.6 of the blood serum from $\text{pH} = 7.6$ to 7.8 . In clinical acidosis $\text{pH} = 7.3$ to 7.1 and in dogs just before death from experimental acidosis $\text{pH} = 6.9$. Henderson has shown that the blood is able to dispose of considerable quantities of alkali or acid without much change in its reaction. There must necessarily however be a limit to this and one may conclude from the observations recorded by the author that besides the chemical and physical reactions of the blood itself there are other chemical and physical factors which when once a certain limit has been overstepped may lead to grave disturbances of circulation, and one can easily conceive of certain pathological processes such as inflammations, thromboses, necroses and other local possibly even systemic, affections originating in this manner.

GEORGE E. BRILL

Auer, J., and Gates, F. L.: The Absorption of Adrenalin After Intratracheal Injection. *J. Exp. Med.* 1916 xlviii 757

In order to subject a living organism to the systematic action of any soluble substance it is obvious that the substance must first reach the circulating fluids of this organism, from the lymph and blood streams the drug may then pass into the tissues and exert its effect. The main routes available for bringing any substance into contact with the tissues are as follows: (1) by introduction into the gastrointestinal canal (2) by subcutaneous intramuscular intravenous or intraspinal injection (3) by incision through the skin, and (4) through the respiratory tract.

Auer and Gates purpose in this paper has been to test the possibilities of the respiratory route and they have submitted evidence of an experimental nature which shows that a simple intratracheal in-

jection of a solution in a normally breathing rabbit penetrates within a few seconds to the alveoli chiefly those of the left lower lobe, that absorption is rapid and well maintained and that the procedure may be repeated effectively a number of times even with a substance like adrenalin which decreases absorption. It was also shown that absorption of adrenalin from the lung could be obtained at a time when double the dose given intramuscularly exerted no blood-pressure effect whatever and that absorption could still take place after the development of pulmonary oedema, when there was an undoubted diffusion of the injection solution with a serum-containing liquid and when a diminution of the absorptive field had occurred.

The solution injected, after reaching the alveoli is probably largely taken up by the capillaries of the pulmonary veins. This is indicated by the great rapidity with which an intratracheal injection of adrenalin may cause a rise of blood pressure. In numerous instances for example the pressure began to rise less than five seconds after the completion of an injection equaling and even surpassing in rapidity of effect intramuscular injection. Absorption by the lymphatics probably plays a secondary part, an assumption rendered all the more likely when it is considered that lymph nodes are interpolated in the lymphatic pulmonary path, where the bed of the lymph stream becomes greatly widened and the current slowed.

Injection into the lungs, however offers another advantage due to the vascular arrangement of the absorbing field which could be of value therapeutically. Absorption of liquids injected into the lung probably takes place largely through the capillaries of the pulmonary veins to a slight extent possibly through the capillaries of the bronchial veins which empty partly into the pulmonary veins partly into the azygos veins and probably some absorption occurs also through the lymphatics. By far the larger portion of the absorbed material will thus be rapidly delivered to the left auricle and then to the left ventricle. At each succeeding systole, as long as absorption continues, a fraction of the drug will be driven into the coronary arteries and be able to affect the musculature of the cardiac pump. This fact the authors state ought to render the procedure of intratracheal injection a valuable method when it becomes imperative to stimulate a suddenly failing heart as promptly as possible by drugs of the digitalis group.

Intratracheal injection is perhaps better under the conditions mentioned than the intravenous route for the surface veins cannot always be entered with promptness and certainty, even under fairly normal conditions and in cases of cardiac weakness the difficulties will be measurable increased while an intratracheal injection can be carried out with ease. Moreover the authors state it is legitimate to expect that some absorption will take place from the lung alveoli as long as the heart-lung circulation persists no matter how feebly and that thus some

of the drug will reach the heart to act on this structure itself more promptly perhaps than when the drug is administered successfully through surface veins. As far as the intramuscular route is concerned they have shown that the intratracheal injection of adrenalin gives prompt though diminished absorption at a time when double the dose intramuscularly exerts a blood pressure effect whatever.

The technical difficulties of performing intratracheal injection in animals are slight. Traheostomy as practiced by the thoracic pressurization experiments, is not necessary for the injection may be given into the intratrachea without exposure of the trachea. The hypodermic needle is inserted through the skin about 1 cm below the larynx in a slanting caudad direction the entrance of the needle into the trachea being readily felt. The injection should not be so rapid that the injected solution fills the entire tracheal lumen but it should flow down the sides of the trachea. If the lumen is completely filled an expiration may drive some of the injected fluid into the larynx causing cough. In the thoracic experiments each injection of about 0.5 c.c. completed approximately five seconds.

In the human subject data are available that the thoracic rate as far as their knowledge goes but a few others it would seem that intratracheal injection is almost as simple as the lower route. The free hypodermic needle could be inserted into the tracheal lumen immediately below the cricoid cartilage. The needle itself should preferably be connected with the syringe by a short length of rubber tubing to minimize the danger of breaking the needle by a sudden move of the patient. The amount of the solution should not be too small so that at least a fraction of the material has the alcohol as promptly as possible 3 to 5 c.c. probably would suffice.

In conclusion it may be said that the intratracheal injection of drugs by intratracheal injection while not as generally applicable as other methods nevertheless has advantages which warrant its use also in human therapeutics. GORDON E. BARTER

Piglihi, G. The Alterations in the Endocrine of the Gland, Especially the Thyroid, and of the Blood Following Vagotomy (Le alterazioni della ghiandola endocrina, specie del timo e del sangue in seguito alla vagotomia). *Riv. per il fascist. med. leg.* 9 6 XII, 549.

In his researches on the effects of thymectomy on the pig, Piglihi noticed that in some animals in which the two pneumogastric nerves were accidentally sectioned grave dyspnoea and cachexia were produced followed after a few days by death. The most characteristic findings at the autopsy were similar to those found in animals which died in cachexia after thymectomy i.e. dyspnoea, cachexia, venous stasis in many organs, splenic anaemia, great increase in the volume of suprarenal capsules, especially the chromaffin parts.

This coincidence led him to undertake further

studies, particularly to find if similar effects might follow a lesion of the vagus whether or not accompanied by a thymectomy. He therefore carried out a series of experiments on fowls and guinea pigs sectioning the vagus in the vicinity of the neck and studying the clinical syndrome as well as making detailed macro- and microscopical autopsy studies. These studies with the technique described in detail and from them the author deduces the following conclusions.

Fowls do not survive vagotomy more than four to five days guinea pigs about the same time.

Among the effect of vagotomy a clear distinction must be made between those which depend on the altered rhythm of the respiration and circulation with relative spasms of many viscera and a final asphyctic state and those which are directly imputable to the cessation of the action of the vagus innervation on certain glandular or systemic organs. The first effect results in the abolition of the vagus function on the respiration centers and vessels and the second from the suppressed innervation of the vagus upon organs which had a direct functional correlation with the vagus.

1. Among the organs which react directly to vagotomy are the hypophysis the thyroid the chromaffin gland of the capsule which is seen, especially the last named to be in a state of hyperfunction the thymus and spleen which show atrophic processes, especially the thymus which in fowls causes a marked lipoid degeneration the interrenal cortical of the capsule the internal of the ovary and testicle the medullary of the long bones which shows alteration in lipid content the circulating blood shows an abnormal distribution of white corpuscles, a preponderance of neutrophils, and a notable diminution of eosinophiles.

2. The thymus the spleen, the cortical of the capsule the interstitial of the testicle and ovary and the osseous medullary have an exchange and an internal secretion which is in part regulated by the autonomous action of the vagus.

3. The vagus being suppressed, the functions of these organs are consequently diminished, and the sympatheticus tonus is increased which is manifested by the hyperfunctioning of the chromaffin gland of the capsule (and in a lesser degree of the thymus and hypophysis) and in the increase of adrenalin substance in the circulating blood. W. A. BRIDGMAN

RADIOLOGY

Moriarty, D. C. Radium a Palliative Treatment of Ovarian Cancer. Indianapolis 9 6 Sept.

After a limited experience with a small amount of radium in the relief of the symptoms of terminal cancerous conditions of the female breast and pelvis, the author reports six cases in which the pain and hemorrhage had been alleviated. He also mentions that other clinical workers in radium have reported the same results without emphasis, however on its usefulness in this particular field. The

author states that he has made no claim to cure or prolongation of life, simply the alleviation of the symptoms. A synopsis of the cases reported shows that pain was relieved that the odor was markedly controlled, and that hemorrhage ceased. Two died in coma, two months after treatment. Four are alive and hopeful at the present time.

Morlanti believes it possible to produce a toxemia with radium locally which may prove serious, and suggests two precautions when using radium locally. First, a patient with a low leucocyte count should not be given prolonged applications of radium. Second when radium is used locally it should be accompanied by the liberal administration of alkalis. The author worked with only 25 milligrams of radium element, but for periods varying from 250 milligram hours to 9 600 milligram hours continuously. His convictions are that no case of this type is so desperate and no post-operative condition so hopeless that radium should not be used with an expectation of the alleviation of the trying symptoms.

Crosby L. G.: Deep Roentgen Therapy of Benign and Inoperable Malignant Conditions by Improved Technique. *Cole Med* 19 6 xiii, 183.

After brief mention of those physical characteristics of the roentgen rays which are factors in their use as a therapeutic agent, the author describes the chief differences between the technique employed in present-day deep roentgen therapy and that in use prior to two years ago. To the use of Coolidge tubes, filters, accurate devices for measuring dosage and the cross-fire method of treatment he ascribes the very much better results which can now be obtained.

In common with various authors whose reports he cites he has been able to obtain marked improvement or symptomatic cure in a large percentage of deep-seated lesions treated. He concludes that the roentgen ray should be used in all cases of inoperable malignant disease that its post-operative use in malignant cases be universally resorted to that it is a valuable adjunct to other lines of treatment in Gravel disease, splenic leukemia, and Hodgkin's disease and that in menorrhagia and myomatia it be employed in any case in which operation seems ill advised.

ADOLPH HARTMAN

Hirsch I. S.: Roentgenographic Control of the Pneumothorax Treatment of Pulmonary Tuberculosis. *Med Rec* 1916 lxxix 1029.

The application of the roentgen method assists in the selection of cases, permits the estimation of the degree of collapse and of the effect on the opposite of lung. Indicates graphically the displacement of the heart and mediastinum and aids the early discovery of complications.

It appears almost impossible by physical examination to determine the extent of the pneumothorax the position of the collapsed lung or to estimate the displacement of mediastinal structures. These dif-

ficulties demand all the diagnostic means at our disposal.

Both methods roentgenoscopic and roentgenographic, should be employed. With either omitted the examination is incomplete. No description of the fleeting image seen on the fluorescent screen however accurate, can compare as a graphic record with the permanent plate which also gives the finer structural detail not to be seen with the screen.

Roentgen study is made at three periods (1) preliminary for the estimation of the amount of disease (2) during and immediately after the injection and (3) later to determine the amount of the collapse restitution etc.

There appears to exist a belief that opening of the pleura and the admission of air invariably results in immediate and complete collapse of the lung, but it has been demonstrated that the lungs may functionate while there is a large pleural opening and that considerable quantities of gas are necessary to obtain extensive collapse.

Examination after injection gives the following data

- 1 The degree of pneumothorax. Is the air present in all parts of the pleural cavity or confined to a particular part?
- 2 The complete or partial collapse of the lung and its mobility
- 3 Presence or absence of pleural effusion.
- 4 Degree and manner of mediastinal displacement. Is there excessive strain on the blood vessels? (The heart displacement is not proportional to the amount of gas injected and varies with the same amount of gas.)
- 5 The movement and displacement of the diaphragm.
- 6 Subcutaneous emphysema presence and degree
- 7 Restitution and reinflation.
- 8 The effect may be studied from time to time and comparisons made.

DAVID R. BOWEN

Clark, W. L.: The Treatment of *Nævus Flammeus* and Allied Conditions by Filtered Ultraviolet Rays, Employing the Compression Method of Application. *Therap Gaz* 1916 xl 312

Ultraviolet rays, as applied by the author were found most efficacious in the treatment of port wine *nævus*, lupus erythematosus, *eczema rubrum* and *acne rosacea*. He used a Kromayer modification of the Cooper Hewitt mercury vapor lamp for generating the rays which were passed through quartz lenses cooled by a continuous circulation of water. He found the interposition of a thin disk of blue colored quartz of decided advantage, this acting as a filter for the irritating wave lengths and increasing the penetration.

The tissues treated were firmly compressed to produce a temporary ischemia and the surrounding structures were protected by the use of zinc-oxide adhesive plaster which effectively cut off the rays. An application of 30 to 40 minutes was found to pro-

duce the maximum of beneficial results. This was repeated, if necessary after three weeks and some cases required a third or fourth application after a similar interval.

A few hours after treatment a reaction set in. First the area treated became slightly darker and moderately swollen and edematous. This reaction became more intense for about 48 hours and then began to subside. Slight desquamation of the skin occurred and after one or two weeks the nevus became markedly lighter in color. Similar results followed each treatment although to a lesser degree. Brunettes were found less susceptible than blondes. Children reacted more favorably than adults. The best results were obtained with those nevi which faded readily upon pressure. Where connective tissue hypertrophy was present absolute obliteration rarely occurred but marked improvement resulted.

Ten cases of port wine nevi thus treated are cited in detail with results varying from slight improvement to complete success. Partial failure in two cases was ascribed to a coating of carbon on the quartz lenses, and a word of caution is given to avoid this. In some of the cases having scars due to previous treatment marked improvement of the scar followed the ultraviolet light treatment. Enlargement of feet res due to blood engorgement complicating some of the cases was materially reduced.

The author concluded that filtered ultraviolet rays applied by the compression method produces good cosmetic results in the treatment of port wine nevi telangiectasis, rosacea, and other superficial vascular skin lesions. A. HARTMAN.

Burns, J. E. Thorium, A New Agent for Pyelography. *Bull. John B. Pines Hosp.* 9 6 XVII, 57.

Ever since the introduction of pyelography by Voelker and von Lichtenberg in 1906 its prime importance in the rôle of renal diagnosis has readily been recognized. Although various attempts have been made to replace collargol the medium recommended by them for injection, it has proven to be the pyelographic agent par excellence up to the present time. The various colloidal solutions of salts of heavy metals, which have been tried as substitutes, are those of silver, iron, bismuth, copper, lead and mercury as have suspensions of the salts of bismuth, calcium, and magnesium. All of these solutions form sediment at once and while being for the most part quite opaque to the roentgen ray are viscous moreover great many are quite toxic and irritating.

The chief objection to collargol is its irritant action when it escapes into the tissues, and, as a matter of fact, there have been a number of deaths reported following its use. Its elimination from the urinary tract is somewhat prolonged on account of its viscosity. The fact that it stains everything with which it comes in contact makes it objectionable. It

is also quite expensive for this reason its use for cystograms and large hydronephroses is often prohibitive.

Since the opacity of a substance to the roentgen ray depends upon its atomic weight, thorium, being next to the heaviest known element, was quite ideal theoretically and seemed worthy of careful investigation. The nitrate and chloride of thorium are quite readily soluble in water giving a clear, markedly acid and astringent solution. These solutions, however, are quite irritating and it was necessary for the authors to discover some means of combining the substance to render a less irritating product.

After a careful series of chemical studies of the various combinations into which thorium may enter, a solution containing a double citrate of sodium and thorium, together with an excess of sodium citrate and some sodium nitrate, was found to possess the qualities desired as being necessary for an ideal pyelographic medium. After a careful clinical and experimental study the authors conclude as follows:

Thorium solution fulfills all the conditions necessary for an ideal pyelographic medium. Clinically there has never been the slightest evidence of toxicity in a series of one hundred and twenty-five cases, the amounts used in single case varying from a few cubic centimeters to almost a liter. This alone is proof of its non-toxicity.

Experimentally although in a few instances death has followed the injection of large doses into the peritoneal cavity and tissues of animals, larger doses intraperitoneally and intravenously have produced no ill effects. That the solution is non-irritating is shown by the absence of urinary symptoms after its use, and the absolute lack of any such evidence cystoscopically and at operation.

The pyelograms and cystograms made with this solution show a splendid shadow which possesses an unusual clearness of delineation. The solution is clear and watery therefore it possesses a great degree of fluidity permitting its ready elimination from the urinary tract. It is perfectly clean and does not stain the linen. In this particular it possesses another marked advantage over other solutions, particularly those of the silver salts. It is quite inexpensive, being about one-third as expensive as collargol. GEORGE E. BRIDLEY.

MILITARY SURGERY

Metcalf, J. and Keys-Wells, E. N. The Anatomical Position of Localized Foreign Bodies. *Lancet* Lond. 9 6 CIV, 978.

The localization of foreign bodies has been greatly simplified with the improved methods. Many cases arise, however, where it is important to know what structures lie above or below a foreign body. For example, in the thick parts of the body it may not be possible to secure satisfactory pictures in two planes. It is therefore necessary to estimate the depth of the foreign body in centimeters and this can usually be done. The question as to the relations

of the foreign body are not greatly simplified, however unless the depths at which anatomical structures lie are known by the surgeon. For example the radiographer reports a bullet to be 9 centimeters deep from a mark on the front of the thigh over the great trochanter. If the surgeon knows that the average depth from the skin to the great trochanter anteriorly is 10.8 centimeters and from the back 9 centimeters he would be justified in concluding that the foreign body lay just in front of the trochanter.

The author has tabulated a careful list of different parts of the body with the corresponding depths at which the different structures are placed beneath the surface.

J. H. SKILES

Dehelly and Dumas: Sterilization of War Wounds (Stérilisation des blessures de guerre) *Presse méd.* 1916 p. 203.

The authors give the technique of their treatment for the rapid disinfection of war wounds. They use a solution of 1:200 of hypochlorite of sodium prepared according to Dakins method. The special technique for obtaining access to the deeper parts of wounds is described. The treatment comprises surgical intervention, continuous instillation, and careful after treatment. Intervention is done aseptically as under operative conditions and following this it is necessary that all parts of the wound be kept in permanent contact with the antiseptic solution. For closure of the wound the authors prefer adhesive strips to sutures.

Of 155 cases of extensive wounds due to shells, bombs, and mines which have been treated by this method 135 or 87.4 per cent have closed. Of these 119 were cicatrized in less than 30 days. Twenty five of the 155 cases were complicated with fractures and of these 18 were cicatrized in less than 30 days.

W. A. BRENNAN

Fleminger Moiroud Nimier and Vignes Study of Pus in War Surgery by the Pyoculture Method of Delbet (Étude sur le pus en chirurgie de guerre par la méthode de la pyoculture du Delbet) *Presse méd.* 1916 p. 197

The authors have studied the method of pyoculture in a surgical field ambulance and their experience is based on 120 practical tests in different types of war wounds. They have endeavored to ascertain whether pyoculture could determine the kind of operative intervention.

They find that a positive pyoculture does not suffice to indicate intervention thus in 58 per cent of their cases a positive pyoculture was followed by a normal evolution of the wound without intervention. The necessity for intervention is only marked in 33 per cent of the cases. On the other hand when the pyoculture is nil or negative, it does not always indicate that intervention will not be necessary. Thus in 13 per cent of the cases, where the pyoculture was nil or negative intervention was necessary. In the presence of a pyoculture which is nil or nega-

tive expectant treatment may be advised but it may be necessary to resort to operation.

W. A. BRENNAN

Proust R. Considerations on Some War Injuries After Eighteen Months of Campaign (Considérations sur quelques plaies de guerre après dix huit mois de campagne) *Bull. et mém. Soc. de chir. de Par.* 1916 XLII, 1970.

Proust submits some general ideas gained from eighteen months experience in field ambulances. From May 1915 to February 1916 while in charge of Surgical Automobile Ambulance No. 1 Proust cared for 1,800 wounded, most of which had severe, infected wounds. The mortality was 23 per cent.

In injuries to veins or arteries the author ligates the vessel some distance above and below the injury and resects the injured part.

In bone lesions free splinters of bone should be removed but care must be used as regards other lesions.

For articular wounds, Proust believes that when any articulation is traversed by a projectile other than a bullet the opening must be largely widened so as to ensure drainage and certain resections such as of the patella and astragalus may have to be resorted to. Patellectomy has given 15 recoveries in 19 grave wounds of the knee. 16 shoulder resections gave 14 recoveries. Operatory indications are exceptional for nerve-resections.

In the case of wounds which are difficult of disinfection even after free opening up Carrel's method i.e. intermittent instillation of freshly prepared Dakin's solution has given the best results.

When amputations are necessary Proust always resorts to plane section. In the 1,800 wounded treated there were 152 amputations with a global mortality of 15 per cent distributed as follows:

3 thigh amputations	47	per cent mortality
5 leg amputations	5	per cent mortality
9 foot amputations	3	per cent mortality
20 arm amputations	7	per cent mortality
4 forearm amputations	2	per cent mortality

The mortality however has decreased under better conditions, etc. Thus from June to July the mortality was 72 per cent from September to November 32 per cent from December to January 20 per cent.

W. A. BRENNAN

Freund II: Experiences with Gaseous Gangrene in War Surgery (Kriegschirurgische Erfahrungen bei Gasgangrän) *Beitr. z. klin. Chir.*, 1916 xciv, 447.

Freund gives his experience with gas gangrene based on the treatment of 39 cases, 10 of which were of the epifascial type and 29 deep muscular tissue gangrene.

The history of gas gangrene is traced since Velpeau first made observations on the condition in 1855 and since the discovery of the gas bacillus by Fraenkel in 1883. The epifascial form of gas gangrene gives its indications between the skin and the

fascia. The typical discoloration of the skin, the intense edema, the changes in the subcutaneous tissues, and the finding of the gas bacillus are characteristic. This epithelial form is sharply differentiated from the subfascial muscular form and may be considered a distinct entity. The specific symptoms appear on the third or fourth day.

The subfascial form of gas gangrene is distinguished by the unusually violent halting pains in the wound remarkably accelerated pulse and great unrest of the patient. The clinical picture is not occasioned by the severity of the injury nor by any local symptoms but the vicinity of the injury is exceedingly sensitive.

Fruend describes the three different stages of alteration which may be observed in the muscles due to gas gangrene. In every case it is observed that the peripheral part of the injured muscle is more involved than the proximal part.

In the lighter forms, incisions in the fascia, widening of the wound, and oxygen insufflation suffice to effect recovery but in the subfascial forms even deep and wide multiple incisions will often not suffice and in 8 cases so treated by the author he was obliged to amputate the limb in 6 with deaths. Kuemmel's statistics of mortality was 3 per cent and Franz's 53 per cent in subfascial cases.

In the treatment of the subfascial form early diagnosis is important. Free opening up of the parts and excision of the diseased parts of the muscle is the best procedure. Sometimes it may be necessary to remove a whole group of muscles.

Amputation must be resorted to when in spite of the energetic action the necrotic conditions are seen to spread in the muscles or the muscles of the proximal joint are involved. W. A. BREIDEN

Pollicard, A. and Desplas, B. *Researches on the Secondary Suture of War Wounds (Recherches sur la suture secondaire des plaies de guerre)* *Lyon chir.* 9 6 411, 43

This article which is the result of the collaboration of biologist and surgeon is said to be only a preliminary study. The authors give the details of four observations, describe their technique, and discuss the physiology of wounds with regard to secondary suture. They think that there is an essential difference between secondary reunion in wounds and reunion by first intention in the case of operative wounds.

In the latter the phenomena are exclusively those of conjunctive regeneration. But war wounds are always infected, even if only slightly so, and to the tissue repairment must be added the defense against infection. The coexistence of an inflammatory reaction with conjunctive repairment gives special phase to such injuries.

Study of such war wound between two points of suture shows that there is multiplication of germs while scarcely one may be found in the exudate before suture after 12, 30 or even 80

germs may be found, including streptococci bacillus pyocyanus, etc. This multiplication begins immediately after suture and lasts three to five days. From the fourth to the seventh day germs are no longer found.

At the same time there coexists a notable leucocytary reaction. There is an afflux of neutrophile polymorphs. When the inflammatory reaction is subsiding masses of leucocytes undergoing a clear transformation are always met with, and the presence of such when noted is always an excellent index of the satisfactory evolution of a sutured wound.

It is important to follow the evolution of a secondarily sutured wound by frequent microscopical examination of the serosity which flows between the two points of suture. The mode of a secondary suture is little known but it represents such a surgical and social advance that multiple researches by discovering and comparing the factors which constitute it will lead to its generalization.

Perret, M. *Results Obtained from Employing Carrel's Method in War Surgery (Résultats obtenus par l'emploi de la méthode Carrel en chirurgie de guerre)* *Bull. Acad. de méd. Par.* 9 6 427, 434.

From August to December 1915, Perret treated 111 severely wounded cases in his ambulance service by the Carrel method. Of the series 78 were lesions of the soft parts, 33 were osseous lesions. There were no deaths. All the wounded have recovered and are in good condition. Not a single amputation was necessary. The method has eliminated infection according to the author.

The author states that all surgeons at the front are unanimous in declaring that the wounded treated by the Carrel method rapidly recover. As to whether Dakin's fluid is the only one capable of bringing about this result or not there is no longer any doubt and any delay in applying he considers grave fault.

W. A. BREIDEN

Uffoltz. *Secondary Union of War Wounds by First Intention in the Field Hospitals (La Réunion secondaire des plaies de guerre par première intention dans les formations sanitaires de 1^{er} vant)* *Bull. Acad. de méd. Par.* 9 6 437, 335.

The results obtained by Carrel and his confrères in the secondary reunion of non-sutured wounds were obtained under very favorable surgical conditions in a rear hospital but it was questioned whether these results would have been obtained in a field service hospital where such favorable conditions did not exist. The memoir now submitted is in answer to this criticism. This independent report of Uffoltz demonstrates that Carrel's abortive method of infection, if it may be so termed, is applicable at the front as well as at the rear.

Of 8 wounds in which the method was followed with success, 12 were shell or grenade wounds, which are generally infected, and 6 were caused by

rifle bullets but of such a nature that they might be classed as infected wounds. The rule has been followed in these cases of not suturing contused or infected wounds and allowing them to unite by secondary intention.

In his communication of October last Carrel discussed suturing. He preferred the employment of agglutinative strips to draw together the external as well as the deep edges of the wound. In large and deep wounds the strips are applied after having the deep edges approximated by some strengthening stitches. This procedure favors cicatrization from depth to surface. In the 18 cases now reported 10 were sutured but the suturing was late and after the freshening of the edges. In 6 cases adhesive strips alone were used and in 1 case of a large and deep wound shell of the arm reunion was effected by deep sutures on the ninth day. This was followed by the use of adhesive strips and cicatrization was complete by the forty-eighth day. Under the usual treatment the repair of such a wound would take from three to four months. The author believes that the Carrel method has abridged the treatment of war wounds by one half or two-thirds.

The technique followed in these cases is that of Carrel, but Pozzi is not quite sure that the modified form of Dakin's solution has been used. Carrel has intimated that he now uses Dakin's solution prepared as follows:

For 10 liters	
Chloride of chalk	200 grams
Carbonate of soda, dry	100 grams
Bicarbonate of soda	80 grams

The ingredients are mixed cold with 5 liters of ordinary water triturated, etc. No heat is employed.

W. A. BRENNAN

Enderlen, Experiences of a Consulting Surgeon
(Erfahrungen eines beratenden Chirurgen) *Beitr. z. klin. Chir.* 1916, cviii, 419

Enderlen gives his experiences of German war surgery from his diary notes. In the early part of the war the conservative treatment of wounds was found to be unsuccessful and after October 1914, active treatment was instituted in lieu of it.

Gas phlegmons, or gas burns as they are called by Fraenkel, were seen not only in the superficial but in the deeper tissues and seemed to result from all kinds of wounds. In the lighter epifascial phlegmons incisions and bandages soaked with H_2O_2 , or acetic acid and oxygen insufflation generally sufficed but in the more serious cases and deep involvement amputations of limbs was necessary.

During 1914 Enderlen lost 27 out of 34 cases of tetanus, although all the usual means were used. The scarcity of tetanus at the present time is due to prophylactic vaccination.

Cranial wounds since October 1914 have been re-examined and active measures instituted. Drainage and suturing have given good results. In the case of chest wounds the thorax was closed when possible. In larger defects of the chest wall the

lungs were sutured in to prevent mediastinum depression. Autopsy in two cases showed completely collapsed lungs and empyema. Hence it is best before closing the chest cavity to inflate the lung by ample pressure.

Enderlen operated from the beginning in intestinal gunshot wounds and had 67 successful cases out of 154. After ten hours if not operated the chances of success are slight. Liver and kidney injuries are better adapted for conservative treatment. Intraperitoneal bladder injuries are mostly fatal. Extraperitoneal bladder injuries can usually be managed with continuous catheterization. Urethrotomy is generally called for in urethral injuries.

In spinal region injuries the outlook is not entirely hopeless. Treatment should be instituted even though the prognosis is gloomy. In the lumbar spine the results give even better promise. Enderlen mentions a few cases of sectioned nerves which were sutured with good anatomic result.

For vascular injuries Enderlen has used ligatures, suturing and transplantation. The ligature is generally confined to the smaller vessels but suture will be used in the femoralis popliteal carotids and other large vessels as in these cases the ligature of the vessel is liable to cause gangrene in the limb. In the brachial and femoralis Enderlen both sutured and transplanted with good results.

W. A. BRENNAN

Pottle, J. and P.: The Advanced Surgical Post (Le poste chirurgical avancé) *Rev. de chir.* 1916, xxv, 302

The authors believe the establishment of advanced surgical posts in the battle line is necessary. In such a post properly constructed and protected the surgeon can operate safely and calmly. Such operations are not only acceptable, but are demanded by the wounded. The utility of such posts as regards hemorrhagic injuries is unquestionable.

In other conditions such as abdominal wounds early intervention is the essential condition for success. For such the advanced post is necessary. Amputations must yield to early resections. Infection is next to hemorrhage the cause of numerous amputations which can be avoided by care and attention in the advanced post. Where wounded cannot be despatched every day to clearing hospitals the advanced surgical post is indispensable.

Details are given of 84 operations carried out in such a post also of the necessary accommodations, construction and equipment.

GYNECOLOGY

UTERUS

Clark, S. M. D. Discussion of Cancer of the Cervix Uteri with Especial Reference to the Combination Method of Treatment. *T. St. J. Med.* 9 6, 25, 3

For convenience of discussion, cervical carcinomata are divided into four groups as follows:

1. In the first group are found the incipient cases. The ulceration is strictly limited to the cervix and there is no evidence of lateral infiltration. The uterus is freely movable. Menstruation is slightly prolonged with an occasional irregular show. There is an irritating vaginal discharge. The patient is constitutionally unimpaired and a good surgical risk. Cases falling in this group are treated by combining at the one sitting the application of the heat and the radical removal. The Wertheim removal is undertaken.

In fat women, the Percy cautery alone gives these early cases their best chance of cure since the technical difficulty of carrying out the radical plan is too great and further the high primary mortality would discount its feasibility.

It is most deplorable that more cases do not fall under this first group. Once there is thorough co-operation of an alert profession with an educated public the percentage of early cases will increase.

2. In the second group the cervix is well infiltrated with carcinoma, with a slight extension to the vaginal wall. Though as yet there is no pain in the sides, still a definite thickening and slight involvement of the parametrium can be palpated. The uterus is still movable with irregular flowing and at times, profuse loss of blood. There is secondary anemia and the patient is constitutionally below par. Many of these cases succumb from the operation since they are poor surgical risks. These cases must be transformed constitutionally before being subjected to the major operation. It is here that the Percy cautery in combination with ligation of both the internal iliac and ovarian arteries, as two-at-one sitting, so excellently serves the desired ends.

After the preliminary sitting, these patients are kept in bed for ten days when they are allowed to be up and are placed on forced feeding and Bland pills. From three to five weeks there will be noted a marked change both locally and constitutionally. With the cessation of the hemorrhage as well as the toxemia, the hemoglobin will have risen from 5 to 30 per cent, the vessels are full, the entire economy has improved and from having been a doubtful surgical risk, the case is now in frankly operable state. Radiotherapy is in its swaddling clothes. It is now in its experimental stage and it is

too early to come to conclusions. The only attitude to be taken is that of receptive state of mind.

3. In the third group the cervix is markedly infiltrated with carcinoma having extended at least an inch into the vaginal wall. Usually there is a large crater-like cauliflower mass bulging into the vaginal canal. There is marked impairment of mobility with noted lateral infiltration from the lower segment of the uterus. Pain in one or both sides is experienced. Pronounced cachexia and anemia are present. Constitutionally and locally they are inoperable. Heretofore these cases have been treated from the utterly hopeless standpoint.

The combinative method of treatment can be adopted to advantage in this group. While in the abdomen for ligature a thorough prospectus of the extension of the disease can be gained and the lymphatics removed as guide to the possibility of future surgical procedure. It is in this stage of the disease that we are put in the repeated use of the cautery to injure the bladder or possibly the rectum. In some of these cases the local and constitutional condition will have so decidedly improved after the cautery and ligation that judging from the mobility of the uterus, it will be thought possible to do a complete operation for after the upper two-thirds of the uterus is freed and the ureters detached from the focus, one usually finds that the upper two-thirds of the uterus part from the lower infiltrated segment.

4. The fourth group comprises the absolutely hopeless class of cases. The rectum, bladder and vagina are in one conglomerate, infiltrated mass. There is frequent and at times, copious flowing with foul vaginal discharge, advanced cachexia, wrecked constitution besides, the patients are usually addicted to taking large doses of morphine. More damage than good follows any attempt at local treatment in these cases. Deep X-ray exposure or massive doses of radium will give some relief from pain, but the cases are hopeless.

EDWARD L. CORNELL.

Tennant, C. E. The Use of Heat in the Control of Inoperable Cancer. *Cal. Med.* 9 6, 25, 76

Modern investigations seem to prove conclusively that heat is one of the most effective therapeutic means we have in the control of cancer provided it is properly applied. The subsequent use of the X-ray with cross-fire applications of the rays from hard tube is, no doubt, good after-treatment. The source of the heat may be varied from hot water to the actual cautery but it must be constant, long-continued and free from insulation, in order to spread evenly a temperature of 120 to 150° F. throughout the mass.

In applying the treatment to carcinoma of the pelvis or other easily accessible structures the Percy cautery irons are probably most satisfactory. The use of heat with the Percy irons, as a method of treatment is proving very satisfactory in inoperable cancers of the lip, face, neck, and breast. This should be followed later by radical excision thereby doing away with the possibility of metastatic recurrence.

The experiments which the author has made on large masses of beef lead him to believe that in the d'Arsonval current we also have a very potent and serviceable means of obtaining the same or even better results in tumor masses located in some of the more inaccessible portions of the body. This conclusion is based upon the fact that in every test made the d'Arsonval current raised the average temperature of a given mass 24° F. higher than the cautery irons did in just one half the time consumed by the latter.

EDWARD L. CORNELL.

Chiaje, S. delle: Red Myoma of the Uterus (Míloma rosso del útero). *Ann. di ostet. e ginec.* 1916 xxxviii 197.

The so-called red myoma of the uterus was first described in 1905 by Polioson and Violet who reported a few cases. The tumor is so-called on account of the characteristic red color like raw flesh in appearance which it presents in section. Since 1905 a few other cases have been described.

The author gives a summary of all cases found in the literature and describes a case of his own. In discussing these tumors the author considers that from the anatomopathologic standpoint they are usually situated on the anterior wall of the uterus and are constantly interstitial. They are almost always homogeneous and when exceptionally distinct nodules occur they never have the same structure but are fibrous in character. The tumors are covered with a fibrous capsule and in section show the characteristic coloring. The anatomopathologic features which confer a certain special physiognomy on these tumors are: (1) intense vascular hyperplasia, (2) interstitial hemorrhagic foci more or less diffuse (3) embryonic character of the muscular elements. Clinically the tumors are observed to increase rapidly and gave rise to pain and fever.

The brusque manifestations the manner in which they occur and the periodicity which they assume, give a certain clinical picture which has a diagnostic value. In the interpretation of these phenomena congestion is an element of the greatest importance. The morbid conditions with which red tumor of the uterus may be confounded are benign or sarcomatous fibromata in course of degeneration. A careful examination of the characters of the phenomena will permit of a differential diagnosis but it is more difficult to distinguish the tumor from an ovarian cyst with torsion of its pedicle.

In the case reported by Chiaje the patient showed the local and general clinical features of a pelvic tumor and the case was diagnosed as an ovarian

cyst with twisted pedicle. This diagnosis however was altered on opening the abdomen when it was seen that the tumor was developed on the anterior uterine wall and a hysterectomy was done. Examination of the tumor showed the anatomic characteristics of a red myoma. W. A. BRENNAN.

Deluca F. A.: A Case of Unilateral Polypiform Oedematous Elongation of the Uterine Cervix (A proposito de un caso de elongacion oedematosa cervical polipiforme unilateral). *Rev. de la Asoc. Méd. Argent.* 1916 xxiv 611.

A case of this very rare complication of labor is reported by the author in a woman of 28 a II para, who twelve hours after the onset of labor showed a fleshy tumor in the vulva, the size of a hen's egg which though reduced reappeared as the pains became frequent and intense. The woman was removed to the hospital. The tumor was then the size of an orange soft and pasty wine red in color and situated on the anterior cervical labium. One hour later the labor terminated spontaneously. After the birth the tumor gradually diminished in size and disappeared about two months later.

The author's research shows that this complication originates usually during labor and that its situation is by choice on the anterior labium. Several factors contribute to its causation. It is characterized by a distention and prolapse of the anterior wall of the inferior segment, elongation of the supravaginal portion of the uterine neck and oedematous tumoration of its intravaginal part, the dilatation of the neck being at the expense of the posterior cervical labium.

Deluca thinks that the condition should more correctly be termed cervicosegmentarial or 14th micocervical unilateral polypiformoedematous elongation (of Rouver).

It always occurs with a cephalic presentation and nearly always in multiparae. Spontaneous birth is always possible. The causes may be predisposing or determining. In the first group are comprised the anatomic constitution of the inferior segment, multiparity, narrow pelvis, prolapse and uterine anteversion, exaggerated softening of the inferior segment posterior presentation etc. in the second group energetic uterine contractions early presentation, and premature expulsive force.

W. A. BRENNAN.

Wallace, C. H.: Essential Hemorrhage of the Uterus. *J. Mo. St. M. Ass.* 1916. xiii, 20.

According to Wallace, essential hemorrhage must be diagnosed by elimination from the following:

- 1 Hemorrhage from retained secundines.
- 2 Hemorrhage from placenta previa.
- 3 Hemorrhage from fibroid tumors of the uterus.
- 4 Hemorrhage from endometritis.
- 5 Hemorrhage from chronic oophoritis or cystic ovary.
- 6 Hemorrhage from tubo-ovarian cyst.

7. Hemorrhage from deciduoma malignum and uterine cancer.

8. Hemorrhage due to senile vascular changes and hemophilia.

Once the diagnosis is made certain the author believes that hysterectomy or oblation of the uterine cavity by atmocautic is the only treatment.

HARVEY B. MATTHEWS

Fitzgibbon, G. The Etiology of Uterine Prolapse and Cystocele. *Surg. Gynec. & Obst.* 96 p. 33.

The author considers that some operation should be devised as the all around basis for the surgical treatment of these conditions. All evidence points to the fact that prolapse of the uterus is not the result of some damage done during parturition. The probability is that it is the same structure which is damaged in nearly all the cases. In nulliparous women the defect is probably the same, but here the fault is congenital and requires.

Lacerations of the peritoneum no matter how extensive have no effect upon the elevation of the uterus, and such lacerations could not possibly involve that part of the levator ani muscle which supports the cervix uteri. The structure which is considered the main support of the pelvic organs is the visceral or endopelvic layer of pelvic fascia. This is very fully described and shown to form complete pelvic diaphragm broken by the passage through of the viscera and parts attached to them. This together with the levator ani muscles forms the pelvic diaphragm, the fascia taking up the constant strain and the muscle acting by re-enforcing the fascia against pressure.

In descriptions of the fascia the upper or true supporting part of the fascia is quite neglected and the thin part which follows the levator ani muscles as their inner sheath is shown as if it were the whole of the rectovaginal fascia whereas it is very unimportant part. The vagina is shown by diagrams to lie obliquely below the fascia, the fornices only slightly go above the plane of the fascia while the uterus is chiefly above having its greatest attachments in front of the plane of the broad ligaments. The bladder is wholly above the fascia which separates it from the anterior vaginal wall. Prolapse of the uterus is the result of rupture of the fascial sling across the pelvis attached to the sides of the cervix and the lateral vaginal fornices. When this is damaged prolapse of the uterus alone takes place, the vaginal fornices being gradually inverted but the bladder being retained well up. When the fascia in front of the cervix and the anterior vaginal wall is ruptured cystocele develops, but the cervix is fully maintained. These two conditions may be combined and the whole pelvic contents comes down.

The failure of the present-day operations is the result of efforts to cure prolapse of the uterus by an operation only suitable for the cure of cystocele and the failure to recognize that interposition is useless unless the cervix is maintained well up. This is effected in a certain number of cases by the practice

of doing a high amputation of the cervix and covering over the stump with the vaginal wall, in doing so a certain amount of fascia is caught in and those cases in which a sufficient amount of fascia is caught result in cures while the others elapse but the need of catching in the fascia is not recognized. The pelvic viscera can be fully supported by an operation to unite the broken fascia in front of the cervix and below the bladder and this can be done without removal of organs or such distortion as will render childbearing in any way hazardous and can therefore be adopted in the young parous woman without sterilization.

Pascal, A. Treatment of Uterine Prolapse (Treatement du prolapsus uterini). *Presse med.* 96 p. 33.

For simple retroversion where there is no adnexal lesion Pascal believes that Alexander's operation under local anesthesia will suffice. If adnexal inflammation is suspected a laparotomy should be done and the procedure of Döderlein followed, which consists in fixation of the two round ligaments in a buttonhole made in the two large right muscles. If the ligaments are weak an abdominal hysterectomy may be necessitated.

For prolapse with predominance of cystocele in women of 40 Pascal recommends vesicovaginal interposition limited to women between 35 and 45 years.

For prolapse with atrophied uterus, flaccid vaginal walls, and gaping vulva the author is of the opinion that the Kocher operation does not give sufficient guarantee to assure the fusion of the uterus with the anterior abdominal wall and he therefore uses the Murphy operation, following the Mayo technique.

In the case of women with atrophied uterus and relaxed walls gaping vulva, and permanent cystocele the author uses vaginal hysterectomy completed by median suture of the two large ligaments and perineal reconstitution. In old hysterectomized subjects where the ligamental stump was not sutured to the uterine or vaginal stump it is necessary to excise the vagina, or in case of a younger patient to make laparotomy and fix the vaginal or cervical stump to the abdominal wall.

Whenever an operation for prolapse has been carried out the surgeon must remember that the muscular tissues are insufficient semi-atrophied, and that such operations leave behind a tissue of fragile cicatrices. If the technique is good, surgical recovery is the rule but it is highly necessary to strengthen the recovery by a regeneration of the muscles. This can be effected by general hygiene and Brandt gymnastics which restore tonus to the atrophied muscles.

W. A. BRECKEN

McCann, F. J. The Treatment of Backward Displacements of the Uterus. *Med. Press & Circ.* 96 cl. 410.

McCann has written a very lengthy paper upon the old but very important subject of backward

displacement of the uterus and the methods generally employed for its correction.

Treatment as the author states, has very markedly improved in recent years owing largely to the advances made in gynecological surgery and to a better understanding of the causation and sequelae of this condition.

The subject is outlined as follows

- 1 Congenital uterine displacement
- 2 Retrodisplacement due to excessive mobility
- 3 Traumatic uterine backward displacement
- 4 Treatment of backward displacement in virgins.

5 Treatment of backward displacement in multiparae (a) method of replacing the uterus, (b) treatment by pessary, (c) treatment of backward displacement when pain and tenderness exist (d) treatment of fixed backward displacement

6 Treatment of backward displacement in parous women (a) when the uterus is replaceable (b) when it is fixed.

7 Operations for the correction of backward displacement (a) abdominal (b) vaginal.

8 Backward displacement after the menopause.

9 Backward displacement in association with uterine and ovarian tumors.

10 Backward displacement of the gravid uterus.

Treatment may consist in (1) spontaneous replacement (2) bimanual replacement (3) operative replacement.

The author has given under each of these headings a general plan of procedure calling particular attention to those methods most successful in his hands. Some of his methods are original the majority however are those of other gynecologic surgeons modified or not HARVEY B. MATTHEWS.

Taylor J. C. Vaginal Hysterectomy V I M J 1916 cl 53

After a brief historical sketch regarding vaginal hysterectomy, the author elaborates upon the present-day indications for the operation and describes his method of performing it.

The indications for vaginal hysterectomy as given by the author may be tabulated as follows

1 All cases in which conservation of the uterus is not to be considered except where tumefaction renders the uterus too large to be delivered per vagina or where extensive adhesions render impossible the proper approach to the uterus.

2 In intraligamentous and retroperitoneal growths

3 In women past the menopause who for any reason require hysterectomy except in those cases where the size of the uterus prohibits its delivery through the vagina.

4 In complete prolapse of the uterus after the menopause

5 In cancer of the cervix where the disease is too far advanced for a Wertheim operation yet it is deemed advisable to remove the uterus for the relief of pain and foul discharges. Such cases

may however be radiumized and later a Wertheim operation performed.

6 In cancer of the fundus where the growth is still localized.

7 In epithelioma of the cervix occurring in old women who have serious heart or kidney trouble.

The vaginal route should never be chosen where there is any involvement of the appendix or in testicles which might need attention or in complete prolapse occurring in young women.

The author's method of performing vaginal hysterectomy consists in the usual anterior and posterior separation from below upward after which the uterus is bisected the adnexa inspected adhesions if present are freed, and then each half of the uterus is removed by clamping from above downward. The space between the clamps is properly packed with iodoform gauze and a self retaining catheter is left in the bladder. The clamps are removed in forty-eight hours. The gauze packing is removed on the sixth or seventh day and lighter packing replaced until healing is completed.

This technique is modified in the presence of fibroids or complete prolapse. Where fibroids increase the size of the tumor very materially V-shaped pieces may be continuously cut away until the top of the fundus is reached when division of the remaining tumor may be accomplished. In case of complete prolapse the ovarian and uterine vessels are ligated the clamps removed and the base of each broad ligament is sutured into the vault of the vagina which is sufficient to hold the vaginal vault high and keep the bladder in normal position.

In conclusion the author states that in a series of over 300 vaginal hysterectomies there has not been a single death traceable to the operation itself and therefore he highly recommends this operation in all suitable cases HARVEY B. MATTHEWS.

Truecaldle P. E. Vaginal Hysterectomy for Prolapsed Uteri with a Report of Fifty Cases. Boston M & S J 1916 clxxv 13

The author employing a special technique has performed 50 vaginal hysterectomies for the cure of prolapsed uteri. The procedure as recommended is limited to the class of cases in which conservation of the uterus may be disregarded. The author's cases averaged 50 years of age.

The technique employed differs from the usual vaginal hysterectomy in that the author instead of making the incision through the broad ligaments in the usual manner extends the line of incision inward far enough to include a considerable portion of uterine muscle. By bringing together the broad ligaments with their appended portion of uterine muscle there is formed a central body for the resistance of intra abdominal pressure and firm support for the bladder.

This method, as the author says, is the same as the Watkins-Wertheim procedure, except that the greater part of the uterus and all the cervix are removed before the interposing act is accomplished.

extensive adhesions this procedure is of great value and is more applicable than the bi-lingual incision.

The advantages of the method are ease of exposure of round ligaments, rapidity of operation, single incision later hidden for most part by the pubic hair, the pull is in a forward rather than a lateral direction and permits of the application of a Pfannenstiel or Peterson procedure.

Claims for originality are: (1) All other operators employing the transverse suprapubic incision do so with a predetermined intention of opening the abdomen either in the midline or by the Pfannenstiel method which the author only exceptionally resorts to; (2) simple fixation of round ligaments in the midline to the abdominal fascia instead of to Ioupart's ligament or the inguinal fascial wound and certain features in connection with the technique.

Stanton, E. M.: End Results in Cases Operated for Salpingitis. *Am J Obst. N Y* 9 6 lxviii 1958.

The author bases his report on a careful study of the end results of 100 cases he has operated upon for pelvic peritonitis of tubal origin, and a study of the literature on this subject. Among 93 patients not subjected to hysterectomy there were several who for a time complained of leucorrhœa but gradually the uterine infection subsided and today he thinks each of these women is better off with her organs intact than she would otherwise have been. His experience confirmed by carefully checking the late results following operation has led him to believe that the operator should remove as little as possible and trust much to nature. C. H. Davis

MISCELLANEOUS

Heineberg, A.: The Causes and Treatment of Sterility in Women. *Therap Gaz.*, 19 6 xl, 463

Various types of sterility are recognized: (1) primary (2) relative and (3) secondary.

Primary sterility is that type in which the possibility of conception is precluded because of permanent congenital or developmental defects in the structure or function of the genital organs.

Relative sterility is a state in which the absence of conception is attributable to causes which are susceptible of correction. These causes may be structural, chemical, functional or emotional.

Secondary sterility, or what is commonly known as one-child sterility, occurs in those women who fail to conceive after the birth of one child.

The successful treatment of sterility in the female depends largely upon the recognition of its causative factors. Any case that seeks relief requires to be studied with infinite care in order to determine the cause or combination of causes which may be operative. Cognizance of the many complicated and baffling causes of sterility should cause one to hesitate to undertake its correction with the same non-chalance which has characterized most previous efforts in that direction.

The lessons to be learned from a review of this subject would seem to be:

1 Sterility in the female may be due to many causes, some apparent and easily determined, others obscure and discovered only after careful investigation.

2 Surgical treatment for its correction should not be instituted until an honest and thorough investigation has shown that the sterility may reasonably be attributed to structural changes in the female generative organs.

3 No investigation can be considered complete which does not in some way include examination of the semen. EDWARD L. CORNELL.

Stauffer, W. H.: The Relation of the Rectum to the Female Pelvic Organs. *J Mo St M Ass* 1916 xiii, 325.

The author draws attention to the anatomical relationship existing between the female pelvic organs and the lower bowel.

Diseases of the vagina, rectum or urethra and adjacent glands may have a common beginning and the etiology of the existing trouble be entirely overlooked because of the failure to make a thorough and complete examination of adjacent organs. As examples of such mistakes, gonorrhœa and syphilis may exist in one or all of these organs, i. e., vagina, urethra, or rectum, and if not properly diagnosed and treated in each organ, failure to relieve the patient will be the ultimate result.

In conclusion, the author urges a closer relationship between the work of gynecologist, urologist, and proctologist in order to insure the correct diagnosis and therefore the proper treatment in each given case. HARVEY B. MATTHEWS.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Williamson, H. *Pregnancy Toxemia: a Study of Acidosis in Pregnancy*. (in *Med.*)

To determine the presence of alkalosis, four tests were employed: (1) the estimation of the alkalinity or rather the acid neutralizing property of the blood serum; (2) the estimation of the proportion of nitroge excreted in the urine; (3) the formation of ammonium salt; (4) the demonstration of acetone and diacetic acid in the urine. As the determination of the amount of sodium bicarbonate (administered by the mouth) necessary to render the urine alkaline.

1. The alkalinity of the blood was determined by a modification of the method described by Albroth Wright. In normal pregnancy the blood is found to be slightly alkaline; in toxemia the alkalinity of the blood is increased. In pregnancy the amount of sodium bicarbonate found to be necessary to render the urine alkaline is found to be much less than in normal pregnancy.

2. The total nitrogen estimated by Kjeldahl's method in the blood was found to be normal in all cases of toxemia. The ammonia content was high, the urea content normal, and the quantity of undetermined nitrogen in the serum of the nephritis there was not much higher than in normal conditions.

3. Acetone and diacetic acid were found in all cases of marked toxemia of pregnancy, and in no cases of normal pregnancy. In cases of chronic nephritis no acetone was shown, and no diacetic acid, but 5 cases had an acetoneuria which was the result of supervening toxemia of pregnancy.

4. The amount of sodium bicarbonate necessary to render the urine alkaline, as found to be high in the toxemia.

The conclusions drawn by the author are as follows: From the evidence before us we are justified in concluding that condition of acidosis is usually associated with pregnancy toxemia. In the milder and slighter cases the tests applied failed to demonstrate the presence of an acidosis, and in a severe case of eclampsia recently under my care a similar negative result was obtained.

This case has convinced me that further investigations are required and that certain conditions with which yet we are very imperfectly acquainted must be ascertained before we can definitely establish the relation existing between pregnancy toxemia and acidosis.

I do not believe that the symptoms of toxemia are due to the acidosis, but that the acidosis is a result of the toxemia. I believe that the acidosis is a result of the toxemia, and that the toxemia is a result of the acidosis. I believe that the acidosis is a result of the toxemia, and that the toxemia is a result of the acidosis. I believe that the acidosis is a result of the toxemia, and that the toxemia is a result of the acidosis.

I regard it as probable that those who believe that chloroform should be used in the treatment of cases of pregnancy toxemia, should also use the chloroform. I believe that the chloroform should be used in the treatment of cases of pregnancy toxemia, and that the toxemia is a result of the chloroform.

Boero, A. *Lat. Conservativa Caesarian Operation with a Vert. Presentation for Obstetrical Atrial of the Vagina*. (in *Med.*)

It was seen in a woman of 25 years of age, who had been married for 10 years, and who had 4 children. The first child was born at term, and the second child was born at term. The third child was born at term, and the fourth child was born at term. The fifth child was born at term, and the sixth child was born at term. The seventh child was born at term, and the eighth child was born at term. The ninth child was born at term, and the tenth child was born at term.

All reported cases of cicatricial atresia in which operative intervention has been made, have a mortality of 43 per cent. In 130 cases, conservative cases are reported. In 24 cases under similar conditions, has given a mortality of 41 per cent.

If the aliter of the vagina is very narrow, if the uterine neck has not been placed already for atresia or for any other cause, the post-caesarian foetal retention is a grave consequence which will be as in cases where an amniotic infection exists. Imposes a subtotal hysterectomy or a total operation. If on the contrary the clear state of the vagina and the uterine neck permits the hope of a good drainage in a conservative caesarian, if the

conditions which are necessary exist it should be given the preference. These conditions existed in the case reported.

W A BRECKMAN

Harrar J A. Post Mortem Cesarean Section; a Report of Ten Cases. 4th J Obst N Y 1916 lxxiii, 1046

The author gives a brief review of the literature on this interesting subject and a brief history of ten cases from the New York Lying-In Hospital.

In the series reported three babies were stillborn. It is probable that the death of all these children occurred before the death of the mother. Four babies were born with hearts feebly beating but there was no attempt at respiration during prolonged efforts at resuscitation. One baby gave a few feeble gasps and died shortly after delivery. One baby slightly asphyxiated at birth died on the sixth day of pneumonia. One baby badly asphyxiated at birth left the hospital living and well and one crying spontaneously at delivery was also discharged living and well.

C H DAVIS.

Sonnenburg, C. N. Cesarean Section Performed with a Pocket Knife After Death of Mother Resulting in Normal and Living Child. *In diaspora* 3 M J 1916 xiv 340.

The patient had had two uneventful previous pregnancies and no miscarriages. She had marked arteriosclerosis with blood pressure varying during her pregnancy from 180 to 210. The urine contained no albumin or casts. Two days before entering the hospital there was edema of the lower extremities which continued. There was evidence of congestion of both lungs. Endocarditis, myocarditis, and acute dilatation were observed. One morning she had a pulmonary hemorrhage and before the author could reach her she died.

So much time had elapsed in the effort to restore the patient that Sonnenburg feared to wait for the instruments and so performed a cesarean section with a pearl handled knife, 5.5 inches in length with a 2.5-inch blade. The baby girl was resuscitated in four minutes and has been gaining in weight rapidly. It was a full term infant weighed seven and one-half pounds, and was normal in all respects.

EDWARD L. CONNELL.

Waegeli, C. Interstitial Pregnancy (La grossesse interstitielle). *Rev de gynéc. et de chi* abd 1916 xlii, 405 441

Interstitial pregnancy is rare and Waegeli in a very extensive research of the literature on the subject has been able to collect only 150 cases, and of these many are very doubtful as both the macroscopic and microscopic descriptions are either lacking or incomplete. On this account Waegeli rejects 38 cases. Of the remaining 112 cases, many do not on examination satisfy the elementary postulates concerning which most authors are agreed and such cases if admitted must be taken on faith rather than on the evidence submitted by them.

The interpretation of an interstitial pregnancy is always difficult. It can easily be confounded with an angular pregnancy, with that in a rudimentary uterine cornua, or with a tubal isthmic pregnancy. From these considerations and from lack of satisfactory internal evidence Waegeli reduces the number of cases of genuine interstitial pregnancy reported in the literature to 53.

He describes with great detail and exactness the macro- and microscopical features of two cases which came under his observation in the Gynecological Clinic of the University of Geneva. In both cases the macroscopical and microscopical findings demonstrated clearly the development of a left interstitial pregnancy.

In the first case, the uterine fundus was strongly inclined (sign of Ruge Simon) the left round ligament laterally inserted and there was asymmetry of the insertion of the adnexa the left being much higher than the right. The fetal cavity is clearly separated from the uterine cavity the hernia of the uterine caducons into the fetal sac showed that this caducons did not continue any part directly with an analogous formation in the ovular cavity. Sections from the tube show that there is no sign of an ovular graft. The greater part of its interstitial portions has no connection whatever with the ovular sac. All the evidence is in favor of a clear intramuscular or intramural insertion of the ovule and not intratubal or intracanicular. The fetal sac is developed in the muscular tissue itself. Neither does the microscopic examination show the least sign whatever of any inflammatory process in either tube.

In the second case the macroscopic and microscopical findings, which were almost identical in character also establish the development of a left interstitial pregnancy. A muscular septum several millimeters thick separated the uterine and fetal cavities. Sections of the left tube in the vicinity of the fetal sac show the complete absence of ovular graft. The uterine fundus is quite vertical and the left adnexa are almost 5 cm. higher than the right. It is quite clear in this case also that the ovule is inserted in the muscular wall surrounding the tube but not in the tubal canal itself and the wall of the fetal sac shows clearly that it is constituted entirely of muscular tissue.

From a further study of the cases Waegeli thinks that the irruptions of the chorial villousities and their epithelium into the wall of the fetal sac does not occur during the early period of pregnancy and not until it is two or three months advanced.

In the second part of his extensive study Waegeli from a consideration of his own cases and the details furnished by others, endeavors to build up a complete clinical picture of interstitial pregnancy. After full consideration of the various classifications of other authors he finally classifies this affection in the following manner:

1. Interstitial pregnancy intramural or paramural (a) with evolution against the uterine

seron, (b) with evolution against the uterine cavity (c) with evolution in the two above-stated directions.

3. Canalicular interstitial pregnancy. This classification will, according to Waegell, include every reported case.

Waegell thinks that the etiology of interstitial pregnancy is the most obscure chapter in the history of the affection. Having considered the various etiological theories submitted he declines to express any opinion in favor of one or the other. The truth is probably that different anomalies of the uterus and adnexa concur to facilitate the interstitial insertion of the ovule. Today we are scarcely more advanced than Velpeau, who in 1837 wrote that the mechanism of interstitial pregnancy was still totally unknown.

The symptoms and signs of an interstitial pregnancy are rarely distinguishable before operation or removal. The pregnancy most frequently ends by rupture, thus occurring in the majority of recorded cases from the second to the fourth month, although it may extend to the seventh month. But in rare cases the resolution of the pregnancy may be by a uterine abortion of the complete ovule or by an incomplete uterine abortion. The latter has occurred in four of the recorded cases. However, the pathological anatomy is characteristic. Macroscopically there is a round tumor in the corresponding uterine cornua. This tumor contains the fetal sac inserted in the parietal musculature. A direct consequence of its development is the separation of the insertions of the round ligament from the ovarian and tubal ligaments. A muscular wall formed between the uterine muscular septum was found to exist in 5 of the cases recorded. The absence of such a septum implies canalicula interstitial pregnancy with uterine evolution.

But perhaps the most characteristic sign is the extraordinary position assumed by the uterine fundus. This becomes more and more inclined until it is almost if not quite vertical. Some, however, dispute the pathognomonic value of this sign. In the cases collected by Waegell the sign was present in 33; it was not present in 5 and its presence was not indicated in 15. It was present in both the author's personal cases. While this sign is present in the majority of cases its absence can not be held to be a criterion of disqualification.

Waegell discusses the other macroscopic concomitants of interstitial pregnancy: the insertion of the round ligament in laterality of the fetal sac; modification of position of the adnexa. Interstitial pregnancy is accompanied by a characteristic asymmetry of the tubes that on the gravid side is in the immense majority of cases being higher than the other.

In the microscopic anatomy the question which dominates all others is that of the formation of caducous in the fetal interstitial cavity. Opinions on this are well divided and Waegell discusses the various arguments without arriving at any very definite conclusions.

The clinical diagnosis, prognosis, and treatment are finally discussed. In the statistics it is shown that in 9 cases where intervention was made before rupture all recovered. Twenty-nine which were operated upon after rupture gave a mortality of 75 per cent. The operation of choice is the excision of the gravid uterine cornua and the corresponding tube. Total hysterectomy is indicated only if there is infection. The rule adopted by the author is to immediately operate upon every case of interstitial pregnancy when such a diagnosis is made; moreover it is absolutely necessary to intervene even in cases where an interstitial pregnancy is only suspected. The dangers of an immediate laparotomy are less serious than those occurring from a delay which may at any moment result in a fatality.

W. A. DAWSON.

Fetal Blood Ferment in Pregnancy. *M. J. 96, xxx.*

The author believes the following conclusions express the attitude of most workers toward the Abderhalden test.

The Abderhalden test is not a specific and infallible test for the diagnosis of pregnancy cancer or any other condition.

A negative reaction in a given case is of great value as speaking against the possibility of pregnancy.

A positive reaction must be interpreted as only speaking for the diagnosis of pregnancy and that only in absence of a large number of pathologic conditions some of which attention has already been called.

The ferments are increased in the blood during pregnancy. As yet, however, no way has been devised for differentiating between these ferments and the ferments mobilized in many pathologic conditions.

The test should be done in all cases in which the diagnosis of pregnancy is in doubt with a full knowledge of its limitations and possible errors. It should be regarded as corroborative evidence together with other clinical phenomena.

D. J. L. BORO.

Kraus, H. A. Pregnancy Complicated by Syphilis. *M. J. 96, xxx, 2.*

If a woman has a genital chancre at the time of conception or shortly after it, course is often protracted and the ulcerations are deeper and more extensive than usual. Secondary lesions and subjective symptoms are often aggravated.

Syphilis is a frequent cause of abortion and premature delivery especially between the sixth and eighth months. In the majority of cases miscarriages are caused by the death of the fetus.

The effect of syphilis on the ovum varies. The child may be born healthy and remain so or it may develop signs of syphilis in three to six weeks, or it may show distinctive signs at birth. Other symptoms may appear which are the result of disease (hemorrhage, jaundice, etc.). The child may

show various congenital malformations, or it may die before birth, and characteristic lesions may or may not be shown in the placenta following abortion.

Early treatment must be instituted before the middle period of pregnancy. A mixed treatment of mercury and arsenic is advised. Children born without lesions and a negative Wassermann should be treated. The author uses a daily injection of some soluble salt of mercury increasing the amount to the point of salivation. A weekly intravenous injection of 0.1 grain of neosalvarsan is given with the mercury. D. H. Boro

Smead, L. F.: Gunshot Wounds of the Abdomen in Pregnant Women. *Tr Am Ass Obs & Gynec* Indianapolis, 1916 Sept.

The author reports the case of a pregnant woman shot through the abdomen both mother and child recovering. The bullet perforated the colon and the uterus of the mother the placenta, and the child's hand.

Gunshot wounds of the abdomen are more dangerous during pregnancy than at other times. The abdomen should be opened in all cases if possible. The uterus at full term should be emptied by cesarean section and at earlier periods if the organ is badly injured. A uterus during labor is likely to spread any infection which is free in the abdomen and a pregnant uterus is therefore a menace to the patient if peritonitis develops.

The uterus is usually emptied by cesarean section or hysterotomy because the abdomen is open.

Hysterectomy is usually not indicated in gunshot wounds of the abdomen unless the uterus is badly lacerated.

Drainage should always be used in these cases and irrigation very rarely.

About thirty cases of gunshot wounds of the abdomen in pregnant women are cited.

LABOR AND ITS COMPLICATIONS

Freeland, J. R.: Scopolamine-Morphine Anesthesia in Labor; a Report of Seven Years Experience. *Penn. M J* 1916 xix 768

The author uses Merck's scopolamine. He thinks it advisable to confine oneself to one preparation when contradictory results have been obtained by various investigators.

The author's method of administration is the one usually adopted except that he eliminates much of the mental suggestion that is associated with darkened rooms softly stepping attendants whispered orders, cotton in the patient's ears etc. In his opinion, too dark a room interferes with observation of the patient. A dimly lighted but not gloomy room, free from extraneous noises and interruptions, adds to the effectiveness of the drug but carried to the extreme and associated with the other elements of suggestion already mentioned creates an atmosphere potentially harmful to patients in the receptive mental state caused by scopolamine.

Therefore all movements, conversation and manipulations are carried out in a natural manner and not with the hushed mysterious air of moths at a funeral or assistants at a magician's entertainment.

Great capital has been made out of the popular belief that a specially equipped hospital is necessary for deriving the greatest benefit from scopolamine. This is of course a nonsensical contention. With a trained nurse capable of counting the fetal heart beat and conversant with the care of patients who have been anesthetized for any purpose, the average home offers the atmosphere of quiet that is claimed to be a necessity. In this one respect the best-equipped hospital in the world has no advantage over the quiet bedroom to which the patient is accustomed.

Regarding the effect on the child it has been claimed that a condition of apnea frequently follows the use of scopolamine. The author's results show this to be no more frequent than after any other anesthetic, and it is much more likely to be caused by morphine than by scopolamine. Resuscitation of asphyxiated infants was not required oftener in the scopolamine than in the other cases.

There were no children born alive who died because of failure of resuscitation, except one case of cerebral hemorrhage the diagnosis being confirmed by autopsy. The fetal mortality in 470 cases was 8 or 3 per cent excluding four children that were macerated. The causes of death in the stillborn infants were cerebral hemorrhage 2 cord around neck 1 cause unknown as no autopsy was allowed 3. Two died after delivery one from stenosis of the larynx and one from cerebral hemorrhage, both diagnoses being confirmed by autopsy.

As to the effect on the duration of labor in 236 primiparae the average duration of labor was twenty-two and one-sixth hours. These patients were of all ages.

There is one type of cases in which scopolamine does delay labor and increase the frequency of forceps application that is those patients in whom it produces delirium and uncontrollable restlessness.

One point should always be remembered in connection with the question of the duration of labor and that is that a sedative is most needed by patients in whom labor is prolonged and will most often be used in cases of this type to the detriment of the reputation of whatever sedative is used if unequalled statistics are presented. The patients who have short quiet labors require no anesthetic and so lower the average duration of labor in their particular group. On the other hand, scopolamine, if useful at all is useful in cases of inertia and extreme susceptibility to pain.

As regards the occurrence of abnormalities, those in the author's series comprise: forceps 66 or 16 per cent breech 9 or 2.02 per cent face 3 post partum hemorrhage 4 or 1 per cent contracted pelvis 7 persistent occiput posterior position 6 acute chorea 1 chronic chorea 1 eclampsia 6 epilepsy 5 pyelitis 1 pulmonary tuberculosis 3 lobar pneumonia 1

exophthalmic goiter 1 heart-disease 2, syphilis 3 and hydatidiform mole 1. None of these can be said to have been caused by the use of scopolamine.

Regarding the effect on the consciousness of pain and the effect on the mind of the mother the author's results were as follows: (1) complete relief of pain 64 or 75.3 per cent; (2) great relief of pain, sleep between, patient waking during height of contraction 23.6, or 57.5 per cent; (3) marked relief but no sleep 6.9 or 17 per cent; (4) no effect 4.1 or 10 per cent; (5) delirium 5 cases.

In considering these results and the low percent age of occurrence of amnesia, one point needs emphasis. The author never deliberately pushes the drug with the object of obtaining amnesia, but uses it with the idea that its object is accomplished if the patient sleeps between pains and awakens during them. The harmful effects so often obtained result from endeavoring to get amnesia in all cases.

The author suggests that scopolamine be withheld if the patient shows any marked reaction on the stimulative side such as delirium, inconsequential talk, or even the well-known atropine flush which often appears after the first dose in those patients in whom a second dose causes delirium.

The conclusions are: (1) Scopolamine is a useful sedative, not anæsthetic, when not pushed to the extreme of physiologic tolerance. (2) Under these conditions it is without danger to the child. (3) It does not have a retarding influence upon the progress of labor. (4) Suggestion should be avoided. (5) Injurious mental results can and do commonly occur and care should be taken to avoid its use in patients whose make up suggests such possibilities.

EDWARD L. CORVILL.

Valens, J. A. Pituitrin in Labor. *Bull. M. Soc.* 96 Jul 3.

The author draws the following conclusions as to the use of pituitrin in labor:

1. It enables the doctor to use general anæsthetic to lessen the suffering of the patient in many cases where he could not otherwise give it on account of stopping the progress of the confinement. Pituitrin stimulates the contractions, hastens the progress of the delivery and at the same time allows the use of a general anæsthetic. This in the author's opinion makes pituitrin one of the greatest medicines discovered in later years.

It should not be given without a general anæsthetic unless in very small doses, and even then it is preferable that an anæsthetic be given.

3. The size of the dose should be governed by the condition of the case.

4. In opposition to many writers, the author believes the extract of the pituitary has a large place in so-called normal labor.

5. He has never seen a cyanosis or any sign of severe compression of the fetus in connection with its use.

6. The extract produces strong intermittent contractions the contractions often prolonged above

the normal especially when a large dose is given. Labor seems to set in at physiologic hour etc.

7. No sign of tetanic uterine contraction occurred in any of the above cases.

8. Used in only one case of miscarriage of two months standing to produce placental separation had no effect whatever.

9. No sign of any rupture of the uterus noted but the above belief might possibly occur in cases of obstruction with too large a dose of the extract.

10. Action begins in from three to six minutes and lasts from twenty to thirty minutes.

Gandino, N. T. F. d. A Case of Intra-uterine Crying. (L. asc. de gent. ut. terine) P. mid Argent. 9 Jul 15.

Intra-uterine crying is such a mysterious phenomenon that its existence is denied by many who have never had the occasion of observing it.

The interruption of the circulation of the umbilical cord causes the fetus to become venous. This causes an asphyxia which produces reflexly an inspiration and an expiration. This is the cause of the local cords are tense and determine the cry.

The case cited was that of a lady, Gandino, 29. The woman was a multipara who had four pregnancies terminating in term. The fifth was a twin pregnancy the first fetus was stillborn the rupture of the second bag of water took place five days later and it was at that time that the intra-uterine cry could be heard and it was repeated when the forceps were introduced to terminate the labor. The fatal cry was similar to that of a suffocating person.

In the discussion several speakers gave their opinion regarding the questionable occurrence of intra-uterine crying. It was urged that this also be put on record.

W. A. BORD.

Hymanson, A. and Kahn, M. Lipoid Content of Maternal and Fetal Blood. *Am. J. Obst. & Gyn.* 96 April 1.

After a general discussion of this subject with a description of the technique used in their tests the authors conclude as follows:

The data from their experiments carried out show that on an average the total lipid content of the maternal blood is less than the total lipid content of the newborn infant's blood, the figures being respectively 4.75 and 4.8 parts of fat per thousand parts of blood. The cholesterol content on the other hand shows, in general the opposite state of affairs, i.e. 1 part of cholesterol per thousand parts of infant blood and 2.9 cholesterol per thousand parts of maternal blood.

The authors believe that the chorionic villi have the function of discriminating which part and how much of each lipid shall pass into the fetal circulation.

C. H. DAVIS.

DeLee J B : A Bacteriologic Study of the Causes of Some Stillbirths Preliminary Report
J Am M Ass 1916 lxvii 344

Thirteen years ago the author saw a child of a healthy mother born with a temperature of 101, which within a few hours rose to 103. The child died of streptococcic septicæmia, the mother showing no signs of infection. A year later a physician's wife after a mild pharyngitis developed albuminuria and eclampsia. Artificial delivery was performed. Out of the child's nostrils pure pus exuded. The pneumococcus was found in it. Several other cases have indicated that the child can become ill independently of its mother and may even die the mother being only indirectly affected or not at all.

This opens up an immense field for study that we may thus find the cause of many cases of so-called 'habitual abortion' and repeated premature labor after viability and before term, and that we may discover new problems of immunity local infections nephritis during pregnancy eclampsia, puerperal sepsis, blood borne transmissions and new aspects of the transmissions of bacteria.

EDWARD L. CORNELL.

Decree: A Case of Obstetrical Paralysis (Un caso de parálisis obstétrica). *Siglo med* 1916 lxi 360.

The case is reported of an infant of two months which at birth did not move the right arm. The family physician stated that the birth had been protracted and that axillary traction was necessitated.

This traction occasioned traumatic lesions of the shoulder resulting in the arm being completely pendulous and absolutely immobilized.

In these cases Decree avails himself of Gault's procedure which is to place the shoulder in a position of extension abduction and external rotation forming a right angle with the arm. This position is maintained by means of a ring which takes the form of a banneret at the end of a pole and which serves also to keep the arm in the position indicated.

After 15 days more or less movement begins to be noted since there is a restitution of the articular elements. Reduction alone as in this case, suffices generally for complete restitution. If the immobility has occasioned trophic or degenerative lesions electrotherapy is indicated.

W. A. BREXVAX.

Thomas, T T : Obstetrical or Brachial Birth Palsy. *Am J Obst N* 1916 lxxiii, 577.

The author reports 11 cases of brachial birth palsy and gives an interesting review of the literature

together with his views regarding the etiology and treatment of this condition. He rejects the plexus theory for most cases.

His interest in obstetrical palsies resulted from observations on adult brachial palsies from injuries to the shoulder region. He claims that a palsy due to injury to the shoulder region and associated with an ankylosis of the shoulder joint which disappears with the restoration of normal motion to the shoulder joint must be due to an injury to that joint. He believes that this conception also applies to obstetrical palsies, and that the treatment based upon it is the best.

The author bases his treatment upon the simple principle of restoring as nearly as possible the normal function of the shoulder joint. From an experience with 24 palsied arms in 23 patients he found that when there was no displacement in the shoulder joint a perfect recovery could be obtained from exercise alone. In all of his cases of birth palsy with the typical internal rotation of the limb and the characteristic limitation of abduction and external rotation as old as two or three years he has not yet failed to find present a posterior subluxation of the shoulder joint.

The strongest evidence of a traumatic origin at birth of these subluxations is the bending downward and forward of the anterior portion of the acromion which is practically always present. An injury to the brachial plexus cannot explain it. It is obviously due to the same pressure which pushed the humeral head backward during delivery. A ray will not show the bent portion of the acromion as the patients are too young. However he has found it by operation every time except on a patient in whom the acromion showed distinct evidence of pressure. The absence of the normal humeral prominence under the posterior edge of the acromion and the bending downward and forward of the anterior portion of the acromion will establish the diagnosis of a posterior subluxation. It is important to recognize it at or soon after birth and its diagnosis is so difficult then for the reasons already given, that he does not hesitate to mildly etherize the young patient in order to assure the diagnosis. In doubtful cases he takes advantage of the anæsthetic to make sure the humeral head is in good position and fix it there for six weeks by a light cast with the arm in abduction and external rotation.

Operative reduction of these dislocations is in its infancy and as yet no method of operation has received much attention.

C. H. DAVIS.

GENITO-URINARY SURGERY

ADRENAL, KIDNEY AND URETER

Payne R. L., J.: Unilateral Hematuria Associated with Fibroids and a Multiple Microscopic Calculi of the Renal Papillae. *Surg. Gynec. & Obst.*, 9 6 xiii, 76.

Reference is made to previous experimental work by the author in which acutely developing vascular lesions were eliminated as cause of symptomless unilateral renal hemorrhage.

The author then reports a case of symptomless unilateral hematuria in which dissection of the kidney showed microscopically a normal cortex and parenchyma but every papilla presented a cherry red appearance typical of angioma.

The kidney was removed and careful microscopic studies disclosed an absence of pathological findings in the cortex or parenchyma proper but the papillae showed definite chronic inflammatory changes.

These changes consisted of (1) an overgrowth of connective tissue (2) multiple microscopic calculi (3) dilated capillaries with the small blood vessel in close apposition or the capillaries surrounded by the connective-tissue proliferation (4) a network of dilated capillaries on the surface of the papillae many of which were ruptured with free blood escaping.

These numerous though small varices were evidently the source of the hemorrhage and the inference is that the numerous calculi, aided by the connective tissue they had originated, succeeded in causing an obstruction to the venous return with subsequent dilatation of the capillaries and resulting varicoidities.

The paper is illustrated with microphotographs showing the microscopic calculi, the connective tissue proliferation, and numerous dilated capillaries which have ruptured on the surface of the papillae with free blood escaping.

The author claims that this is the first case recorded in which there is definitely shown the cause and source of a symptomless unilateral hematuria.

The facts presented would lend further weight to the contention of those who believe chronic inflammation to be the cause of unilateral renal hemorrhage.

Bissell, D.: Surgical Replacement of the Pro-lapsed Kidney. *Surg. Gynec. & Obst.* 19 6 xiii, 100.

The approach to the kidney advocated is by exact dissection of the tissues in the lumbar region occasioning the least trauma, or injury to the tissues encountered, at the same time facilitating deep manipulation in delivering the kidney.

The skin incision is four inches—beginning at a point immediately above the angle formed by the last rib and the erect spine and extending to a point immediately above the right triangle. The terminal fibers of the latissimus dorsi are now incised along the line of their attachment to the erector spinae and the muscle is transferred to the center margin of the wound. A section is next made in the upper area or superior triangle of the lumbar fascia immediately below and parallel with the twelfth rib this dissection being extended inward and outward as far as may be found necessary. The lateral curve usually found to the inner side of this incision. The kidney is then directly approached by blunt dissection through the fatty capsule. The finger is hooked into the cellular tissue about one of the poles preferably the upper and the organ delivered. The fatty capsule is completely freed from its attachment to the kidney and a crescentic incision of the fibrous capsule is made on the posterior surface extending almost from pole to pole and the two margins of the bladder. Two stainless steel sutures of egret like dyed silkworm gut are passed completely around the poles penetrating the attached portion of the fibrous capsule at several points to fix their position. When the kidney is replaced these sutures are passed through muscle, fascia, and skin and tied over a bolster of rolled muslin gauze.

The protractor shield, formed by the crescentic portion of the fibrous capsule separated from the posterior surface of the kidney is sutured to the under surface of the lumbar fascia to prevent the fatty capsule which is not removed but forced anteriorly from wedging between the raw posterior surface of the kidney and the sheath of the quadratus lumborum. The fascial incision is closed with a continuous suture of plain catgut No. 1. The latissimus dorsi is sutured to its original position with plain catgut No. 1. The skin should always be united with a permanent suture as the edges of the upper portion will separate by pressure from the bolster of gauze if the suture material is soluble. The silkworm gut sutures are tied on the inner side of the looper on the nineteenth day after operation and the patient is allowed to get out of bed immediately. The sutures are removed any time within the next two days.

Abell, I.: Giant Ureteral Calculi: Anomalous Development of the Genito-Urinary Tract. *Surg. Gynec. & Obst.* 9 6, xiii, 33.

The case reported was that of a male white aged 32 whose personal history was negative for acute severe illness and venereal infection. The patient

applied for relief of pain in his back of ten days duration. Irregular left lumbar pain was first noted at 18 at 28 similar pain was noted on the right side. Latterly pain recurred monthly never sufficiently severe to require opiates and until the present attack persisting only a day or two. Herebefore relief had been afforded by rest hot baths hot water bottle etc. Between paroxysms there was urinary frequency four to five times daily during an attack once to twice daily. Blood was noted in the urine on a number of occasions.

The patient was thin but well-developed and muscular pulse 100 temperature 100.2 F heart and lungs normal right kidney palpable tender apparently as large as a medium-sized grape fruit. The left kidney not palpable no tenderness on that side. The urine was a muddy color acid s.g. 1.020 marked trace of albumin occasional blood and pus cells calcium oxalate crystals amorphous phosphates moderate number of bacteria.

Cystoscopy showed that the bladder was practically normal the left ureteral orifice appeared normal the catheter readily entered the renal pelvis. The orifice of the right ureter was oedematous the catheter encountered obstruction at 2.5 cm. The urine from the left kidney showed no albumin nor pus an occasional blood-cell blood count normal.

Radiography of the calculeous pelvic portion of each ureter showed the left to be of moderate size the right extended from the sacro-iliac joint to the meniscus. The diagnosis was bilateral ureteral calculi right-sided hydronephrosis.

The operation consisted of a bilateral gridiron incision enlarged downward by incising the rectus sheath the peritoneum was displaced medially the ureters were approached extraperitoneally. There was considerable thickening about the right ureter and it was separated with difficulty from the surrounding structures. The ureter was incised at the pelvic brim and the calculus removed by traction. After a similar procedure on the left side the ureteral incisions were closed by interrupted catgut. The external wounds were drained by strips of rubber sheeting.

The post-operative history was uneventful the patient resuming work at the end of the third week. The right calculus was oblong with a distinct curve at either extremity length 7.5 cm circumference 7 cm weight 24 grams the left stone was more ovoid weight 2 grams.

The literature shows that Desguin removed ureteral calculus irregularly triangular 36 by 23 mm weighing 10 grams Baker 94 grains Parker over 3/4 ounce Bovee, 2 3/4 by 1 1/4 by 1 1/4 inches weight 1,310 grains Buerger (1) more than four inches long 6 mm. to 1 cm. in diameter (2) 2 3/4 inches long by 1 3/4 inches wide Specklin 11 cm long weight 51 grams Federoff length 19 cm, weight 53 grams Rovsing length 18 cm width of a bean Israel (1) length 13 cm circumference 9 cm. weight 54.4 grams (2) length 17 cm circumference 9 cm. 10x11 weight 34.5 grams

Lloyd length 5.5 inches circumference 2.5 inches Morris nearly 6 inches long (libson 3/2 inch in diameter nearly round.

The second case occurred in a female white aged nineteen who had been married three years with no pregnancy nor menstruation. The first attack was diagnosed as appendicitis. When the second attack occurred the patient was taken to the hospital. Her pulse was 120 temperature 103 F abdomen markedly distended exquisite tenderness in the lower zone. While her figure was typically feminine examination revealed the absence of a vagina the external genitals were normal in appearance. The urine was acid trace of albumin slight sediment few blood-cells many pus cells and rod-shaped bacilli. The blood count showed haemoglobin 90 per cent white cells 10,500 polynuclears 82 per cent. The tender mass in the left pelvis was thought to be retained and infected menstrual secretion.

Celiotomy with median incision disclosed a pelvic kidney in front and to the left of the sacro-iliac synchondrosis. The right kidney uterus tubes, and ovaries were absent. The appendix was removed. The operative finding was pyelitis in a single pelvic kidney.

Three weeks later urine from the ureter and the bladder was negative upon culture. Radiography showed the renal pelvis to be normal in size and shape with a single ureter three or four inches long. A cystogram showed the bladder pressing upon the kidney the latter producing a variation in the normal vesical outline. The rectum was in the right pelvis.

In the literature Anders cites one case of single kidney based upon 92,690 autopsies the occurrence of the anomaly was one in 1,817. He refers to 285 cases in the literature. Among 36 gross renal and ureteral anomalies in the Mayo clinic during five years 12 were horseshoe and 6 single type. Thomas reports a case of pelvic kidney in a female diagnosed prior to operation for pelvic disease the vagina and uterus absent. Cullen mentions a case of a girl of seventeen with right pelvic kidney vagina uterus and left kidney absent tubes and ovaries prolapsed in the inguinal region. Blissell successfully reimplanted a right pelvic kidney. A single kidney has been observed at autopsy by Ward Glazebrook Secher, Stengel and others. Lolk removed a single right kidney located in the pelvis the patient perishing after thirteen days of complete anuria. Mayer and Nelkin speak of subperitoneal traumatic rupture of a solitary right kidney.

BLADDER, URETHRA AND PENIS

Granger A.: The Use of Oxygen in Cystography, with a Preliminary Report on the Use of Oxygen in Pyelography *Am J Roentgenol* 1916 III 351.

Beginning in 1900 the author began using washed and filtered air to distend the urinary bladder in an effort to obtain better cystographs but found it was

abscesses with extensive destruction of tissues, long standing cases of hard fibrous sclerotic vesicles, cases in which the vesicle and ampulla are produced by symptoms referable to the ureter and selected cases of extreme nervous origin unaltered by the usual treatment.

Vasculotomy is considered in all cases of spermatorrhea, all cases of pus and blood in the ejaculate and following massage and in the acute catarrhal and suppurative types. H. G. HAWES.

Crowell, A. J. Urinary Retention Due to Prostatic Obstruction. *Urol. & Gynec. Rev.* 9, 6, 11, 55.

In the first type of prostatic obstruction, prostatic abscess, the author believes that the prostate should be drained perineally without opening the urethra. In the second class of cases, prostatic hypertrophy the author believes in perineal prostatectomy for the reason that the wound and the kidneys are both drained from the most dependent point, the perineum. He believes that the mortality following the perineal operation is not as great as that following the suprapubic. If the prostatic hypertrophy is accompanied by an abscess of the prostate the abscess cavity also can be better drained through the perineum.

In malignant disease of the prostate a tenillon is called to the fact that the prostate, its capsule, the seminal vesicles, and the bladder trigone can all be removed perineally. In performing this operation the growth may be entirely removed, the only drawback being that incontinence of urine usually ensues. He recounts two cases in which he has used the Young punch to remove a prostatic bar. In one case a man of 82 who had had kidney function, 4 ounces of residual urine and was in poor physical condition, the punch operation was entirely successful. In the next case, a man 35 years of age who had 16 ounces of residual urine, the median bar was removed by the punch. After the operation he was able to empty his bladder without difficulty. B. S. BARRON, JR.

Gordon, G. S.: The Internal Sphincter Following Prostatectomy. *Surg. Gynec. & Obst.* 19, 6, 1221, 620.

After removal of adenomata through the internal sphincter the sphincter on regaining its full functional power often forms a raised crescentic fold which in ratio to its size obstructs urination, with the result that there still remains some abnormal back pressure at urination on the bladder, ureters, and kidneys which encourages the continuance of infection and interferes with renal secretion. Be-

hind this obstruction is a pouch of residual urine in which stone may form. If the free edge of the sphincter has been denuded and its purse string action is strong enough it may obliterate the outlet entirely and so that healing may occur. The author believes the obstruction should be dealt with at operation and he suggests the entire removal of this flap or that it be slit and applied to the denuded prostate bed.

MISCELLANEOUS

Beck, E. G. A Report of a Series of Unusual Fecal and Genito-Urinary Cases Treated by Bismuth Paste. *S. & G. Soc. & Obs.* 19, 6, 11, 507.

The author reports 38 cases, 17 post-operative fecal fistulae and 21 cases of urinary fistulae all treated with bismuth paste. Most of these were preceded by more than one operation, some of them by many. Most of these cases were known before the surgical society and the histories of the paper must be read in order to learn the most recent progress in technique in this treatment. It is only this way that the best result may be obtained and Beck has shown that can be accomplished under proper conditions.

The roentgenogram which illustrates clinically the past is instructive both from a diagnostic and therapeutic standpoint. It is shown that a bicus of the spine or the hip-joint may perforate the bladder and thus cause urinary fistulae through an opening about the hips.

In a series of post-operative suppurative fistulae after nephrectomy, the cases have invariably healed if they have waited for many years.

The cases of fecal fistulae reported detail a series of unusual types. In one case the entire digestive content had escaped from a laparotomy wound for months without any surgical interference caused by purely the bismuth treatment, the fecal fistula closed with unusual rapidity and the patient increased in weight from 90 to 180 lbs. within one year. In none of the fecal fistula cases did the author resort to any surgical treatment and only one case out of the series of seventeen could not be cured by this method, this being a fistula of the small intestine.

The author lays special stress on the technique which he has observed to be faulty and responsible in many cases of fistula which have come under his observation and from other sources.

Bismuth poisoning has not occurred in any of his cases and he believes it can be prevented in every last case.

SURGERY OF THE EYE AND EAR

EYE

Willmer W H : Three Years Experience in Sclerocorneal Trephining in Glaucoma. *Arch Ophth* 1916 xlv 333

Case histories of patients on whom sclerocorneal trephining for glaucoma was done are presented the author stating that by reason of the small number he has been able to carefully follow up the cases.

His results have been very favorable tension being lowered and pain relieved in nine eyes after the La Grange operation or iridectomy had failed and miotics had been used in many cases over periods of years.

He protests against the present unfavorable attitude toward the operation he believes that the pendulum is swinging too far to the opposite from the procedure a enthusiastic reception, and states that in his opinion sclerocorneal trephining is the easiest safest and most effective method yet suggested for permanently reducing excessive tension.

Late infections he believes, can be lessened by taking care to dissect up all the subconjunctival tissue with the conjunctiva in order to make the flaps as thick and protective as possible.

Synechiae lenticular opacities, hemorrhages and relapses are said to be no more frequently met with after this than after other methods of operating and it has the advantages that both eyes can be operated upon at the same time the patient does not have to be long confined. It does not reduce the visual fields or cause astigmatism to an accountable extent there is only a negligible risk of the loss of vitreous and no danger of the escape of the lens and the operation may be repeated. S S HOWE.

EAR

Moure E. I : A New Method of Examining the Vestibular Labyrinth (Sur un nouveau mode d'examen du labyrinthe vestibulaire) *Bull de Acad de med* Par 1916 lxxv 413

For some years past Moure has made it a practice in examining the vestibular labyrinth to submit the patient to a series of experiments in which provoked nystagmus occupies an important place. According to the duration and intensity of the nystagmus and the time it takes to appear he deduces that the labyrinth is normally hyper or hypo-excitable.

The number of labyrinthine affections occurring during the war has afforded many opportunities for putting this method into use. W A BRENNAN

Hays, H : The Corroborative Diagnosis of Mastoiditis by Means of the X Ray. *A F M J* 1916 cli 1163

The author cites cases to show the value of the roentgenogram in corroborating the clinical evidences of mastoid disease. He does not insist upon the necessity of having an X ray taken before a diagnosis of mastoiditis can be made but he does consider it of more value than a consultation particularly in atypical cases or when weighing the evidence for and against operative interference. Besides this knowledge a roentgenogram shows the position of the sinus the size and shape of the mastoid and the extent of zygomatic cells. OTTO M. ROTT

Lent, E. J : Chronic Suppurative Mastoiditis Accompanied by Intracranial Pressure. *J Indl and St M Ass* 1916 ix, 290

A case is cited in which operation disclosed the presence of a large cyst apparently not dependent upon the middle ear infection, as the fluid in the cyst was sterile. The patient ultimately recovered after symptoms of meningeal irritation had supervened. The cyst was drained and later allowed to become infected after which the discharge was gradually lessened in amount and finally ceased.

The author briefly discusses the question of cerebral cysts dividing them into four classes (1) parasitic, (2) traumatic, (3) apoplectic (4) and degenerated neoplasms.

1 Parasitic cysts are due either to the cysticercus or echinococci.

2 Traumatic cysts are not very clearly defined in origin. They may be explained on the ground of long-continued circulatory disturbances with consequent local accumulations of serum, or shrinking of cerebral tissues in the region of injury the result of sclerotic changes in the cerebral substances the contraction leading to the formation of a vacuum which becomes filled with fluid derived from the surrounding membranes.

3 In apoplectic cysts the blood-clot contracts and changes from a red to a brownish color due to the transformation of the hemoglobin into hema-toidin. The pigment is diffused in the neighboring tissues giving a yellowish tinge the detritus is transformed and absorbed so that a cavity remains containing fluid, the so-called apoplectic cyst.

4 In degenerated neoplasms cysts may be found on microscopic examination to be the end result of an almost complete degeneration of a glioma.

Mayer E. Angioma of the Larynx. *Med Rec* 1916 lxxix 1084

From a study of his own case and the forty others found in the literature the author reaches the following conclusions

1 Angioma of the larynx is a rare disease occurring mostly in adults and the proportion of males to females is approximately four to one

2 It may be mistaken for cancer

3 Endolaryngeal removal of a portion of the growth for diagnosis, or its complete removal in this manner is fraught with danger and may have serious results.

4. Laryngofissure, removal and suturing the mucosa, are entirely safe and feasible procedures.

OTTO M ROTT

MOUTH

Mayes, W. C. and Wilson W. and C. F.: Focal Infections. Results of Overcoming Same. *South M J* 1916 lx 400

Many diseases, the etiology of which has been obscure are due to metastasis or absorption of toxins from a primary focal infection and in order to conserve the best body economy it is essential not only to treat symptoms but to remove the primary focus or at least overcome the infection.

In diseases due to focal infection if a cure is not effected by the removal of a diseased focus or if further metastases occur then further search must be made for another focus by exhausting every aid the laboratory X-ray and one's diagnostic ability afford

If for anatomical reasons the focus cannot be removed or the infection is same controlled, often the removal of a diseased tonsil or the draining of an apical dental abscess or accessory nasal sinuses will allow the body economy so to recuperate that a cure will be effected in the original offending focus

ELLEN J PATTERSON

Horsley J S.: Cancer of the Mouth and Tongue with Special Reference to Metastases in the Neck. *South M J* 1916 lx 512

An account is given of eight cases of carcinoma of the mouth and tongue illustrated by post-operative and micrographical results of the pathological sections.

The author lays stress on the harmfulness of the procedure of excising a specimen of the growth and allowing some time to elapse before operation is done. In case pathological examination is necessary for the diagnosis he advises that the excision of the specimen be done with the canterly and the complete operation follow immediately

In the three cases which are alive and living from one to four years after operation there was no primary incision for diagnosis made. The five who are dead all had incisions made into the tumor mass to confirm the diagnosis.

The results of operations for carcinomata of the floor of the mouth are discouraging unless a wide dissection is made including in the block a part of the jaw bone. The author has found that the slow cautery is the best method of dealing with massive recurrences.

HARRY G SLOAN

Hofmann, E.: Melanosarcoma of the Buccal Mucosa (Melansarkom der Mundschleimhaut). *Munchen med Wchnschr* 1916 lxxli 322

The case reported by Hofmann was in a man of 58 who in January, 1911 presented himself with a tumor which had first appeared about a year previous. This was situated in the external part of the ascending branch of the maxillary about the size of a cherry hard, dark-colored and with linear radiating furrows. The tumor with the proximate tissue was extirpated under local anesthesia by the galvanocautery. In the following week the dark lines which traversed the velum were cauterized and an energetic salvarsan treatment instituted. Two months after the first operation a dark discolored spot showed in one of the extremes of the cicatrix which had resulted after the operation.

The tissue in which this spot was situated was circumscribed by the thermocautery and removed radiotherapy treatment being instituted later. Histologic examination showed that this tissue as well as the original tumor which was removed was typical melanosisarcoma.

The patient was lost sight of until 1915. For about a year the patient lost weight rapidly losing 45 kilos in weight in little more than a month. Blackish streaks were ejected in the expectoration and microscopic examination of these showed melanic nuclei identical with the primary tumor.

In the lobule of the left lung there were catarrhal manifestations which suggested the existence of metastases. The patient was again put under salvarsan treatment

SURGERY OF THE CHEST

Chest Wall and Breast

Anatomic study of the lymphatics of the breast from the viewpoint of lymphatic extension of cancer. P. MORRARD. Rev. d. chir. 9 6 II, 46.

The early diagnosis of cancer of the breast. G. A. PICK. Am. J. Surg., 9 6 xxx, 38. [454]

Acute mammary carcinoma. M. L. LEARMONTE. Canad. M. Ass. J. 9 6 vi, 499. [451]

The relation between chronic mastitis and carcinoma of the breast. W. C. MACCARTHY and E. H. MURPHY. St. Paul M. J. 9 6 xviii, 64. [451]

A rare mammary tumor. J. LAMBERTHSEN. Nord. med. Ark., Stockholm, 9 6 Kirurg. No. 6. [452]

Sarcoma of scapula, histological diagnosis made by study of blood aspirated from pulsating portion of the tumor. C. E. ROYCE. Surg. Gynec. & Obst. 9 6 xix, 74.

Resection of the shoulder in surgery. FOURMEREUX. Bull. et mémo. Soc. de chir. d. Par. 9 6 xii, 677.

Stab wounds of the chest involving the diaphragm with diaphragmatic hernia or eversion. C. C. GREEN. J. Am. M. Ass. 9 6 lxvii, 78.

Chylothorax, report of case. P. LEWIS. Am. J. M. Sc. 9 6 cli, 7.

Bullet wound of the thorax, presenting some unusual features. R. J. G. PARRELL. Practitioner Lond. 9 6 xxvii, 93.

Recent progress in the operative treatment of empyema of the thorax. H. LUTHERHAL and M. W. WARR. Med. Rec. 9 6, xc, 86.

A new sign by change of tinted in encysted pneumothorax: critical emphysema. FURSTNER and HOFFMANN. Rev. gén. de clin. et de thérap. 9 6 xxx, 359.

Primary tumors of the pleura. E. FALLAS and C. ROCHET. Ann. de méd. 9 6 lli, 243. [452]

Blebs in past in chronic suppurative empyema and empyema. Incorrect technique as cause of failure in its operation. E. G. BROWN. J. Am. M. Ass. 9 6 lxvii, 111.

Extraction of free bullet from left pleura after establishment of an artificial pneumothorax. GOULDING and ARCELON. Lyon méd. 9 6 cxix. [452]

Lymphosarcoma of the mediastinum. J. DRAKE. J. Mo. St. M. Ass. 9 6 xii, 36.

Two cases of mediastinal tumor treated by radiotherapy. F. J. UGALL. J. d. rad. et d'électr., 9 6 li, 9. [452]

The surgical treatment of suppurations in the posterior mediastinum. V. G. UGALL. Ann. Surg. Phila., 9 6 lxvii, 53.

Trachea and Lungs

Gambol wound of spinal cord and trachea, recovery. G. W. THOMPSON and G. W. S. AXLEY. Brit. M. J. 9 6 li, 74.

Primary tracheal sarcoma. S. BERGREN. Hygiea Stockholm 9 6 lxviii, 755.

Contribution to the technique of tracheotomy in the adult. H. LUTHERHAL. Presse méd. 9 6 p. 350.

Endothorax of the right bronchus removed by peroral bronchoscopy. C. J. W. T. Am. Laryngol. Ass. Washington, 9 6 li, v.

Broncho-oesophageal fistula. R. D. CARMAN. Am. J. Roentgenol. 9 6 li, 370.

The therapeutics of chronic non tuberculous suppurative bronchiectasis. H. LUTHERHAL. Ann. Surg. Phila., 9 6 li, 8.

Complete bronchiogenic fistula. C. V. DOWN. Ann. Surg. Phila. 9 6 li, 5.

Foreign body in lung. A. LUTHERHAL. Presse méd. 9 6 p. 350.

The late extraction of intrapulmonary projectiles: operative technique of lung surgery. P. DUVAL. Rev. d. chir. 9 6 li, 365.

Report of the removal of fragment of tracheotomy tube from the lung six years after its inspiration. I. R. PARKER. T. Am. Laryngol. Ass. Washington 9 6 li, 2.

Heart and Vascular System

Rapid migration of a shrapnel bullet free in the right ventricle. GRADSTEIN. Presse méd. 9 6 p. 365.

Projectile in the right lobe of the heart after traversing the ca. v. inferior. A. LUTHERHAL and MASSARINI. Clin. chir. 9 6 vii, 377. [452]

Gambol wound of pericardium and heart: pneumothorax: operation: recovery. L. J. JONES. Brit. J. Surg. 9 6 li, 5.

Extraction of piece of shell from the right ventricle. BISHOP. Bull. et mémo. Soc. d. chir. d. Par. 9 6 xlii, 60. [452]

Pharynx and Oesophagus

Radiogram of the oesophagus of a case of carcinoma which presented itself as achalasia. W. M. MORRISON. Proc. Roy. Soc. Med. 9 6 li, Laryngol. Sect. 9 6.

Carcinoma of the oesophagus perforating into the right bronchus. J. GUTHRIE and T. W. HILD. Med. Rec. 9 6 li, 30. [452]

Oesophageal obstruction. C. L. KAMLER. Clinique, Chicago 9 6 lxvii, 53.

Oesophageal stricture. H. F. GOODWIN and C. H. KNOWN. Med. Rec., 9 6 xc, 65.

Oesophageal stricture and its successful treatment by electrolysis after forty years standing. W. S. W. THOMSON. Pacific M. J. 9 6 li, 406.

SURGERY OF THE ABDOMEN

Abdominal Wall and Peritoneum

Abdominal pain, especially when associated with abnormal temperature, an indication for caution in the use of purgatives. J. SWANN. N. Orl. M. & S. J. 9 6 lxviii, 799.

Phases of the chronic abdomen and of the acute abdomen. J. H. OUTLAND and L. CLIMBERGEN. J. Terr. M. J. 9 6 lxviii, 337.

Chylous ascites and chylothorax due to carcinoma of the stomach. J. H. OUTLAND and L. CLIMBERGEN. J. Am. M. Ass. 9 6 li, 833. [452]

Symptoms of abdominal injury W B WOOD Med. Summary 1916, xxviii, 143

Transient abdominal tumor in a child of five years, with redundant colon. E P COPELAND Am. J. Obst. N Y 1916 lxiv 170.

Stab wound of the abdomen involving the liver, stomach, and omentum. W L DUFFIELD Long Island M J., 1916 x, 284

Pistol-shot wound of the stomach. C. A. ATWOOD Boston M & S J 1916 cxlv 136

Fifty laparotomies performed for gunshot wounds of the abdomen. G H STEVENSON J J M SHAW and C. MACKEITH. Lancet, Lond. 1916 cxcl, 173
Chylothorax, chylous ascites, and lymphosarcoma. H. E. TULLEY and S. GRAVES. J Am. M. Ass. 1916 lvi, 1844. [454]

Treatment of gonorrhoeal conjunctivitis in the newborn and the adult. J. H. CLAIBORNE. *Virg. M. Semi-Month.* 1916 xvi, 188

A case of retention of dead foetus. DELGOLLADA. *Rev. de cien. méd. Barcel.* 1916 xiii, 568

A bacteriologic study of the causes of some stillbirths preliminary report. J. B. DELUC. *J. Am. M. Ass.* 1916, lxxvii, 344. [509]

A case of obstetrical paralysis. DECRET. *Siglo méd.* 1916 lxxii, 380. [509]

Obstetrical or brachial birth palsy. T. T. THOMAS. *Am. J. Obst. N. Y.*, 1916 lxxiii 577 [509]

Teratogenesis of a human atherosclerotic, aortic, aortic tricuspid with numerous agenesis. E. O. WHITE. *Surg. Gynec. & Obst.*, 1916 xxxiii 38

Septicemia, with proper uterine drainage. B. A. McBURNEY. *Clinique, Chicago* 1916 xxxvii 313.

Puericulture: French and German obstetrics. A. PIVARD. *Ann. de gynec. et d'obst.*, 1916 xiii, 213

The curved lines of suction. M. KASAHARA. *Am. J. Dis. Child.* 1916 xii, 73

The training in obstetrics that the state should demand before licensing a physician to practice. B. C. HIRST. *Am. J. Obst. N. Y.*, 1916 lxxiv 53

Preparedness in obstetrical practice. W. T. MARKS. *South. Pract.* 1916 xxxviii, 265

Edinburgh scheme for maternity service and child welfare. M. WILLIAMSON. *Brit. M. J.* 1916 ii, 79

The significance of syphilis in obstetrics. W. D. FULERTON. *Am. J. Obst., N. Y.*, 1916 lxxiv 23

Proposed midwives act for Ireland. J. POWER. *Brit. M. J.* 1916, ii 159

The art of obstetrics. H. CRUTCHER. *Am. Med.* 1916 xi, 516

The lost art in obstetrics. J. HUNTER. *Canad. Pract. & Rev.* 1916 xii, 282

Conservatism in obstetrics. E. B. CRAIG. *N. Y. M. J.* 1916 clv 1

GENITO-URINARY SURGERY

Adrenal Kidney and Ureter

- Multiple calculi of the kidney and ureter. J. DEAN. *J. Mo. St. M. Ass.*, 1916 xiii 361
- Unilateral hematuria associated with fibroids and a multiple microscopic calculi of the renal papillae. R. L. PAYNE, JR. *Surg., Gynec. & Obst.*, 1916 xxiii, 76 [510]

Fate of patients who have had stones removed from the kidney. J. BLAND-SUTTON. *Lancet, Lond.* 1916 cxi 1

Surgical replacement of the p. dilated kidney. D. BRILL. *Surg., Gynec. & Obst.* 9 6 xxiii, 100. [510]

Acute infections of the kidney. J. HUNTER and S. LOCKE. *South. M. J.* 1916 ix, 633

Clinical picture of nephritic colic. ASCARRIETA. *Rev. de cien. méd., Barcel.* 1916 xiii 41

Single kidney and nephritis. L. REXY, and R. M. G. Bull. et mém. Soc. méd. d. hôp. de Par. 9 6 xl, 855.

Sarcoma of the kidney treated by X-ray. A. LAMPE. Ann. J. Obst. N. Y. 9 6 lxii, 60.

Unilocular cyst of the kidney. M. SCHULMAN. N. Y. M. J. 9 6 cl, 8.

Contribution to renal surgery. P. ARA. Polich. Roma, 9 6, xiii, sex. chir. 5.

Giant ureteral calculus anomalous development of the genito-urinary tract. I. A. W. Surg. Gynec. & Obst. 9 6 xii, 35. [510]

Calculated glands mistaken for ureteral calculus. D. KELL. Med. J. Austral. 9 6, x, 1.

Structure of the ureter. G. L. H. N. Y. M. J. 9 6 cl, 5.

Treatment of ureteral structure. The special red on retrograde dilatation. G. L. HUN. South M. J. 9 6 cl, 66.

Bladder Urethra and Penis

The use of oxygen in cystoscopy. The preliminary report on the use of oxygen in proctography. A. C. R. Am. J. Roentgenol. 9 6 vii, 15. [511]

Rupture of the bladder. Report of the case. I. P. OMAN. J. Lancet, 9 6 xxxv, 384.

Fracture of pelvis rupture of bladder. J. T. H. Long Island M. J. 9 6, 5.

Rupture of bladder associated with fracture of pelvis. E. P. QUAIN. Surg. Gynec. & Obst. 9 6, 55. [512]

Hernias of the urinary bladder. A. I. H. Chicago M. Recorder, 9 6 vi, 24. [512]

Atrophy of the bladder. J. L. H. U. of & Clin. Rev. 9 6 xii, 376.

A case of permeability of the urethra. I. C. Siglo. Méd. 9 6 lxii, 3. [512]

Calculus of the prostatic urethra. J. W. T. Scars. Rev. méd. d. Seville, 9 6.

Traumatic fracture of the urethra by projectile. The unexpected trajectory. Luc. J. d. med. 9 6, 131. [513]

Bordeaux, 9 6 lxxvii, 96.

Genital Organs

Dermoid cyst of the spermatic cord. R. F. FOX. J. Mich. St. M. Soc. 9 6 xv, 335.

Hydrocoel and orchitis their relation to trauma. H. RAY. A. J. Surg. 9 6 xxx, 20.

Hematocoele of the tunica vaginalis: report of an unusual case. C. M. WATTS. Boston M. & S. J. 9 6 clxxv, 5.

Seminal excaltr. I. W. WATTS. Urol. & C. tan. Rev. 9 6 xii, 370.

Urinary retention due to prostatic obstruction. J. C. W. Urol. & C. tan. Rev. 9 6 xii, 55. [514]

Chronic prostatitis and the technique of prostatic massage. W. J. R. W. Am. J. Clin. Med. 9 6 xii, 5.

The human prostate gland in middle age. O. S. LOW. Med. R. 9 6, 1.

A fistula in the upper pole of the prostate. J. H. W. and S. L. N. Urol. M. & S. J. 9 6, 100.

A method of preventing and controlling hemorrhage following prostatectomy. L. H. C. Urol. Gynec. & Obst. 9 6, 100.

The internal sphincter following prostatectomy. C. S. R. Surg. Gynec. & Obst. 9 6 xii, 620. [514]

Recurrence of the retention after prostatectomy. P. M. and S. R. W. Rev. de med. méd. 9 6, 131, 73.

Miscellaneous

Notes on some interesting genito-urinary cases. H. H. R. Med. J. Austral. 9 6, 100.

Cysticoma multilocular of the anal region in the male. A. H. W. J. Am. M. Soc. 9 6 lxvi, 60.

Method of determining presence of penile urethra. I. J. T. T. M. N. Y. 9 6, 12, 53.

A case of fistula of the urethra. J. J. CO. L. d. & C. tan. Rev. 9 6, 145.

Calculus of the urethra. J. W. M. S. N. Y. Surg. Phila. 9 6, 145.

A report of series of unusual fecal and genito-urinary cases treated by lithotomy. L. G. H. & R. G. H. & Obst. 9 6, 145. [514]

SURGERY OF THE EYE AND EAR

Eye

The value of accurate localization of the foreign body in the orbit. C. C. C. Ophthalmol. 9 6, 305.

Foreign body retained in right eye of child. R. W. W. Arch. Ophthalm. 9 6 cl, 373.

Final result of eyeball wall injuries especially intraocular. P. P. P. Ann. d. ocul. 9 6 cl, 73.

A remarkable case of tolerance of foreign body in the eye. P. P. P. Presse méd. 9 6, 305.

Eye treatment of injuries of the eyes and eyelids in the military. Clin. Ophthalm. 9 6 vii, 305.

Diagnosis of glaucoma, iritis, and incipient cataract. F. H. C. Indianapolis M. J. 9 6 xiv, 8.

Chronic glaucoma in a child five years old. R. G. R. Arch. Ophthalm. 9 6 cl, 374.

The treatment of glaucoma. J. J. B. M. J. Ophthalm. & Otol. 9 6, 305.

The experience in sclerocorneal trephining in glaucoma. W. H. W. M. Arch. Ophthalm. 9 6 cl, 373. [515]

A case of removal of the corneal margin. A. O. P. South M. J. 9 6, 657.

The operative treatment of partial trephining of the cornea and of fistula of the cornea. The conjunctival flap, conjunctiva keratoplasty. A. H. W. Arch. Ophthalm. 9 6, 145.

Some newer principles in dealing with complicated cataract. D. T. V. Arch. Ophthalm. 9 6 cl, 307.

The American method of cataract extraction. J. P. W. Ophthalmol. 9 6 cl, 667.

The intracapsular and the capsulotomy operation for senile cataract. W. A. F. Ophthalmol. 9 6 cl, 672.

Operative indications for cataract in the wounded. ROULET and VESTER. Clin. Ophth. 1916 vii 348

Preliminary capsulotomy in immature cataract. W. E. BRUXER. J. Am. M. Ass. 1916 lxvii, 351

Infection following a cataract extraction. ELLETT J. Ophth. & Oto-Laryngol. 1916 x, 327

Orbital prosthetics. G. VALOIS and J. ROUVREUX. Presse méd. 1916, p. 375

The reconstitution of eyelids and of the orbital cavity in the wounded. MAGNIOT. Clin. Ophth. 1916 vii, 360

The preparation of the patient for operation. W. B. LANCASTER. J. Am. M. Ass. 1916 lxvii, 353

Strabismus produced by operations for strabismus: a consideration of causes producing deformities following strabismus operations, with suggestions for corrective operative procedures. F. C. TOWN. J. Am. M. Ass. 1916 lxvii, 364

Sudden blindness associated with choked disk and nasal sinus disease. E. J. BROWN. J. Am. M. Ass., 1916 lxvii, 34

Double optic neuritis cured by puncture of the callous body. BOURGUIT and ROUMANT. Ann. ocul. 1916 cxlii, 590

Recent work on ophthalmology. L. V. CARROLL. Practitioner Lond., 1916 xcvi, 44

The treatment of the blind after the war. B. C. BELL. Pract. & Rev. 1916 xli, 277

Atoidal rupture of the sclera. G. S. DIXON. Arch. Ophth. 1916 xiv 376

Orbital detachment relieved by trephine operation. H. CURTIS. Arch. Ophth., 1916 xiv 367

The uses of the desiccation method in ophthalmology, with special reference to epitheliomas of lids, canthi and conjunctiva. W. L. CLARK. J. Am. M. Ass., 1916 lxvii, 17

Lachrymal tumors. JOCQUE. Clin. Ophth. 1916 vii, 313

The hypothyroid eye. A. C. JACOBSON. Med. Times, 1916 xli 207

Dissection of crystalline lens. E. JACKSON. J. Am. M. Ass., 1916 lxvii, 347

Pterygium. L. EMERSON. Arch. Ophth. 1916 xiv 365

A primary intradural tumor of the optic nerve removal with preservation of the ball. E. C. ELLETT. J. Am. M. Ass., 1916 lxvii, 304

Tomotomy of the right inferior oblique. DUANZ. Arch. Ophth., 1916 xiv 363

Traumatic pulsating exophthalmos. W. ZENTMEYER. J. Am. M. Ass. 1916 lxvii, 163

Early enucleation in destructive injuries of the eyeball. R. A. WRIGHT. Internat. J. Surg. 1916 xxix, 335

Lagrange operation upon a case of buphthalmos. B. W. KEY. Arch. Ophth., 1916 xiv 371

The importance of blood pressure to the eye specialist. F. P. HOOVER. Med. Rec., 1916 xc, 17

A case of sella turcica decompression with remarkable results. G. F. SUTER. Illinois M. J. 1916 xxx, 65

Plastic operation for the relief of lupus involving the lids and surrounding skin, conjunctiva, anterior parts of the orbit, and ethmoid bone. SCHUMBERG. Arch. Ophth., 1916 xiv 374

A case of oblique hernianopia from wound of optic chiasma. P. STEWART and A. D. GRISTITH. Lancet Lond. 1916 ccd, 104

A new shortening technique with report of forty two operations. R. O'CONNOR. J. Am. M. Ass. 1916 lxvii 268

Ear

Foreign bodies in the ear in infants. A. S. LAGOMAR. Sino Semaloe med 1916 xciii, 32

A new method of examining the vestibular labyrinth. E. I. MOORE. Bull. Acad. de méd. Par., 1916 lxxv 4 3 [515]

A new method of opening the drum membrane in purulent otitis media by means of a trephine. J. GUTTMAN. Laryngoscope, 1916 xxvi, 1043

Indications for the labyrinth operation with report of three cases of meningitis. C. E. FRANKLIN. Laryngoscope, 1916 xxvi, 1012

The chronic running ear. E. S. COLVIN. Atlanta J. Rec. Med., 1916 lxvii 153

The cerobasal diagnosis of mastoiditis by means of the x-ray. H. HAYS. N. Y. M. J. 1916 cii 1163 [518]

Case of mastoiditis complicated by purulent cerebrospinal meningitis operation and recovery. W. H. HORTON. J. Am. M. Ass., 1916 lxvii 30

Streptococcus mucosus capsulatus infection of the mastoid bone. R. L. LOUGHRAN. Laryngoscope, 1916 xxvi, 962

Chronic suppurative mastoiditis accompanied by intra cranial pressure. E. J. LEST. J. Indiana St. M. Ass., 1916 ix 200 [515]

Blood-clot dressing in simple mastoid abscess. K. K. WHEELLOCK. J. Indiana St. M. Ass., 1916 ix 240

SURGERY OF THE NOSE THROAT AND MOUTH

Nose

Value of the roentgen rays in the diagnosis of diseases of the accessory sinuses, with new technique for the spine noid. G. E. FRAHLER. Laryngoscope, 1916, xxvi, 10 8

The accessory sinuses of the nose in their relation to the cranial nerves. L. G. KAMMETER. Laryngoscope, 1916 xxvi, 1034

The relation of diseases of the accessory sinuses to diseases of the eye especially in children, report of two cases. J. H. BRYAN. Tr. Am. Laryngol. Ass. Washing- ton 1916 M y

Bacteriology of nasal sinus disease. J. J. KYLE. Calif. St. J. Med. 1916 xiv 238 [516]

Disinfection of deep sinuses. F. D. VALE. Brit. M. J., 1916 li, 42

Cases of chronic frontal sinus empyema treated by the intranasal method. H. TILLEY. Proc. Roy. Soc. Med., 1916 lx Laryngol. Sect., 10

Endonasal treatment of frontal sinusitis. L. DE KLEIJN. Nederl. Tijds. v. Geneesk., 1916 li 124

Brain abscess from chronic suppuration of the frontal sinus. T. P. BERENS. T. Am. Laryngol. Ass., Wash- ington, 1916 May
